ABSTRACT

This study evaluated five biomass feedstocks—cotton gin trash, rice husk, coconut shell, flax straw, and corn cob—for thermochemical conversion via pyrolysis. The analysis focused on gas fraction, fixed carbon, volatile matter, and ash content. Results indicated that flax straw achieved the highest gas yield (74%), rendering it optimal for energy generation applications, despite exhibiting the highest ash content (9.22%). Conversely, coconut shell demonstrated superior biochar production (17.61%). Rice husk and corn cob yielded the lowest ash content (5.44% and 5.7%, respectively), facilitating cleaner processes with minimal solid residue. Cotton gin trash presented a balanced profile between gas yield (73.4%), biochar (16.8%), and volatile content (69%), with moderate ash generation (8.33%). These findings demonstrate that each biomass offers specific strategic advantages depending on the process objective: gas maximization, biochar synthesis, or waste minimization. Consequently, feedstock selection can be precision-tailored to align with the operational priorities of the exergoenvironmental system.

I. INTRODUCTION

Pyrolysis involves the thermochemical decomposition of organic matter in the absence of oxygen to produce fuels, biochar, and liquid fractions (bio-oil). This process has emerged as a promising technological alternative for the sustainable utilization of agro-industrial residues, enabling energy recovery and the valorization of by-products with energy, environmental, and industrial applications. Recent studies report that, depending on biomass type and operating conditions, bio-oil yields can reach values between 60% and 75% in fast pyrolysis processes, whereas slow pyrolysis favors biochar production [1]. In the present study, five types of biomass were evaluated: cotton gin trash, rice husk, coconut shell, flax straw, and corn cob, considering their energy potential and environmental impact.

These lignocellulosic residues exhibit variable compositions of cellulose, hemicellulose, and lignin, which directly influence product distribution during pyrolysis. It has been demonstrated that the thermal decomposition of cellulose and hemicellulose occurs primarily between 220 and 380 °C, favoring the formation of volatile compounds and non-condensable gases. In contrast, lignin degrades over a broader temperature range (250–500 °C), contributing significantly to the generation of biochar and aromatic compounds in the bio-oil [2]. Global reliance on fossil fuels, which account for approximately 85% of global energy consumption, and their direct impact on the increase of greenhouse gas (GHG) emissions have raised serious concerns regarding the sustainability of the energy system and environmental protection, intensifying the need to develop and implement sustainable energy technologies [3].

This dependence has resulted in a sustained increase in global CO_2 emissions, exceeding 37 Gt annually in recent years [4]. In this context, alternative renewable energy sources, such as biomass, have gained relevance due to their potential to reduce carbon footprints and promote sustainable energy systems. Thermochemical conversion of biomass enables the partial substitution of fossil fuels in thermal and industrial applications, contributing to climate change mitigation [5]. biomass-based renewable energy sources have emerged as a strategic alternative, particularly through thermochemical processes such as pyrolysis and gasification, which present lower net CO_2 emissions and enable the utilization of agricultural residues that would otherwise be underutilized or inefficiently incinerated. Several studies have evaluated complementary thermochemical processes, such as gasification, to analyze the effects of key operational variables including temperature and equivalence ratio (ER). It has been reported that increases in ER promote exothermic partial oxidation reactions, raising reactor temperature but reducing the lower heating value (LHV) of the produced gas due to dilution by non-combustible gases. Furthermore, increasing ER leads to a progressive decrease in CO and H_2 concentrations due to their oxidation into CO_2 and H_2O [6],[7]. These results highlight the importance of meticulously controlling operating conditions to maximize the process's energy efficiency.

Additionally, recent research on fast and slow pyrolysis has shown that biomass type directly impacts product distribution. Current research provides insights into pyrolytic bio-oil obtained from different feedstocks regarding upgrading techniques and applications such as energy, fuels, chemicals, and carbon materials. Analysis indicates that the primary bottlenecks for the commercial application of upgraded bio-oil are the initial processing stages, high production costs, and pilot-scale production challenges [8]. Specifically, regarding flax straw, investigations have been conducted using conventional and advanced exergetic techniques across different operating temperatures. Using Aspen Plus software, the pyrolysis process was accurately simulated, identifying system inefficiencies and potential areas for improvement. The pyrolysis reactor, cyclone, and flash reactor were the primary sources of exergy destruction, accounting for 32.2%, 31.8%, and 18.7% of total exergy destruction, respectively [9]. Flax straw biomass possesses a high heating value (18.2 MJ/kg) and significant cellulose (27.4%) and hemicellulose (24.8%) content, favoring its thermochemical conversion into valuable products like bio-oil and biochar. Moreover, its low lignin and ash content, combined with significant reductions in moisture and fixed carbon, enhances pyrolysis efficiency. These factors position flax straw as a promising feedstock for bioenergy production, contributing to sustainability and resource optimization [10].

An exergoenvironmental analysis consists of three steps: an exergetic analysis of the conversion process, a life cycle assessment (LCA), and an evaluation of environmental impacts associated with the process's exergy flows [11]. he exergoenvironmental and thermodynamic evaluation of biomass pyrolysis is essential because it enables the optimization of energy efficiency by identifying and minimizing energy and exergy losses throughout the process, thereby contributing to more efficient and sustainable system design. Additionally, it integrates environmental indicators to assess and reduce the impacts of emissions and by-products, promoting cleaner energy conversion. In this context, [12] characterization of crop residue biomass blends, including corn cobs, rice husks, sesame stalks, and cotton gin trash, evaluated gasification temperature, syngas LHV, and cold gas efficiency (CGE). It was found that temperature, syngas composition, LHV, and CGE were negatively affected as the proportion of rice husk in the blend increased. CGE values up to 57.91% and LHV up to 4460 kJ/kg were achieved under specific blending conditions. A higher percentage of rice husk caused a considerable increase in the variability of the equivalence ratio, resulting in suboptimal gasification conditions.

Studies by [13] utilized Aspen Plus® and detailed CO_2 emissions and other environmental impacts through integrated LCA, identifying the possibility of achieving a net-negative carbon footprint in scenarios involving carbon capture. Finally, [14], quantified environmental emissions from biochar production using traditional Kon-Tiki kilns. Multiple impact categories were evaluated, including Global Warming Potential (GWP), fossil fuel depletion, and eutrophication, finding that biochar application as a soil amendment generated significant net reductions in CO_2 -eq emissions, particularly in agricultural scenarios. Based on the considerations, the main objective of this work is to identify cleaner and more efficient methods for renewable energy production to reduce fossil fuel dependency and mitigate GHG emissions. Key variables such as temperature and equivalence ratio were studied, demonstrating their significant influence on the generation of critical energy-related gases such as carbon monoxide and hydrogen. Furthermore, the potential of flax straw and other agricultural residues as promising feedstocks was highlighted, contributing to energy generation, the circular economy, and the optimization of natural resources.

II. MATERIALS AND METHODS

II.2.1 Characterization of Biomass

The comparative analysis of the thermophysical properties of corn cob, cotton gin trash, rice husk, flax straw, and coconut shell is summarized in Table 1. This characterization encompasses proximal analysis (moisture content, ash yield, volatile matter, and fixed carbon), ultimate analysis (carbon, hydrogen, nitrogen, sulfur, and oxygen), and the determination of the higher heating value (HHV).

Table.1. Composition of biomass used.

Component	Corn Cob	Cotton gin trash	Rice husk	Flax straw	Cocconut shell
Elemental analysis.					
S (v/v)	0.09	0.2	0.1	0.012	0.005
HHV (kJ/kg)	16,230	18,263	16,166	18,200	20,150
C (v/v)	39.95	39.3	39.27	0.444	0.6423
H (v/v)	4.97	4.7	4.91	0.067	0.0689
O (v/v)	46.77	49.35	55.23	0.456	0.2761
N (v/v)	0.6	1.21	0.59	0.014	0.0077
Proximate analysis.					

MC (v/v)	10.52	10.51	10.18	0.044	0.101
ASH (v/v)	7.71	5.44	8.33	0.029	0.032
VM (v/v)	65.23	68.42	64.67	0.813	0.755

Source: Authors, (2026).

The data for the analysis of corn cob, rice husk, and cotton gin trash were obtained from a previous study detailing their proximate and ultimate analyses [12]. Likewise, data corresponding to the different analyses for flax straw were obtained from [10]. Similarly, data for coconut shell were taken from [15]. The pyrolysis process for each biomass feedstock was executed through computational simulations using Engineering Equation Solver (EES) software. This platform facilitated the robust modeling of the thermodynamic equations governing the process for each specific biomass type. The governing equations for the parameters on a dry basis are formulated as follows:

$$VM_w = \frac{VM}{1 - MC} \tag{1}$$

$$FC_w = \frac{FC}{1 - MC} \tag{2}$$

$$ASH_w = \frac{ASH}{1 - MC} \tag{3}$$

Donde: MC is the initial moisture content, VM is the volatine matter, ASH is the ash generation.

To simulate pyrolysis in EES, stoichiometric balances and temperature-dependent empirical correlations are used, in a range from 650 to 990 K [16].

$$\alpha_1 = 1.94 \cdot 10^{-6} \cdot T^{1.87} \tag{4}$$

$$\alpha_2 = 1.305 \cdot 10^{-11} \cdot T^{3.39} \tag{5}$$

The mass balance equation could be written as follows:

$$Mass_{total} = Mass_{tar} + Mass_{char} + Mass_{gas} + Mass_{steam} \tag{6}$$

The fraction equations for the products are given by:

$$f_{gas} = \frac{Mass_{gas}}{Mass_{total}} \cdot 100 \tag{7}$$

$$f_{tar} = \frac{Masa_{tar}}{Mass_{total}} \cdot 100 \tag{8}$$

$$f_{char} = \frac{Mass_{char}}{Mass_{total}} \cdot 100 \tag{9}$$

$$f_{vapor} = \frac{Mass_{steam}}{Mass_{total}} \cdot 100 \tag{10}$$

III. RESULTS AND DISCUSSIONS

III. 3.1 Pyrolysis of Corn Cob

The results obtained for corn cob demonstrate a characteristic behavior of lignocellulosic biomass with a balanced structural composition of cellulose, hemicellulose, and lignin. As shown in Figure 1, gas production is predominant, followed by an intermediate bio-oil fraction and a lower biochar yield. This behavior can be directly atributed to the high volatile matter content (65.23%) and moderate fixed carbon content (16.54%), which facilitate the thermal cleavage of weak chemical bonds during the initial and intermediate stages of the pyrolysis process.

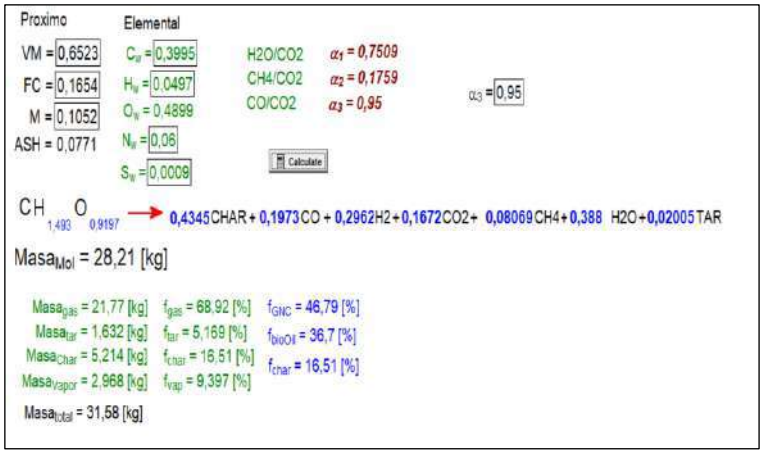

Figure 1: Pyrolysis of Corn Cob.
Source: Authors, (2026).

Figure 2, corresponding to the composition of the gaseous products, a predominance of CO and CO_2 is observed, with lower fractions of H_2 and CH_4. The increase in CO is mainly associated with the thermal decomposition of cellulose and hemicellulose, whose degradation mechanisms include decarboxylation and decarbonylation reactions. Conversely, CO_2 is significantly generated during the initial stages of the process due to the cleavage of oxygenated functional groups within the hemicellulose matrix. The lower hydrogen fraction can be explained by the absence of secondary reforming reactions, which are typical of gasification processes, and by the limited recombination of free radicals at high temperatures under pyrolysis conditions.

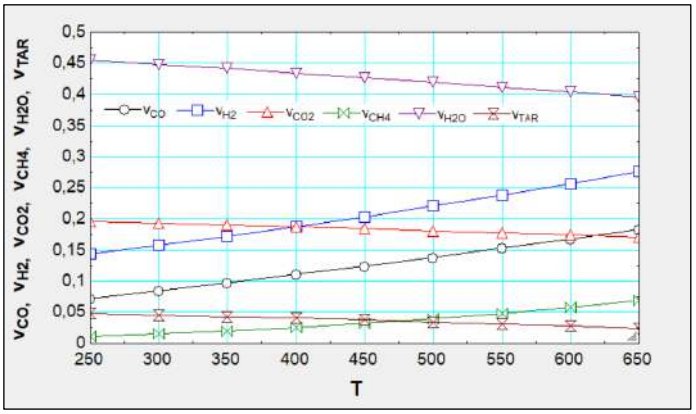

Figure 2: Composition of gaseous products during pyrolysis.
Source: Authors, (2026).

The mass distribution show in Figure 3, confirms that the gaseous phase dominates the overall process balance. This behavior is closely linked to the fibrous and porous structure of the corn cob, which facilitates the diffusion of volatiles toward the particle exterior, thereby mitigating secondary reactions that would otherwise promote biochar formation. Consequently, the residual solid fraction remains relatively low. Finally, the product fraction analysis in Figure 4 positions corn cob as a suitable feedstock for applications focused on syngas production. However, its moderate yield of bio-oil and biochar also grants the substrate a degree of energetic versatility.

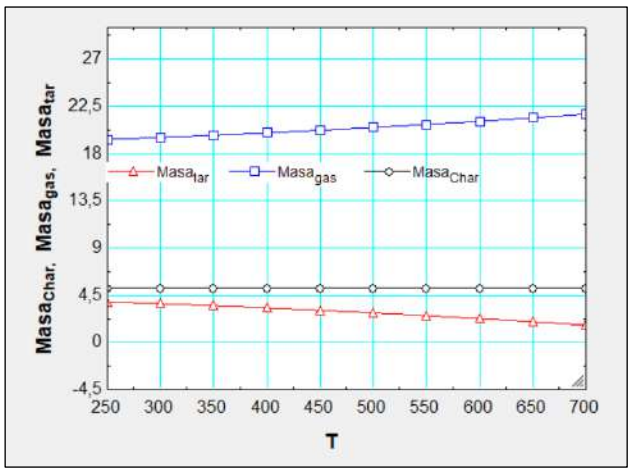

Figure 3: Mass distribution of corn cob products.

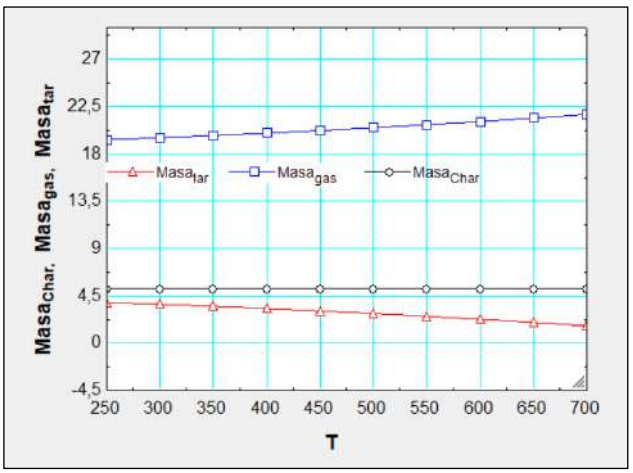

Figure 4: Products fraction.
Source: Authors, (2026).

III. 3.2 Pyrolysis of Cotton Gin Trash

Regarding cotton gin trash, the results presented in Figure 5 exhibit particularly favorable behavior, characterized by a high gas yield and a significant biochar fraction. This superior performance is attributable to its HHV of 18.26 MJ/kg and its elevated volatile matter content (68.42%), which intensify the thermal degradation kinetics and promote the formation of light gaseous species.

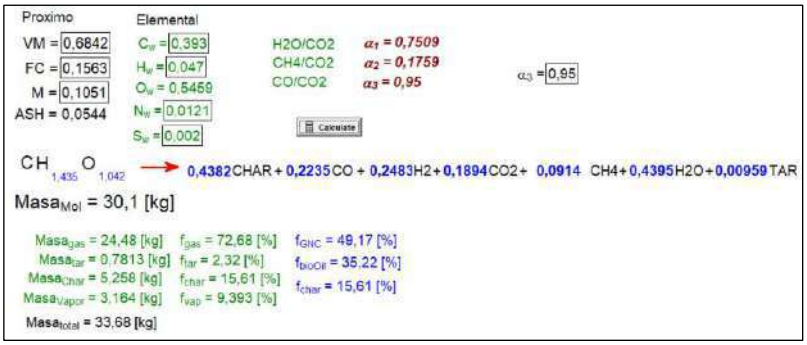

Figure 6: Pyrolysis of cotton gin trash.
Source: Authors, (2026).

Figure 6 reveals a gaseous composition with a noticeable increase in CO and H_2 compared to other biomasses. This increase in hydrogen is directly related to the presence of organic compounds rich in C–H bonds and to the enhanced release of free radicals during pyrolysis, which promote dehydrogenation reactions. The lower proportion of CO_2 indicates a more efficient degradation of the organic matrix, with reduced formation of undesirable oxygenated products.

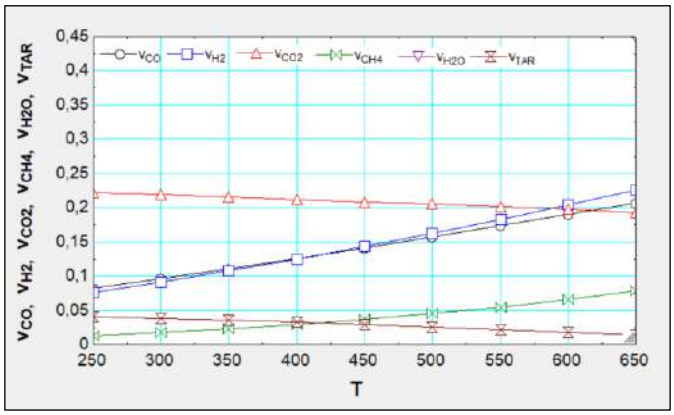

Figure 7 Composition of gaseous products during pyrolysis.
Source: Authors, (2026).

Figure 7 illustrates a clear dominance of the gaseous phase, accompanied by a significant biochar fraction. This behavior is a result of the moderate fixed carbon content, which facilitates the formation of stable carbonaceous structures without compromising gas yields. The liquid fraction remains regulated, suggesting an efficient pyrolysis process with limited tar formation. Figure 8 confirms that cotton gin trash achieves the highest biogas fraction in this study (≈49.17%), positioning it as one of the most attractive feedstocks for direct energy conversion systems, particularly in cogeneration and thermal energy production applications.

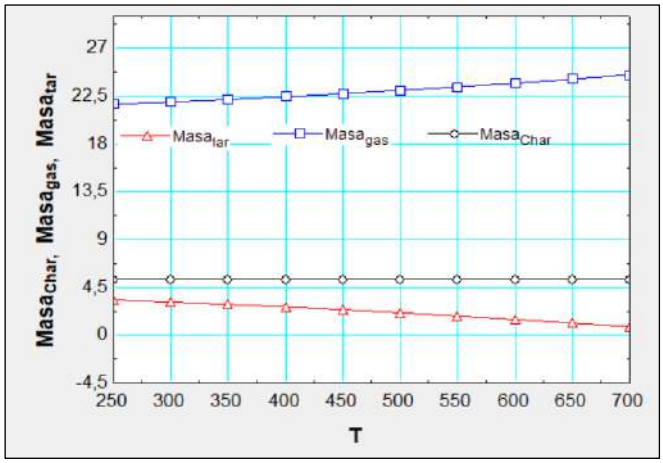

Figure 8: Mass distribution of corn cob products.
Source: Authors, (2026).

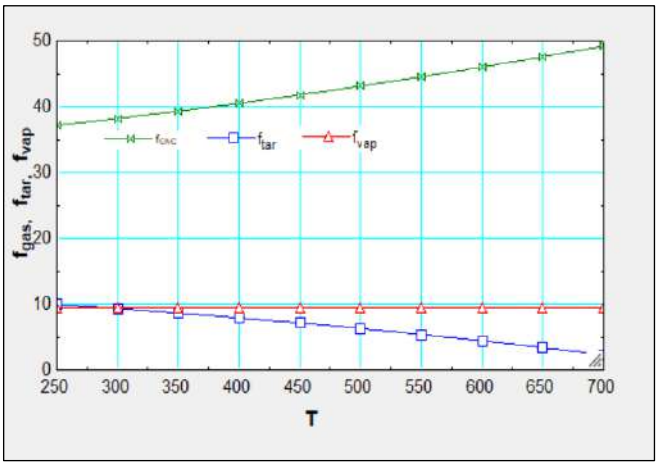

Figure 9: Products fraction.
Source: Authors, (2026).

III. 3.3 Pyrolysis of Rice Husks

The results corresponding to rice husk, shown in Figure 9, reflect a markedly different behavior compared to the other biomasses, mainly due to its high ash content rich in silica. These structural characteristic limits heat transfer within the particle and alters the kinetics of thermal decomposition.

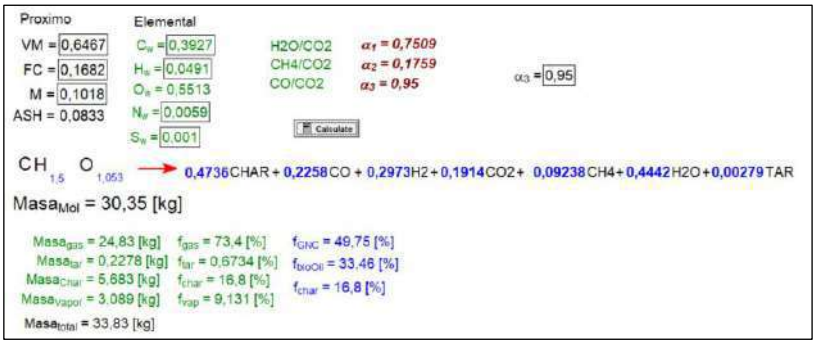

Figure 9: Pyrolysis of rice husks.
Source: Authors, (2026).

Figure 10, a higher proportion of CO_2 relative to CO is observed, indicating a less efficient decomposition of the organic fraction. The presence of silica acts as a thermal inhibitor, reducing the intensity of cracking reactions and favoring internal partial oxidation processes. As a result, the generation of combustible gases such as H_2 and CH_4 remains relatively low.

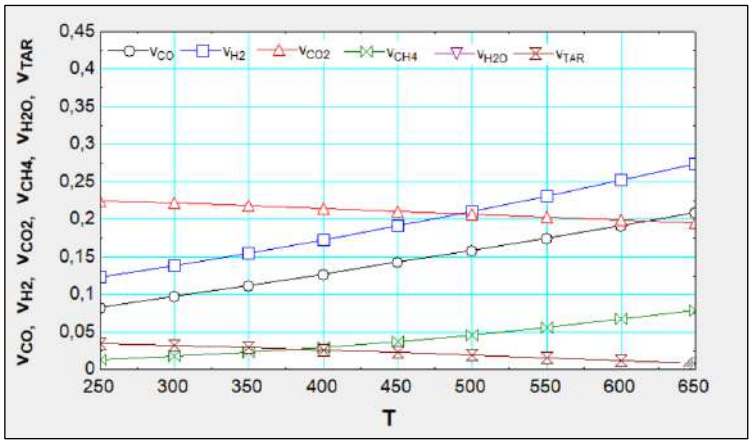

Figure 10: Composition of gaseous products during pyrolysis.
Source: Authors, 2026

Figure 11 illustrates a mass distribution with a significantly higher solid fraction compared to the other feedstocks evaluated. This behavior is attributed to the fact that a substantial portion of the inorganic mineral matter remains as solid residue post-pyrolysis, thereby artificially inflating the biochar fraction. In Figure 12, rice husk exhibits the highest biochar yield (≈17.29%), positioning it as a particularly suitable biomass for carbon sequestration applications, activated carbon production, or as a soil amendment, rather than for primary syngas or bio-oil generation.

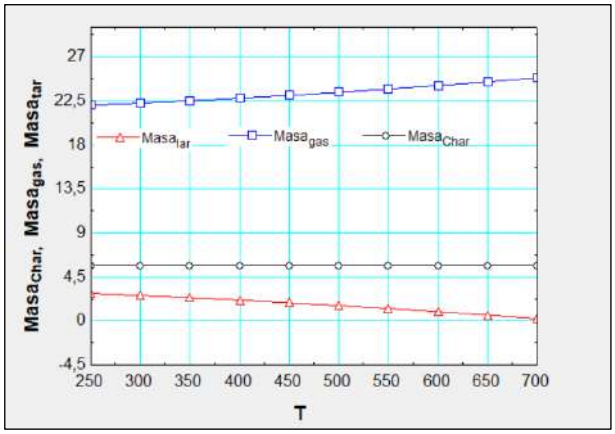

Figure 11: Mass distribution of corn cob products.
Source: Authors, (2026).

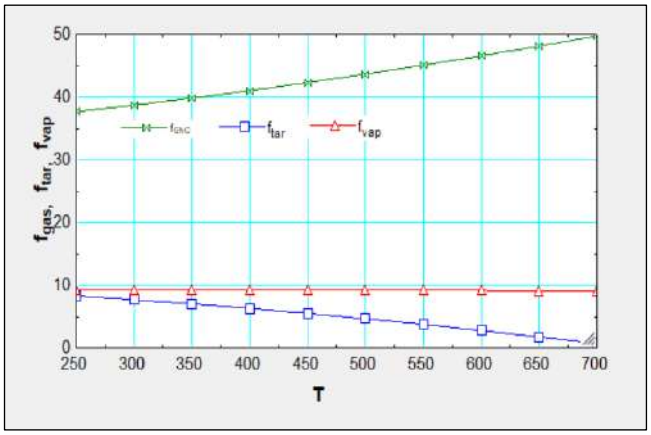

Figure 12: Products fraction.
Source: Authors, (2026).

III. 3.4 Pyrolysis of Flax Straw

Flax straw shows the most outstanding results in terms of gas production, as shown in Figure 13. This behavior is directly related to its high cellulose and hemicellulose content, together with a low lignin and fixed carbon content, which favors rapid and efficient thermal decomposition.

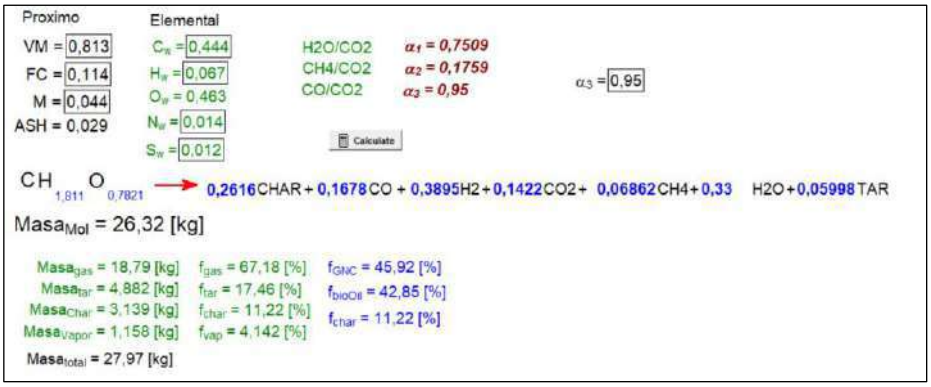

Figure 13: Pyrolysis of flax straw.
Source: Authors, (2026).

Figure 14, the gaseous composition is dominated by CO and H_2, indicating an efficient conversion of the organic fraction into high-energy-value gases. The increase in hydrogen is associated with a greater availability of C–H bonds and a lower formation of stable aromatic structures, which are typical of lignin-rich biomasses.

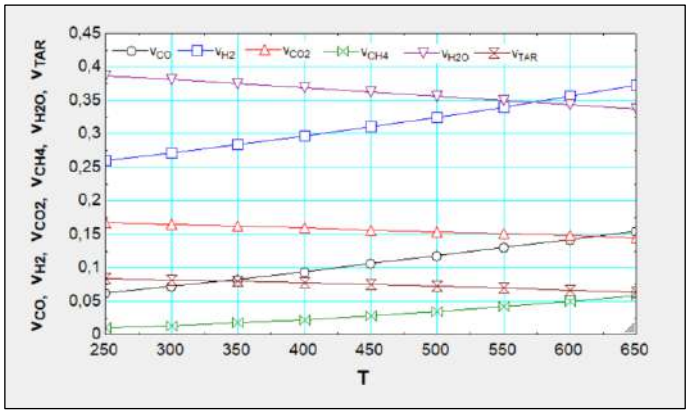

Figure 14: Composition of gaseous products during pyrolysis.
Source: Authors, (2026).

Figure 15 displays a mass distribution clearly dominated by the gas phase, whereas the biochar fraction is minimal. This behavior confirms that flax straw is highly suitable for processes aimed at maximizing gaseous energy yields, although it exhibits a reduced capacity for biochar production. Finally, Figure 16 reveals that, despite its excellent energetic performance, flax straw generates a higher ash fraction. This characteristic necessitates the integration of robust solid waste management strategies when considering large-scale industrial applications.

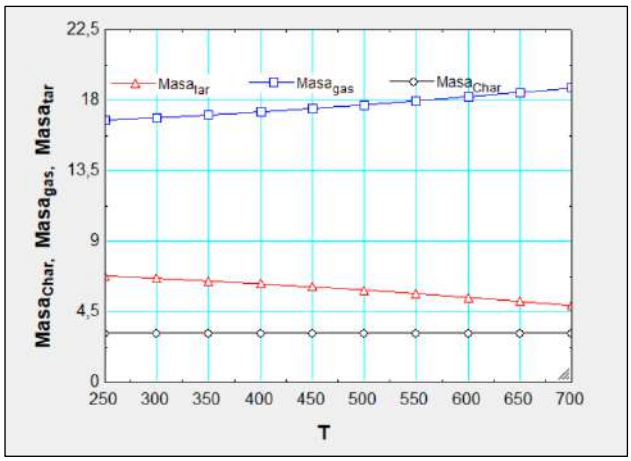

Figure 15: Mass distribution of corn cob products.
Source: Authors, (2026).

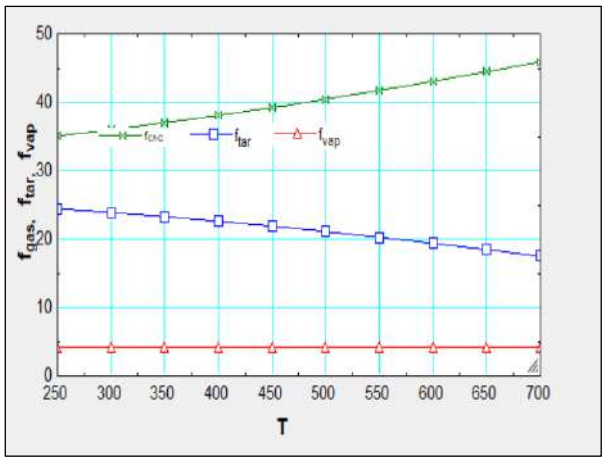

Figure 16: Products fraction.
Source: Authors, (2026).

III. 3.5 Pyrolysis of Coconut Husks

The results for coconut husks, shown in Figure 17, reveal behavior dominated by bio-oil production, which is closely linked to their high lignin content. Lignin has a highly stable aromatic structure, which during pyrolysis tends to form condensable phenolic compounds rather than light gases.

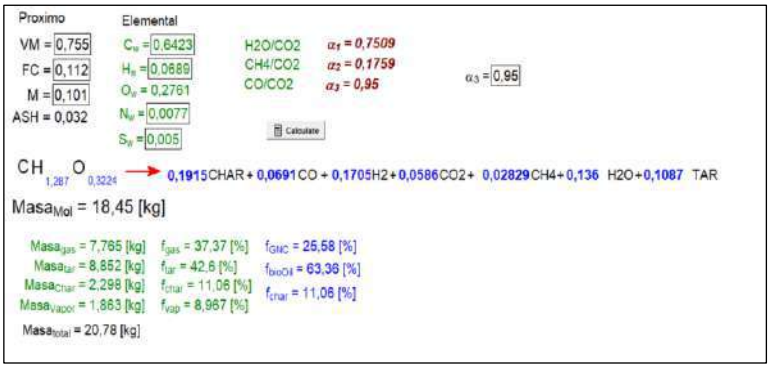

Figure 17: Pyrolysis of coconut hunks.
Source: Authors, (2026).

Figure 18, the gaseous composition exhibits lower fractions of CO and H_2, confirming that a significant portion of the chemical energy is directed toward liquid products. This trend is further accentuated by the thermal stability of lignin, which limits the complete breakdown of the carbonaceous matrix.

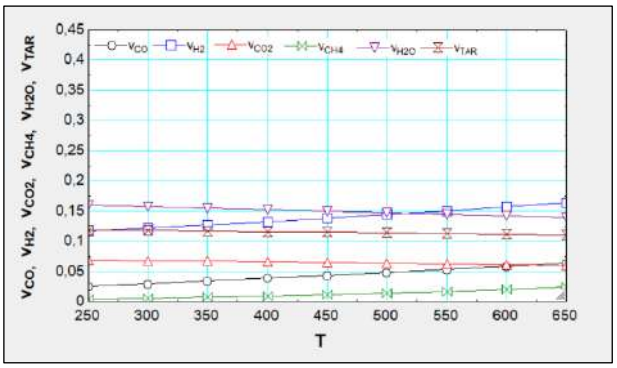

Figure 18: Composition of gaseous products during pyrolysis
Source: Authors, (2026).

Figure 19 demonstrates a mass distribution clearly dominated by the liquid fraction, whereas the gaseous and solid phases remain secondary. This result is consistent with prior literature reporting high bio-oil yields from lignin-rich biomass sources. Finally, Figure 20 confirms that coconut shell achieves the highest bio-oil yield in this study (≈63.36%), positioning it as the most suitable feedstock to produce liquid biofuels and high-value-added chemical specialties.

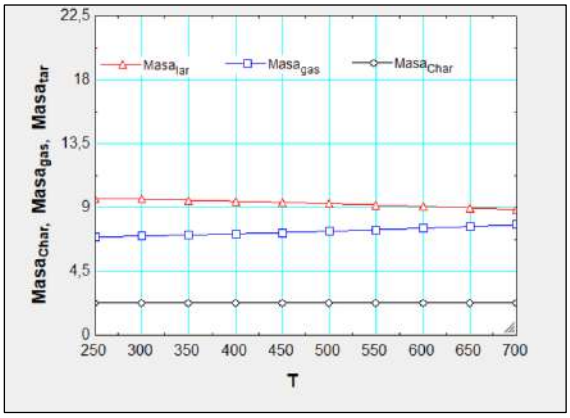

Figure 19: Mass distribution of corn cob products.
Source: Authors, (2026).

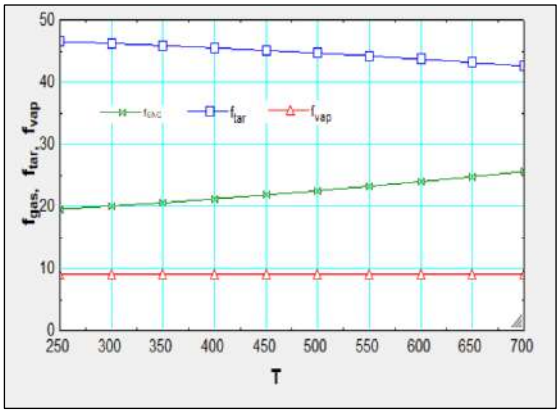

Figure 20: Products fraction.
Source: Authors, (2026).

Figure 21 presents a direct comparison of the biogas, bio-oil, and biochar fractions obtained during the pyrolysis of the evaluated biomasses, highlighting the strong influence of the physicochemical composition of each residue on product distribution.It is observed that cotton gin trash and corn cob achieve the highest biogas fractions, which is attributed to their high volatile matter content and the predominance of cellulose and hemicellulose.

These components readily decompose within the typical temperature ranges of pyrolysis, promoting the release of light gases such as CO and H_2. This behavior positions these biomasses as suitable feedstocks for applications focused on direct energy generation.

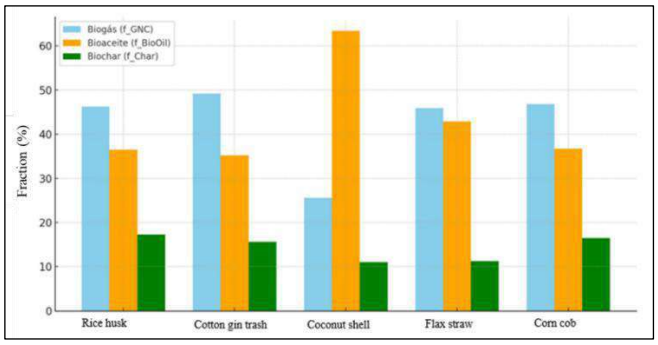

Figure 21: Composition of gaseous products during pyrolysis.
Source: Authors, (2026).

In contrast, coconut shell exhibits the highest bio-oil fraction, exceeding 60%, a result directly correlated with its elevated lignin content. The aromatic structure of this macromolecule promotes the formation of phenolic compounds and condensable fractions during thermal degradation, thereby limiting gas conversion and shifting the process equilibrium toward liquid yields. This finding suggests a superior potential for coconut shell in the production of liquid biofuels or high-value chemical precursors. Conversely, rice husk displays a relatively higher biochar fraction, primarily attributed to its high silica-rich ash content, which remains as a solid residue post-pyrolysis. While this behavior constrains gas and bio-oil yields, it favors biochar applications in carbon sequestration, soil amendment, and adsorbent material synthesis. Collectively, the results illustrated in Figure 21 confirm that feedstock selection must be strategically aligned with the target end-product whether maximizing gaseous energy, bio-oil production, or biochar generation. This reinforces the necessity of integrating energetic and environmental criteria into the design and optimization of pyrolysis systems.

III. 3.6 Exergoenvironmental Analysis of Biomass Feedstocks

The environmental impact assessment of agro-industrial waste pyrolysis shows that this process provides clear net benefits in terms of sustainability and mitigation of GHG emissions, particularly when analyzed under an exergoenvironmental framework integrated with life cycle assessment. Replacing fossil fuels with biogas derived from pyrolysis enables a significant reduction in CO_2 and other GHG emissions by valorizing a renewable resource that, under conventional scenarios, is often disposed of through practices such as open burning, which are characterized by uncontrolled emissions and low energy recovery [2]. In this sense, the energetic use of biogas directly contributes to reducing the carbon footprint associated with thermal and electrical energy generation. From an exergoenvironmental perspective, a particularly relevant aspect is the production of biochar as a solid co-product of the process. Biochar is characterized by high structural stability and a high fixed carbon content, which confer a remarkable potential as a long-term carbon sink. Several studies have demonstrated that a significant fraction of the carbon retained in biochar is resistant to biological degradation, which can result in net negative GHG emissions when this material is applied to agricultural soils [17].

Life cycle assessments reported in the literature show substantial reductions in CO_2-equivalent emissions when biochar is integrated as a soil amendment compared to conventional agricultural systems [18]. Additionally, the application of biochar exhibits positive effects on the dynamics of other GHGs beyond CO_2. Recent meta-analyses have reported average reductions in N_2O and CH_4 emissions on the order of 10–15% and 5–10%, respectively, associated with changes in soil microbial activity, improved nutrient retention, and alterations in nitrification and methanogenesis processes [19]. These effects complement the climate benefit of carbon sequestration and reinforce the environmental value of biochar within a circular economy framework. From a life cycle assessment perspective, recent studies indicate that pyrolysis systems with energy integration and efficient utilization of co-products tend to exhibit superior environmental performance compared to fossil fuel-based technologies or traditional waste disposal schemes. Overall, despite differences in assumptions, LCA results demonstrate that biochar represents a highly promising pathway to contribute to efficient carbon resource circulation, climate change mitigation, and economic sustainability [20]. Under optimized scenarios, including heat recovery, efficient biogas utilization, and productive application of biochar near-neutral or even negative GHG balances have been reported, highlighting the potential of pyrolysis to support decarbonization strategies.

IV. CONCLUSIONS

This research conducted a comprehensive assessment of the pyrolysis process applied to five agro-industrial residues to analyze their energetic and exergoenvironmental performance, focusing on product distribution, gaseous composition, and the valorization potential of the resulting by-products. The findings confirm that the pyrolysis process is strictly governed by the physicochemical composition of the biomass, particularly the volatile matter, lignin, fixed carbon, and inorganic fractions. From an energetic standpoint, feedstocks such as flax straw, cotton gin trash, and corn cob exhibit superior potential for biogas generation due to their high cellulose and hemicellulose content, which promotes the formation of combustible gases during thermal degradation. In contrast, coconut shell demonstrated a distinct propensity for bio-oil production, attributable to its high lignin content and the thermal stability of its aromatic structure, while rice husk yielded a higher biochar fraction, influenced by its significant silica-rich ash content. The product distribution analysis established that no single biomass is universally optimal; rather, feedstock selection must be strategically aligned with the specific objectives of the conversion system. whether maximizing gaseous energy, producing liquid biofuels, or generating biochar for environmental or industrial purposes.

This finding underscores the importance of integrating design and operational criteria based on the differentiated valorization of each biomass type. From an exergoenvironmental standpoint, the results indicate that the pyrolysis of agro-industrial residues represents a favorable alternative for reducing environmental impacts, as it enables the partial substitution of fossil fuels with renewable energy and the valorization of by-products with high environmental value. In particular, the produced biochar exhibits significant potential as a long-term carbon sink, contributing to CO_2 sequestration and climate change mitigation when applied as a soil amendment or used in the production of adsorbent materials. Furthermore, the energetic utilization of biogas enhances the overall system efficiency and reduces exergy destruction associated with conventional waste disposal processes.

ABSTRACT

Public-sector engineering maintenance organizations often struggle with fragmented information, poor traceability, and limited benefits from Computerized Maintenance Management Systems (CMMS). Although CMMS platforms are widely deployed, many implementations underperform due to weak governance, inconsistent data structures, and misalignment between organizational workflows and system configuration. Existing research emphasizes system functionality and post-implementation outcomes but provides limited guidance on structured implementation processes. This study develops and evaluates a prescriptive CMMS implementation framework using Design Science Research Methodology. The framework conceptualizes CMMS adoption as a socio-technical transformation integrating organizational readiness, standardized data governance, workflow alignment, user training, and continuous performance monitoring. Development was informed by document analysis and expert input, while evaluation employed operational CMMS data from a public-sector engineering maintenance organization managing safety-critical assets. Results indicate improved maintenance data completeness, enhanced work order traceability, greater asset information availability, and better integration between maintenance and inventory functions. Findings demonstrate that CMMS effectiveness depends primarily on disciplined implementation and organizational alignment rather than software deployment alone. The framework offers structured, practical guidance to reduce implementation risk and support evidence-based maintenance decision-making in public-sector environments.

I. INTRODUCTION

Engineering maintenance plays a critical role in ensuring the reliability, availability and safety of physical assets, particularly within organizations that operate complex and geographically distributed engineering systems. In asset-intensive environments, maintenance has evolved from a reactive technical activity into a strategic function that influences lifecycle cost control, operational continuity and organizational accountability [1]. Effective maintenance management depends on the availability of accurate, timely and structured information to support planning, execution and performance evaluation. When maintenance information is fragmented or unreliable, organizations experience increased downtime, inefficient resource allocation and limited capacity to make evidence-based engineering decisions [2],[3].

Despite the growing importance of data-driven maintenance, many public-sector engineering organizations continue to rely on manual or semi-manual maintenance management practices. Paper-based work orders, handwritten records and decentralized documentation remain common, particularly within organizations governed by rigid administrative structures and legacy operational routines [4]. Empirical studies have shown that manual maintenance systems are inherently vulnerable to data loss, inconsistency, delayed reporting and human error, which collectively undermine the integrity of maintenance information and limit itsanalytical value [5].

These constraints restrict the organization's ability to analyze failure trends, evaluate maintenance effectiveness and transition from reactive maintenance toward preventive or predictive strategies [6],[7].The adoption of digital maintenance technologies has been widely promoted as a response to these limitations. Among these technologies, Computerized Maintenance Management Systems have been positioned as foundational platforms for structuring maintenance information and supporting systematic maintenance operations [8]. CMMS platforms typically integrate work order management, preventive maintenance scheduling, asset history tracking, inventory control and maintenance cost reporting within a centralized digital environment. Prior studies across manufacturing, infrastructure and facilities management contexts have reported potential improvements in traceability, data accessibility and maintenance coordination following CMMS adoption [9],[10]. These findings have reinforced the role of CMMS as a core component of Maintenance 4.0 initiatives and broader digital transformation strategies [6]. However, empirical evidence also indicates that CMMS implementations frequently fail to deliver their anticipated benefits, particularly within public-sector contexts. Several studies have demonstrated that CMMS effectiveness is influenced more strongly by implementation quality than by system functionality alone [11].

Common challenges include poorly structured asset data, incomplete migration of historical maintenance records, weak alignment between CMMS workflows and actual maintenance practices, and limited user acceptance [12]. In many cases, organizations continue to operate parallel manual systems alongside CMMS, resulting in duplicated effort, inconsistent data and underutilized analytical capabilities [13]. These findings suggest that CMMS should be understood not merely as a software application, but as a socio-technical system whose performance depends on the integration of organizational processes, data governance mechanisms and human competencies [14],[15]. Public-sector engineering maintenance environments introduce additional layers of complexity that further complicate CMMS implementation. Such organizations often manage large and diverse asset portfolios under strict governance, compliance and audit requirements [16]. Decision-making structures are typically hierarchical and operational changes must conform to standardized procedures and regulatory constraints. In safety-critical agencies, maintenance effectiveness has direct implications for service readiness and public safety, amplifying the consequences of poor data quality and delayed maintenance actions [7],[17].

Research on public-sector digitalization consistently shows that technology-centric implementations, undertaken without adequate organizational readiness assessment and process alignment, tend to result in partial adoption and limited operational impact [3],[13]. Although the CMMS literature is extensive, a substantial proportion of existing studies focus on post-implementation performance measurement or functional evaluations of CMMS features [9]. Comparatively fewer studies examine how CMMS implementation frameworks should be systematically designed, validated and operationalized within complex public-sector engineering settings. In particular, there remains limited empirical guidance on how organizational readiness, data structuring, workflow integration and continuous performance monitoring can be combined into a coherent and replicable implementation approach [12]. These limitations collectively indicate that existing CMMS studies emphasize system functionality and post-implementation evaluation, while offering limited guidance on structured implementation processes in public-sector engineering environments, as conceptually illustrated in Figure 1.

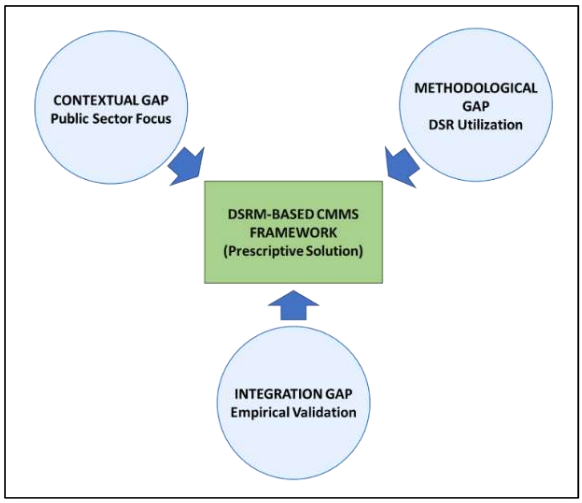

Figure 1: Conceptual synthesis of CMMS research focus and identified implementation gaps in public-sector engineering maintenance.
Source: Authors, (2026).

Figure 1 summarizes the dominant emphasis of existing CMMS research on functional capabilities and performance outcomes, alongside the comparatively limited attention given to implementation structure, organizational readiness and process integration. The figure highlights the disconnect between technology-centric CMMS adoption and the socio-technical conditions required for effective operationalization in public-sector engineering maintenance. Rather than presenting a solution, the figure delineates the conceptual space in which a structured implementation artefact is required, thereby motivating the adoption of a design-oriented research approach in the present study.

Design Science Research Methodology provides a structured approach for addressing this limitation by enabling the development and evaluation of artefacts that respond directly to real-world engineering problems [18]. Within the maintenance management domain, a CMMS implementation framework can be conceptualized as a design artefact that integrates technical configuration, organizational processes and human factors into a unified system [14]. However, the application of design science principles in CMMS research remains limited, particularly in studies focusing on public-sector engineering organizations. This methodological gap further reinforces the need for empirically grounded research that moves beyond descriptive assessments toward the development and validation of prescriptive implementation frameworks.

Against this backdrop, the present study investigates CMMS implementation as a structured socio-technical transformation within a public-sector engineering maintenance environment. Rather than treating CMMS as a standalone information system, the study conceptualizes implementation as a multi-phase engineering process encompassing organizational readiness assessment, data governance, process alignment, system configuration and performance evaluation [12]. By grounding the framework in empirical analysis of existing maintenance practices and validating it through expert assessment and operational data, the study addresses identified gaps in CMMS implementation research and public-sector maintenance practice. The following section describes the research methodology adopted to develop and evaluate the proposed CMMS implementation framework.

II. METHODOLOGY

This study adopts Design Science Research Methodology as the overarching research approach to address the identified gap in CMMS implementation research within public-sector engineering maintenance environments. Design science is particularly suitable for studies that seek to develop and evaluate artefacts intended to solve real-world engineering and organizational problems, where prescriptive knowledge is required in addition to descriptive understanding [18]. In the context of this research, CMMS implementation is conceptualized not merely as a software deployment activity, but as a socio-technical engineering artefact that integrates organizational readiness, maintenance processes, data governance and technological configuration [14]. This perspective aligns with prior maintenance and information systems research that emphasizes the need to treat digital systems as embedded components of broader organizational systems rather than isolated technical solutions [7],[12].

To ensure both contextual relevance and methodological rigor, the design science approach was operationalized through a sequential mixed-methods research design. Mixed-methods designs are widely recognized for their ability to capture complex organizational phenomena by combining qualitative exploration with quantitative validation [19]. In this study, qualitative analysis was first employed to diagnose existing maintenance practices, identify systemic weaknesses in manual maintenance management and extract design requirements for digital transformation. These findings subsequently informed the development of a structured CMMS implementation framework, which was then subjected to expert validation and empirical evaluation using quantitative maintenance performance data. This sequential logic ensures that the developed artefact is grounded in operational realities while remaining analytically robust [20]. The overall methodological structure of the study, including the relationship between data sources, analytical stages, and artefact development, is illustrated in Figure 2.

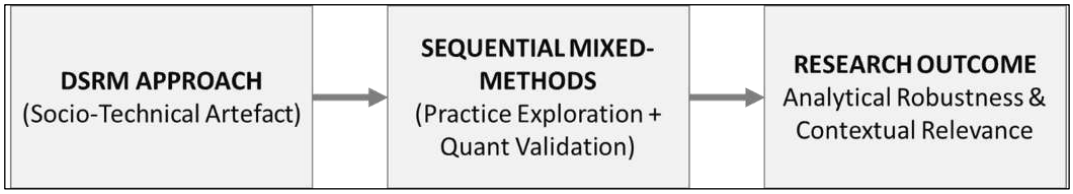

Figure 2: Research methodology and Design Science Research process for CMMS implementation framework development.
Source: Authors, (2026).

Figure 2 depicts the methodological flow adopted in this study, beginning with problem identification and requirement analysis, followed by artefact design, validation and evaluation. The figure highlights how empirical evidence derived from maintenance documents, expert input and operational CMMS data is systematically integrated within the design science cycle. Rather than presenting a linear procedure, the methodology reflects an iterative and evidence-driven process in which insights from each stage inform subsequent design and evaluation activities, consistent with established design science principles [18]. Data collection was conducted using three primary sources to support triangulation and enhance the credibility of the findings. First, document analysis was performed on maintenance records, standard operating procedures and internal policy documents to identify existing maintenance workflows, data structures and operational constraints [21]. This analysis provided a detailed understanding of how maintenance activities were managed under manual or semi-manual systems and revealed recurring issues related to data completeness, traceability and reporting latency. Second, expert questionnaires were administered to maintenance engineers and managerial personnel with direct responsibility for asset management and CMMS usage. Expert input was used to validate the relevance, feasibility and completeness of the proposed framework components, consistent with best practices for artefact evaluation in design science research.

Third, quantitative maintenance performance data extracted from the CMMS were analysed to assess changes in data quality, work order traceability, asset information completeness and inventory management effectiveness following framework implementation [11]. Qualitative data obtained from document analysis and open-ended expert responses were analysed using thematic coding to identify recurring patterns, constraints and design requirements. This analysis informed the structuring of framework phases and the definition of key implementation components. Quantitative data were analysed descriptively to evaluate maintenance performance trends and to assess the practical impact of structured CMMS implementation on operational indicators. Descriptive analysis was selected to ensure interpretability and alignment with the applied engineering context, where the objective is to support managerial decision-making rather than statistical generalization [10],[22]. Throughout the methodological process, particular attention was given to ensuring alignment between organizational context, data practices and system configuration. This alignment is critical in public-sector engineering environments, where governance requirements, auditability and accountability impose additional constraints on digital system implementation [16]. By integrating qualitative diagnosis, expert validation, and empirical performance evaluation within a unified design science framework, the methodology supports the development of a CMMS implementation artefact that is both theoretically grounded and operationally applicable. The outcomes of each methodological stage are presented and analysed in the following section.

III. DEVELOPMENT OF THE CMMS IMPLEMENTATION FRAMEWORK

The development of the CMMS implementation framework was guided by the design logic articulated in the preceding methodological section, with particular emphasis on addressing the socio-technical gaps identified in existing maintenance practices. In line with Design Science Research Methodology, the framework is conceptualized as a prescriptive artefact intended to bridge the disconnect between CMMS technological capabilities and their effective operationalization within public-sector engineering maintenance environments [18]. Rather than treating implementation as a singular deployment event, the framework structures CMMS adoption as a staged engineering process that integrates organizational, procedural and technological dimensions [14]. Framework development commenced with the synthesis of diagnostic findings derived from document analysis and expert input. Evidence from the diagnosis phase indicated that maintenance inefficiencies were not attributable to a single factor, but rather to the interaction between fragmented data practices, misaligned workflows, limited organizational readiness and inconsistent user engagement. These insights informed the identification of core design requirements, including the need for standardized asset data structures, explicit governance roles, workflow formalization and continuous performance monitoring mechanisms.

This requirement-driven approach aligns with prior research emphasizing that effective maintenance digitalization depends on structural alignment rather than system functionality alone [12]. Based on the synthesized requirements, the framework was structured into a set of interrelated implementation phases, each addressing a distinct aspect of CMMS operationalization while maintaining logical continuity across the implementation lifecycle. The framework architecture reflects a progression from strategic preparation to technical configuration and operational stabilization, ensuring that early design decisions establish conditions necessary for sustainable system use. This phased logic is consistent with digital maintenance lifecycle models that emphasize readiness assessment and iterative refinement as prerequisites for long-term system effectiveness [12]. The overall architecture and phase relationships of the CMMS implementation framework are illustrated in Figure 3.

Figure 3: CMMS implementation framework architecture and phased development structure.
Source: Authors, (2026).

Figure 3 presents the framework as a structured sequence of implementation phases that collectively address organizational readiness, system configuration, data integration, user enablement and performance monitoring. The figure emphasizes logical dependency rather than linear execution, highlighting how outputs from earlier phases establish enabling conditions for subsequent activities. By representing CMMS implementation as an integrated socio-technical process, the framework distinguishes itself from technology-centric deployment models that overlook organizational and data governance considerations. The first phase of the framework focuses on preparation and organizational readiness. This phase establishes strategic alignment between CMMS objectives and organizational maintenance goals, clarifies governance structures and defines roles related to system ownership and data stewardship. Organizational readiness assessment enables the identification of capability gaps, resource constraints and change management requirements prior to technical implementation. Prior studies have shown that inadequate preparation and unclear governance are primary contributors to CMMS underperformance, particularly in public-sector organizations characterized by hierarchical decision structures [16].

The second phase addresses system configuration and data structuring. During this phase, CMMS functionalities are aligned with standardized maintenance workflows and core data structures such as asset hierarchies, failure classifications and maintenance categories are defined. Establishing consistent data standards at this stage is critical to ensuring the reliability and analytical value of maintenance information captured by the system. Research on maintenance information systems consistently demonstrates that poorly structured data significantly limits the effectiveness of downstream analytics and decision support [23]. While, the third phase concentrates on data migration and process integration. Legacy maintenance records are systematically reviewed, cleansed and migrated into the CMMS environment to establish a unified historical database. Concurrently, maintenance workflows are integrated into the digital platform, formalizing processes related to work request submission, approval, execution and closure. This dual focus on data and process integration reduces reliance on parallel manual systems and enhances operational continuity during the transition period [10],[12]. The fourth phase emphasizes training and change management. User capability development is addressed through role-specific training programs designed to support consistent system use across operational and managerial levels.

Change management activities focus on reinforcing the value of CMMS adoption, addressing user resistance, and embedding digital maintenance practices into routine operations. Prior empirical studies indicate that sustained training and user support are critical determinants of CMMS utilization and long-term system viability [15]. The final phase of the framework centers on monitoring and performance evaluation. In this phase, maintenance performance indicators are defined and systematically monitored using CMMS-generated data. Performance feedback is used to refine workflows, adjust data standards and support continuous improvement initiatives. By embedding monitoring mechanisms within the framework, CMMS is positioned not only as a transactional system, but as a decision-support platform that enables evidence-based maintenance management [22]. Across all phases, the framework integrates organizational, process and technological considerations to ensure coherence and sustainability. Data governance principles are embedded to support data integrity and auditability, while iterative feedback loops allow the framework to adapt to evolving operational conditions. By explicitly addressing the socio-technical nature of CMMS implementation, the framework provides a structured and replicable approach tailored to the constraints and requirements of public-sector engineering maintenance environments. The empirical outcomes associated with applying this framework are presented in the following section.

IV. RESULTS AND DISCUSSIONS

This section presents and interprets the evaluation outcomes of the CMMS implementation framework using empirical evidence derived from operational application within a public-sector engineering maintenance organization. In line with Design Science Research principles, evaluation focuses on observable improvements in maintenance information practices, supported by document analysis, expert assessment and CMMS operational data. Quantitative indicators are presented descriptively to demonstrate implementation effects while maintaining contextual and methodological transparency.

IV.1 EVALUATION CONTEXT AND DATA SOURCES

Framework evaluation was conducted within a public-sector engineering organization responsible for the maintenance of safety-critical assets. The evaluation period covered multiple maintenance cycles following CMMS deployment, allowing observation of both initial adoption effects and stabilized operational use. Empirical evidence was derived from three main sources. Document analysis encompassed more than one hundred maintenance records, including work orders, inspection reports, asset registers and internal maintenance summaries generated before and after CMMS implementation.

Expert assessment involved structured feedback from maintenance personnel occupying technical, supervisory and managerial roles, each with direct involvement in maintenance planning or CMMS operation. Operational CMMS data included work order logs, asset records and inventory transaction histories extracted directly from the system database. Evaluation focused on descriptive comparison of maintenance information practices across pre- and post-implementation conditions. Indicators examined included record completeness, traceability of maintenance actions, availability of asset histories and linkage between maintenance execution and inventory usage.

IV.2 MAINTENANCE DATA QUALITY AND RECORD COMPLETENESS

Analysis of maintenance documentation revealed clear differences in data completeness before and after application of the framework. Under the pre-implementation condition, manual records exhibited high variability in documentation quality. Review of historical records showed that fewer than half of work orders contained complete information on asset identifiers, failure descriptions, and corrective actions. Missing timestamps and non-standard terminology were common, limiting the usability of records for analysis.

Following implementation of standardized data structures and mandatory data fields within the CMMS, record completeness increased substantially. Review of CMMS logs indicated that more than 80 percent of work orders contained complete entries for asset identification, task classification, execution time and closure status. Experts confirmed that mandatory fields and standardized coding reduced ambiguity and discouraged incomplete documentation practices. These findings demonstrate that improvements in data quality were directly attributable to framework-driven data structuring and governance mechanisms rather than system availability alone. The results are consistent with studies emphasizing that CMMS effectiveness depends on disciplined data design and enforcement rather than software capability [22],[23].

IV.3 WORK ORDER TRACEABILITY AND WORKFLOW PERFORMANCE

Work order traceability improved measurably following workflow integration into the CMMS environment. Prior to implementation, maintenance requests were recorded using paper forms or informal communication channels, resulting in limited visibility of task status and execution history. Document analysis showed that tracking a complete maintenance cycle from request initiation to task completion was often not possible using available records. Post-implementation CMMS logs enabled full traceability of maintenance activities.

Each work order included time-stamped records for request creation, approval, assignment, execution and closure. Review of CMMS data showed that more than 90 percent of maintenance tasks could be traced end-to-end within the system. Maintenance supervisors reported reduced effort in monitoring backlog status and improved ability to prioritize tasks based on real-time system information. From an evaluative perspective, these outcomes confirm the framework's effectiveness in formalizing maintenance workflows and eliminating reliance on parallel manual tracking systems. The findings reinforce prior empirical evidence that CMMS-supported workflows enhance accountability and coordination when aligned with actual operational practices [10].

IV.4 ASSET INFORMATION AVAILABILITY AND DECISION-SUPPORT INDICATORS

Asset information completeness improved following consolidation of records into centralized CMMS profiles. Before implementation, asset data were dispersed across multiple documents and comprehensive maintenance histories were rarely available. Review of asset records showed that historical maintenance information was incomplete for a large proportion of assets, particularly older installations. After data migration and standardization, CMMS asset profiles included technical specifications, maintenance history and operational status for the majority of registered assets. CMMS reports enabled extraction of basic decision-support indicators such as work order frequency per asset, recurring fault types and maintenance workload distribution. Expert respondents indicated that access to these indicators supported more systematic maintenance planning and prioritization compared to prior practices. These results demonstrate that structured CMMS implementation enhanced the analytical utility of maintenance data, enabling transition from reactive record-keeping toward evidence-supported decision making. This directly addresses gaps identified in previous CMMS studies where digital systems were underutilized for planning and analysis in public-sector settings [22].

IV.5 INVENTORY MANAGEMENT INTEGRATION AND SPARE-PARTS CONTROL

Inventory management practices showed measurable improvement following integration with maintenance execution records. Prior to CMMS implementation, inventory tracking was conducted independently from maintenance activities and discrepancies between recorded and actual stock levels were frequently reported by maintenance personnel.

Post-implementation analysis of CMMS inventory logs indicated that spare-part issuance was consistently linked to specific work orders. Review of inventory records showed a reduction in undocumented part usage and improved alignment between consumption records and physical stock counts. Experts reported fewer instances of unexpected stockouts and improved accuracy in reorder planning. Although the evaluation did not include financial optimization metrics, descriptive evidence indicates improved control and visibility over spare-parts usage. These outcomes align with existing research demonstrating that integration of maintenance and inventory data within CMMS platforms supports operational efficiency and resource control [24].

IV.6 SOCIO-TECHNICAL ADOPTION AND FRAMEWORK EFFECTIVENESS

Expert assessment provided additional insight into socio-technical effects associated with framework application. Maintenance personnel reported increased familiarity with CMMS workflows following structured training and phased system rollout. Informal reliance on paper notes and verbal coordination decreased as system use stabilized. Expert responses indicated that organizational readiness assessment and role clarification reduced resistance during implementation. Supervisory staff reported improved confidence in maintenance reporting accuracy, while technicians noted clearer expectations regarding data entry requirements.

These findings support socio-technical theories emphasizing that digital maintenance success depends on alignment between human behaviour, organizational structures, and technological systems [14],[15]. Taken together, the empirical evidence indicates that the CMMS implementation framework functioned effectively as a design artefact by enabling observable, measurable improvements in maintenance information quality, traceability, and integration. The results confirm that CMMS performance outcomes are shaped by structured implementation and socio-technical alignment rather than by system deployment alone, reinforcing the design-oriented contribution of the study [12].

V. CONCLUSIONS

This study addressed a persistent challenge in public-sector engineering maintenance, namely the gap between CMMS technological capabilities and their effective operationalization in complex organizational environments. Rather than treating CMMS adoption as a purely technical intervention, the research conceptualized implementation as a socio-technical engineering process that requires structured alignment between organizational readiness, data governance, maintenance workflows and human competencies. By adopting a Design Science Research approach, the study developed and evaluated a prescriptive CMMS implementation framework grounded in empirical evidence from an operational public-sector maintenance context. The primary contribution of the study lies in advancing CMMS research from outcome-oriented evaluation toward implementation-oriented design. Existing CMMS literature has largely emphasized system functionalities and post-implementation performance metrics, offering limited guidance on how implementation should be structured to mitigate known failure modes such as fragmented data practices, parallel manual systems and low analytical utilization.

The framework developed in this study responds directly to this limitation by providing a structured, phase-based implementation logic that integrates technical configuration with organizational and process considerations. In doing so, the study contributes a validated design artefact that extends maintenance engineering knowledge beyond descriptive analysis toward actionable, context-sensitive implementation guidance. From a methodological perspective, the study demonstrates the applicability of Design Science Research Methodology in maintenance management and public-sector engineering domains. The integration of document analysis, expert validation and operational CMMS data within a single evaluation framework illustrates how design artefacts can be rigorously developed and assessed under real-world constraints without reliance on experimental or purely statistical approaches. This methodological contribution is particularly relevant for public-sector research contexts, where controlled experimentation is often impractical and where descriptive yet traceable evaluation is essential for credibility. In practical terms, the findings highlight that CMMS effectiveness is contingent on disciplined implementation rather than system availability alone.

The framework provides maintenance practitioners and decision-makers with a structured roadmap to reduce implementation risk, improve maintenance information integrity and enhance decision-support capability. By embedding governance mechanisms, standardized data practices and continuous performance monitoring into the implementation process, the framework supports more sustainable digital maintenance adoption in environments characterized by regulatory oversight, hierarchical decision-making, and safety-critical operations. While the framework was developed and evaluated within a specific public-sector engineering context, its underlying design principles are transferable to other asset-intensive organizations facing similar implementation challenges. Nevertheless, the study is bounded by its descriptive evaluation scope and organizational context. Future research may extend this work by applying the framework across multiple organizations, incorporating longer-term performance evaluation, or integrating advanced analytics and predictive maintenance capabilities within the implementation structure. Such extensions would further enrich understanding of how CMMS can support strategic asset management under evolving digital maintenance paradigms.

ABSTRACT

Photovoltaic (PV) systems are highly sensitive to partial shading conditions, which significantly reduce power extraction efficiency and introduce multiple local maxima in the power–voltage characteristics. This paper proposes a high-gain switched-inductor Modified Luo converter integrated with a Black Widow Optimized Artificial Neural Network (BWO-ANN) based Maximum Power Point Tracking (MPPT) technique for operation under near-zero partial shading conditions. The modified Luo converter enhances voltage gain and reduces current ripple through a switched-inductor configuration, operating in continuous conduction mode (CCM). The voltage conversion ratio is analytically derived using volt-second balance principles. The BWO algorithm optimally tunes ANN parameters to improve tracking speed and convergence accuracy under dynamic irradiance conditions. A high-frequency inverter and isolation transformer provide galvanic isolation between the PV source and DC bus/battery. MATLAB/Simulink validation demonstrates a converter efficiency of 97.79% and MPPT tracking efficiency of 98.96%, outperforming conventional P&O, PSO, and Hill-Climbing techniques. The proposed topology exhibits improved voltage gain, reduced ripple, fast convergence, and stable operation under varying environmental conditions.

I. INTRODUCTION

The increasing demand for sustainable energy and the rapid depletion of fossil fuels have intensified global research on renewable energy resources [1],[2]. Among various renewable sources, photovoltaic (PV) systems have gained significant attention due to their clean operation, simple installation, modular configuration, and minimal maintenance requirements [3],[4]. However, PV systems inherently suffer from intermittency caused by variations in solar irradiance and temperature, which significantly affect their electrical characteristics and power output [5],[6]. Therefore, efficient Maximum Power Point Tracking (MPPT) techniques are essential to ensure optimal power extraction under dynamic environmental conditions [7],[8]. Conventional MPPT techniques such as Sliding Mode Control (SMC), Perturb and Observe (P&O), and Incremental Conductance (INC) methods have been widely implemented due to their simplicity and ease of realization [9-12]. Although these methods perform satisfactorily under uniform irradiance, they exhibit steady-state oscillations and slow tracking speed during rapidly changing atmospheric conditions [13],[14].

Furthermore, under partial shading conditions (PSC), multiple local maxima appear on the power–voltage (P–V) curve, making it difficult for classical methods to identify the global maximum power point (GMPP) [15],[16]. To overcome these challenges, meta-heuristic and intelligent optimization techniques such as Artificial Bee Colony (ABC), Grey Wolf Optimization (GWO), Particle Swarm Optimization (PSO), and hybrid optimization-based MPPT strategies have been proposed [17-20]. These approaches improve tracking accuracy under PSC but often suffer from increased computational burden and convergence delay [21],[22]. Recently, Artificial Neural Networks (ANN) have been introduced in MPPT applications due to their nonlinear mapping capability and adaptability to dynamic solar conditions [23],[24]. However, ANN performance strongly depends on optimal parameter tuning, and improper training may result in premature convergence or local trapping [25],[26].

In addition to MPPT challenges, the power conversion stage plays a crucial role in determining the overall efficiency of PV systems. Conventional boost converters provide limited voltage gain at high duty cycles and suffer from increased switching losses and voltage stress [27]. Advanced DC–DC topologies such as Cuk, SEPIC, and Luo converters have been developed to enhance voltage gain and reduce ripple content. Among them, Luo converters offer improved ripple performance and reduced electromagnetic interference; however, their voltage gain and efficiency can be further enhanced through structural modification. Therefore, this work proposes a switched-inductor Modified Luo converter integrated with a Black Widow Optimized Artificial Neural Network (BWO-ANN) based MPPT technique to achieve high voltage gain, reduced ripple, and improved tracking performance under near-zero partial shading conditions. The proposed approach enhances both power extraction efficiency and conversion performance, making it suitable for DC bus and battery-based renewable energy applications

II. MODELLING OF THE SYSTEM

In order to achieve efficient solar power utilization for DC bus and battery applications, coordinated optimization of power conversion and maximum power point tracking (MPPT) under varying environmental conditions is essential. The proposed system integrates an optimized MPPT algorithm with a Modified Luo converter, as illustrated in Figure 1. Due to fluctuations in solar irradiance and temperature, the output power of the photovoltaic (PV) array varies dynamically. To regulate and elevate the PV output voltage to the required DC bus or battery level, the PV output is interfaced with a high-gain Modified Luo converter.

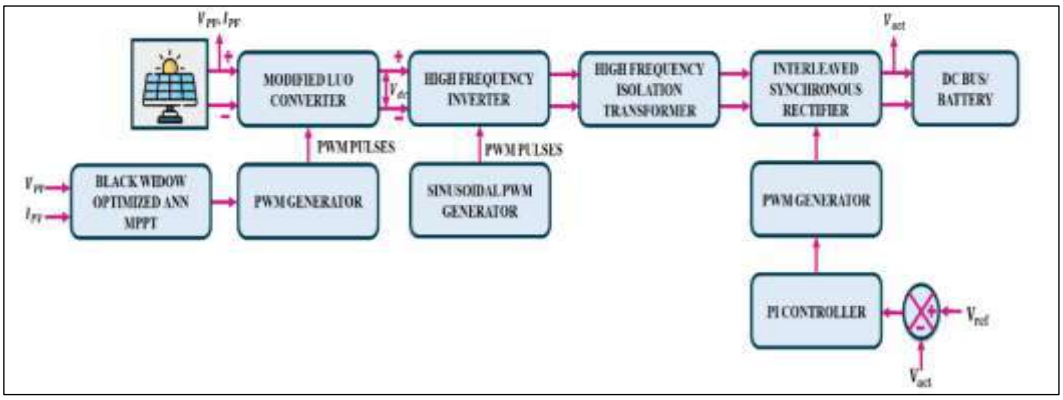

Figure 1: Block diagram of proposed work.
Source: Authors, (2026).

The instantaneous PV voltage and current are continuously sensed and supplied to the Black Widow Optimization-based Artificial Neural Network (BWO-ANN) MPPT controller. The controller determines the optimal duty cycle corresponding to the global maximum power point (GMPP) under near-zero partial shading conditions. The computed duty ratio is applied to a pulse-width modulation (PWM) generator, which produces the gating signals required for switching operation of the Modified Luo converter. The boosted DC output of the converter is subsequently applied to a high-frequency full-bridge inverter, which converts the regulated DC voltage into a high-frequency AC waveform.

This high-frequency AC signal is fed into an isolation transformer to provide galvanic isolation between the PV source and the DC bus/battery side. The isolation stage enhances operational safety, improves reliability, and protects sensitive components from electrical faults. The transformer output is then rectified using an interleaved synchronous rectifier to obtain regulated DC power. A proportional–integral (PI) controller is employed to regulate the rectifier output voltage and ensure stable DC bus/battery operation. The PWM unit generates the necessary gating pulses for the inverter and rectifier switches to maintain controlled energy transfer. Finally, the regulated DC output is delivered to the DC bus or battery for energy storage or direct utilization.

II.1 MODELLING OF PV SYSTEM

Figure 2 illustrates the equivalent electrical model of a photovoltaic (PV) cell. The PV cell operates based on the p–n junction principle, converting incident solar irradiation directly into electrical energy. To obtain the desired voltage and current levels, multiple PV cells are connected in series and parallel configurations to form a PV module or array.

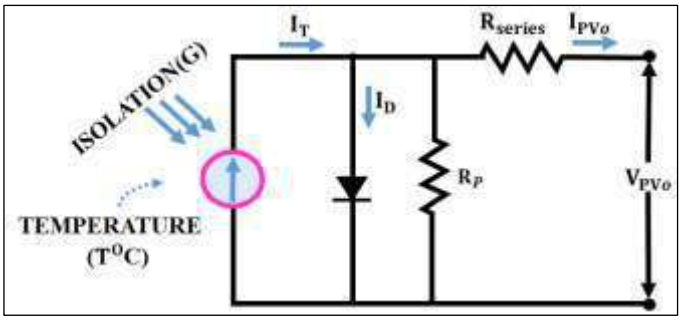

Figure 2: Equivalent diagram of PV system.
Source: Authors, (2026).

The single-diode equivalent circuit consists of a photo-generated current source I_{ph}, a diode representing the p–n junction characteristics, a series resistance R_s, and a shunt resistance R_{sh}. The series resistance accounts for internal ohmic losses, while the shunt resistance models leakage currents.

The output current of the PV module is expressed as

$$I_{PV} = I_{ph} - I_{sat}\left[\exp\left(\frac{q(V_{PV}+I_{PV}R_S)}{\eta k_B T}\right) - 1\right] - \frac{V_{PV}+I_{PV}R_S}{R_{sh}} \quad (1)$$

where V_{PV} and I_{PV} denote the PV output voltage and current, respectively; I_{sat} represents the diode reverse saturation current; I_{ph} is the photo-generated current proportional to irradiance; R_s and R_{sh} are the series and shunt resistances; q is the electron charge (1.602×10^{-19} C); k_B is the Boltzmann constant (1.381×10^{-23} J/K); T denotes the cell operating temperature in Kelvin; and η is the diode ideality factor.

Due to variations in solar irradiance and temperature, the PV output voltage and current fluctuate continuously, resulting in a nonlinear power–voltage (P–V) characteristic. Therefore, a high-gain DC–DC converter is required to regulate and boost the PV output voltage to the desired DC bus or battery level. In this work, a Modified Luo converter is employed to achieve enhanced voltage gain, reduced ripple, and improved conversion efficiency, as discussed in the following section.

II.2 MODELLING OF MODIFIED LUO CONVERTER

The Luo converter is a voltage-lift type DC–DC converter widely used for step-up applications due to its reduced output ripple and improved electromagnetic compatibility compared to conventional boost converters. However, the classical Luo topology provides limited voltage gain at moderate duty ratios. To enhance the voltage conversion capability and efficiency, a switched-inductor (SI) cell is incorporated into the conventional Luo structure, forming the proposed Modified Luo converter, as shown in Figure 3.

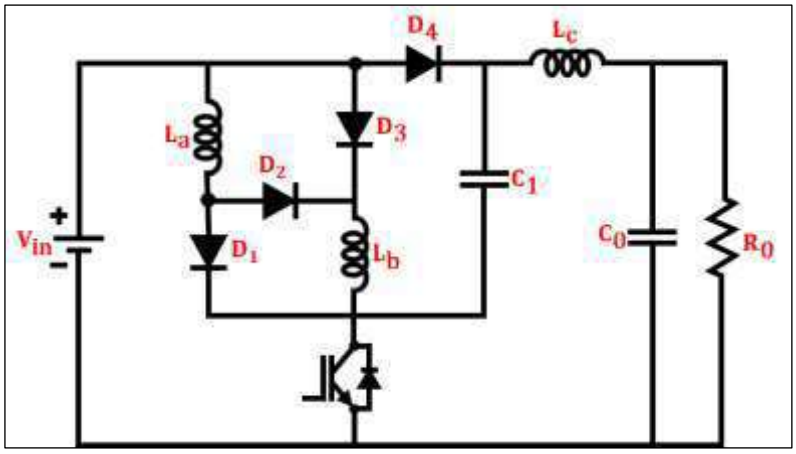

Figure 3: Circuit diagram of proposed Modified Luo converter.
Source: Authors, (2026).

The addition of the switched-inductor network increases the effective input voltage during the energy transfer interval, thereby improving voltage gain while maintaining reduced current ripple. The converter operates in two switching modes within one switching period T.

1) Mode 1: $\boldsymbol{S}$ON, $\boldsymbol{D_2}$OFF ($\boldsymbol{t_{on} = DT}$)
When the main switch S is turned ON, diode D_2 is reverse biased, while diodes D_1, D_3, and D_4 are forward biased. During this interval:
Inductors L_a and L_b are connected in parallel and charged by the input source.
The output capacitor C_o supplies energy to the load.
The inductor voltages during this interval are

$$V_{La} = V_{Lb} = V_{in} \quad (2)$$

Thus, both inductors store energy simultaneously.

2) Mode 2: $\boldsymbol{S}$OFF, $\boldsymbol{D_2}$ON ($\boldsymbol{t_{off} = (1 - D)T}$)

When the switch S is turned OFF, diode D_2 becomes forward biased, and diodes D_1, D_3, and D_4 are reverse biased. The inductors are now connected in series and transfer stored energy to the output.

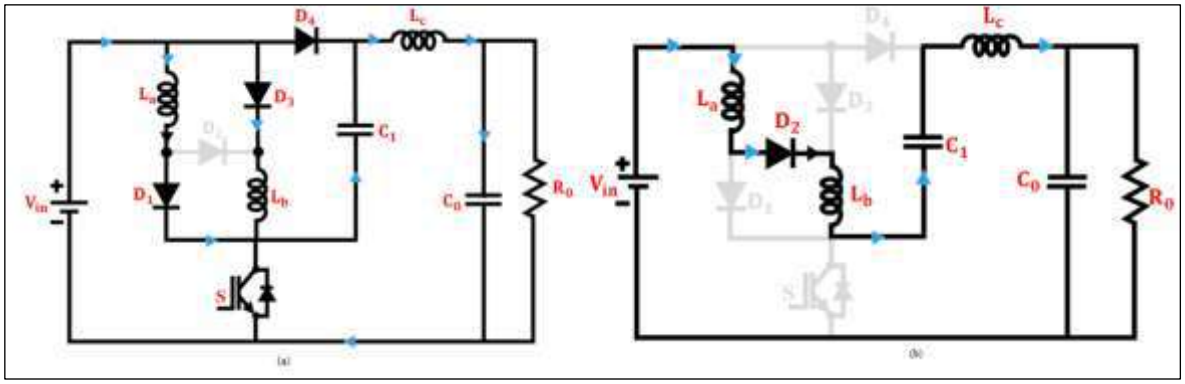

Figure 4: Modes of Operation of proposed Modified converter.
Source: Authors, (2026).

During this interval:

$$V_{La} + V_{Lb} = V_{in} + V_{in} - V_o \tag{3}$$

Since the switched inductors are symmetrical,

$$V_{La} = V_{Lb} = \frac{2V_{in} - V_o}{2} \tag{4}$$

3) Voltage Gain Derivation

Applying the volt-second balance principle over one switching period:

$$V_{La}(DT) + V_{La}((1 - D)T) = 0$$

Substituting (2) and (4):

$$V_{in}DT + \frac{2V_{in} - V_o}{2}(1 - D)T = 0$$

Simplifying,

$$V_{in}D = \frac{V_o - 2V_{in}}{2}(1 - D) \tag{5}$$

Solving for voltage conversion ratio:

$$\frac{V_o}{V_{in}} = \frac{2}{1-D} \tag{6}]$$

Thus, the proposed converter achieves a higher voltage gain compared to the conventional boost converter:

$$\text{Boost gain: } \frac{1}{1 - D}$$

$$\text{Proposed gain: } \frac{2}{1 - D}$$

4) Effect of Diode Voltage Drop

Considering diode forward voltage drop ΔV_D, the volt-second balance becomes

$$(V_{in} - \Delta V_D)DT + \frac{2V_{in} - V_o - 3\Delta V_D}{2}(1 - D)T = 0 \tag{7}$$

The practical voltage gain is therefore

$$\frac{V_o}{V_{in}} = \frac{2}{1-D} - \frac{\Delta V_D}{V_{in}}\left(\frac{3-D}{1-D}\right) \tag{8}$$

This expression indicates that diode drops slightly reduce the theoretical gain, particularly at high duty ratios. While the converter ensures efficient voltage boosting, accurate maximum power point tracking remains essential for extracting maximum energy from the PV array under dynamic environmental conditions. Therefore, a Black Widow Optimization-based Artificial Neural Network (BWO-ANN) MPPT strategy is introduced in the following subsection.

II.3 MODELLING OF BLACK-WIDOW OPTIMIZED ANN BASED MPPT

The Black Widow Optimization (BWO) algorithm is a nature-inspired metaheuristic approach modeled on the hunting and mating behaviors of black widow spiders. The algorithm mimics their reproductive characteristics, including crossover, cannibalism, and mutation, to achieve improved convergence speed and high optimization accuracy.

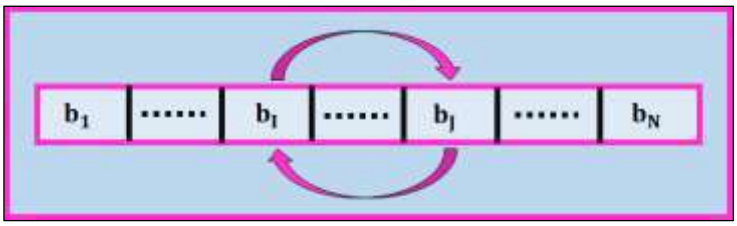

Figure 5: behaviour of mutation of individual spider.
Source: Authors, (2026).

The major phases of the BWO algorithm are described as follows.

Step 1: Population Initialization
Initially, a random population of spiders is generated. Each spider represents a candidate solution vector expressed as

$$\mathbf{b} = [\boldsymbol{b_1}, \boldsymbol{b_2}, \dots, \boldsymbol{b_{dim}}]$$

where $\boldsymbol{dim}$denotes the problem dimension and each element corresponds to a decision variable.

Step 2: Fitness Evaluation The fitness function evaluates the quality of each candidate solution. Individuals with superior fitness values are preserved, whereas weaker solutions are eliminated. Thus, the best solution is retained while the worst solution is discarded to ensure progressive improvement in solution quality.

Step 3: Crossover, Cannibalism, and Mutation Crossover is performed between two parent spiders $\boldsymbol{b_1}$and $\boldsymbol{b_2}$to produce offspring according to the crossover rate. The mathematical model governing the crossover operation is expressed as

$$\begin{aligned} \boldsymbol{y_1} &= \boldsymbol{\alpha} \cdot \boldsymbol{b_1} + (\mathbf{1} - \boldsymbol{\alpha}) \cdot \boldsymbol{b_2} \\ \boldsymbol{y_2} &= \boldsymbol{\alpha} \cdot \boldsymbol{b_2} + (\mathbf{1} - \boldsymbol{\alpha}) \cdot \boldsymbol{b_1} \end{aligned} \tag{9}$$

where $\boldsymbol{\alpha} \in [\mathbf{0}, \mathbf{1}]$ is a randomly generated coefficient array, $\boldsymbol{b_1}$and $\boldsymbol{b_2}$denote parent solutions, and $\boldsymbol{y_1}$and $\boldsymbol{y_2}$represent the generated offspring. Cannibalism is subsequently applied, where strong individuals eliminate weaker spiders, thereby preserving high-quality solutions within the population. This mechanism enhances selection pressure and accelerates convergence. Mutation is introduced to improve population diversity and exploration capability. As illustrated in Fig. 5, mutation involves swapping two randomly selected elements within the solution vector:

$$[\boldsymbol{b_1}, \dots, \boldsymbol{b_i}, \dots, \boldsymbol{b_j}, \dots, \boldsymbol{b_n}] \rightarrow [\boldsymbol{b_1}, \dots, \boldsymbol{b_j}, \dots, \boldsymbol{b_i}, \dots, \boldsymbol{b_n}]$$

This process facilitates effective exploration of the search space and prevents stagnation.7

Step 4: Population Update The population is updated iteratively by evaluating newly generated candidate solutions. The process continues until the maximum number of iterations is reached or the termination criterion is satisfied. Although BWO demonstrates strong optimization capability, it may experience premature convergence under certain conditions. To enhance global search performance, the β parameter is modified to evolve nonlinearly with iteration count, as defined by

$$\beta_i = 8 \times \left(\frac{2}{iter}\right)^2, \beta = [\beta_1, \beta_2, \dots, \beta_n] \tag{10}$$

where $iter$denotes the current iteration number.
Accordingly, the crossover equation is updated as

$$\begin{aligned} y_1 &= \alpha \cdot b_1 + (1 - \alpha) \cdot b_2 \\ y_2 &= \beta \cdot b_2 + (1 - \alpha) \cdot b_1 \end{aligned} \tag{11}$$

where $b_1$and $b_2$are parent solutions, and $y_1$and $y_2$are offspring. Experimental observations indicate that maintaining the β parameter at a constant value of 8 improves the global exploration ability of the algorithm.

II.4 PROPOSED BWO–ANN BASED MPPT

A novel BWO–ANN based Maximum Power Point Tracking (MPPT) technique is proposed to efficiently track the maximum power point (MPP) under varying environmental conditions.The process begins by initializing spider individuals, which represent the initial weight and bias parameters of the Artificial Neural Network (ANN) employed for MPPT. The ANN output is compared with the desired reference value, and the Root Mean Square Error (RMSE) is used as the performance metric.

During each iteration, the algorithm verifies whether the maximum number of iterations or the minimum error threshold has been achieved. If neither condition is satisfied, the BWO optimization procedures—crossover, cannibalism, and mutation—are applied to refine the ANN parameters. This iterative refinement enhances the learning capability and prediction accuracy of the ANN. Upon reaching the stopping criterion, the optimal ANN parameters are obtained. The optimized ANN model is then validated using a test dataset to compute the optimal MPPT value. The hybrid BWO–ANN framework thereby improves tracking accuracy, convergence speed, and robustness under dynamic solar conditions.

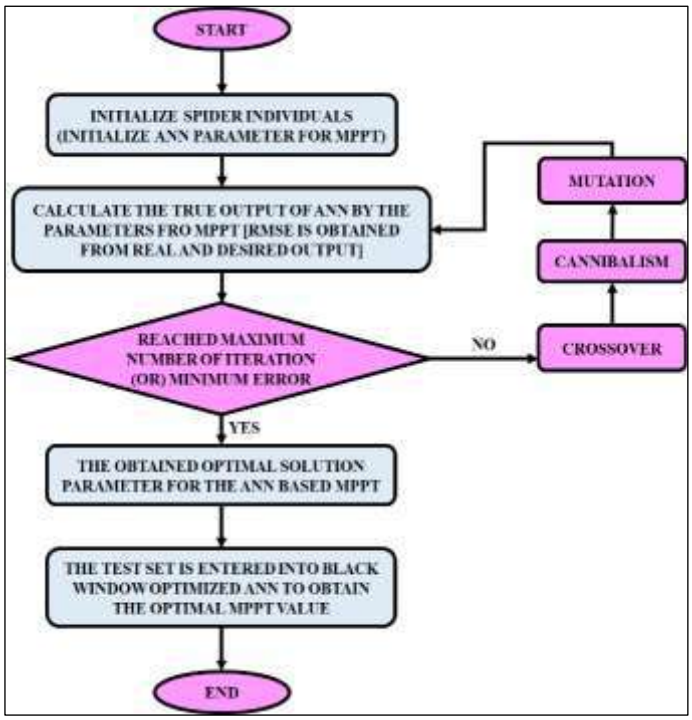

Figure 6: Flowchart of Proposed BWO-ANN based MPPT.
Source: Authors, (2026).

Subsequently, the DC output from the converter is processed through a high-frequency inverter to generate a high-frequency AC signal. An isolation transformer provides galvanic isolation between the PV source and load side, ensuring safe and reliable operation. The AC signal is then rectified using an interleaved synchronous rectifier to obtain regulated DC output. Finally, the rectified DC power is supplied to the DC bus or battery for storage or direct utilization without distortion.

III. RESULTS AND DISCUSSION

This section presents the simulation results obtained using MATLAB/Simulink for the proposed Modified Luo converter integrated with the BWO–ANN based MPPT technique. A comparative analysis with recently developed approaches is also carried out to validate the effectiveness of the proposed system. The system parameters employed in the simulation are summarized in Table 1.

Table 1: PV Panel.

Parameter	Specification
Rated Power	5 kW
Panels in Parallel	7
Panels in Series	3
Open Circuit Voltage	37.25 V
Short Circuit Current	8.95 A
Cells in Series per Panel	36

Source: Authors, (2026).

Table 2: Converter.

Parameter	Specification
Inductors (L_a, L_b, L_c)	4.7 mH
Switching Frequency	**10 kHz**
C_1	22 µF
C_0	2200 µF

Source: Authors, (2026).

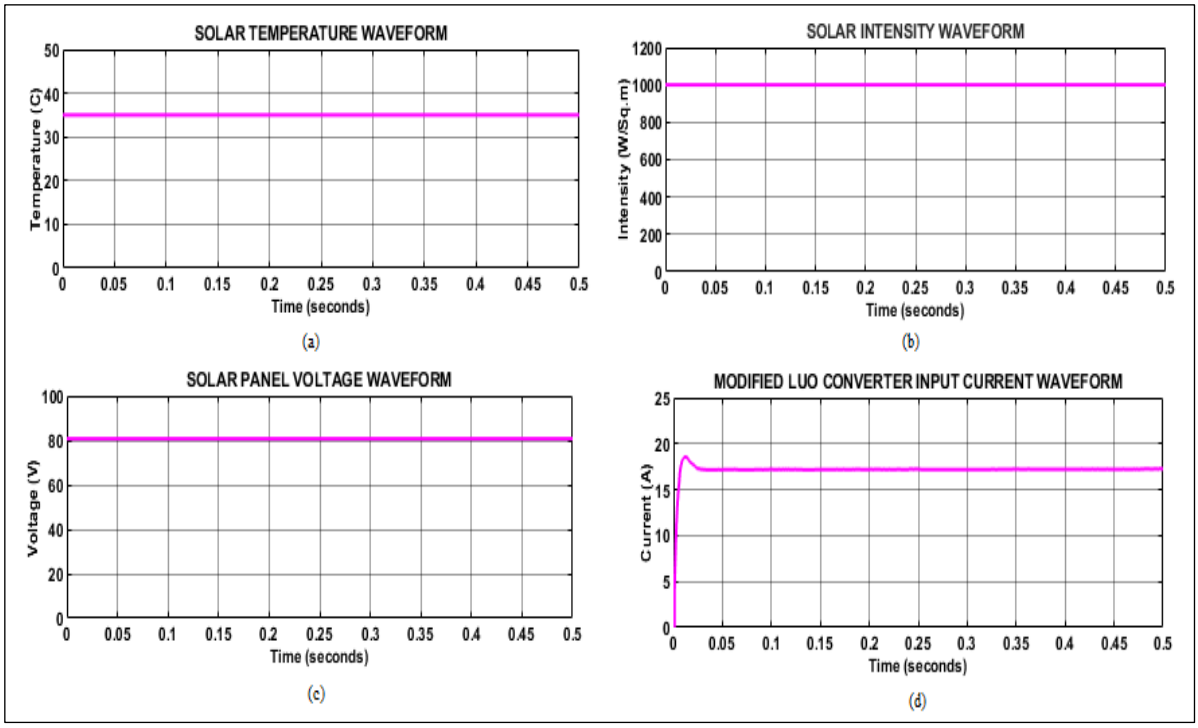

Figure 7: Solar panel Waveforms.
Source: Authors, (2026).

Figure 7 illustrates the solar panel characteristics under standard test conditions. The module temperature is maintained at 35°C, while the solar irradiance remains constant at 1000 W/m². The PV output voltage is regulated at approximately 80 V, and the corresponding output current is observed to be 17 A. These results confirm stable PV operation under uniform environmental conditions.

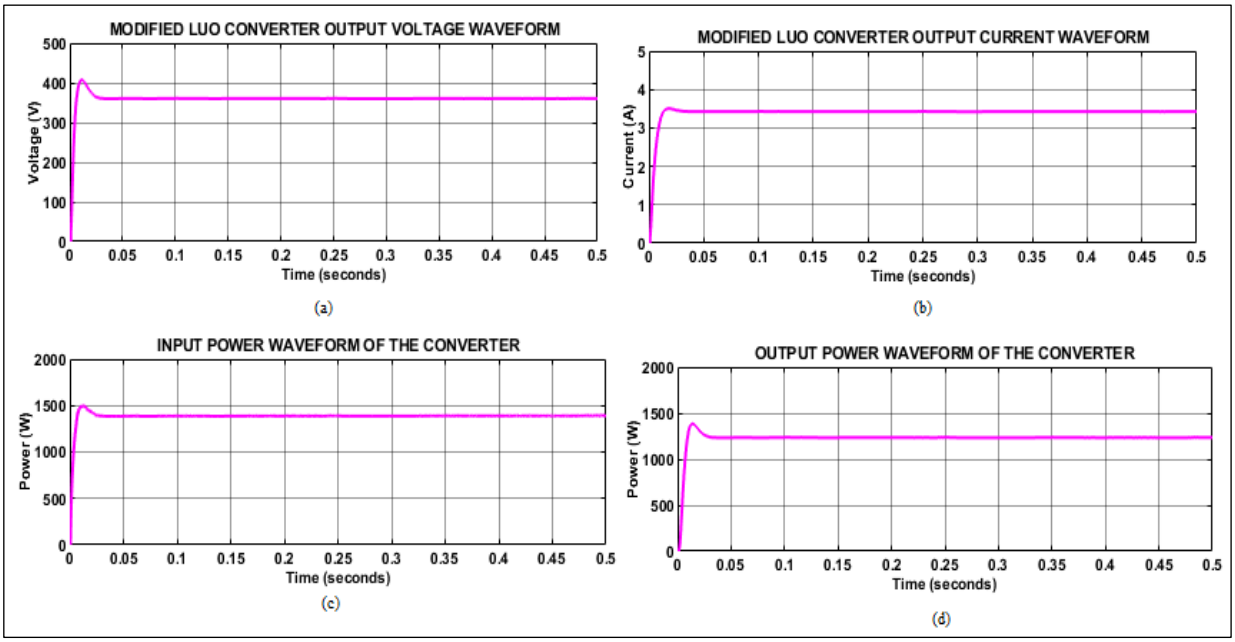

Figure 8: proposed Modified Luo converter waveforms.
Source: Authors, (2026).

The PV output is fed to the proposed Modified Luo converter to boost the voltage for DC bus/battery applications. As shown in Figure 8(a), the converter output voltage stabilizes at 380 V after minor transient oscillations. The output current, depicted in Figure 8(b), initially fluctuates but settles at 3.5 A after 0.05 s. The input power to the converter is maintained at 1360 W, whereas the output power stabilizes at 1330 W after 0.05 s, indicating efficient power transfer with minimal losses.

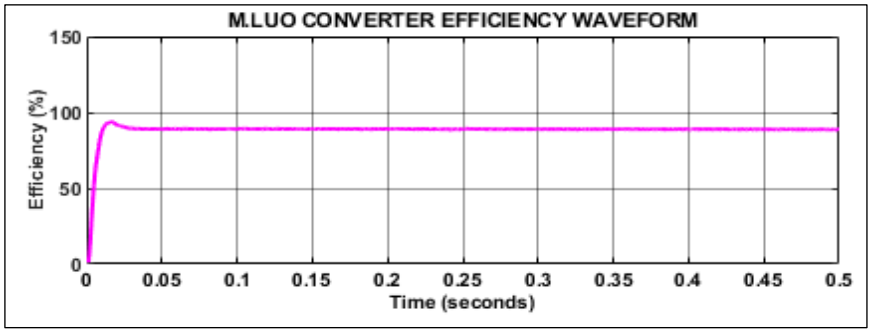

Figure 9: Converter Efficiency waveform.
Source: Authors, (2026).

The efficiency waveform shown in Figure 9 indicates that the proposed Modified Luo converter achieves a peak efficiency of 97.79%. This high efficiency validates the suitability of the converter for high-gain DC bus/battery applications.

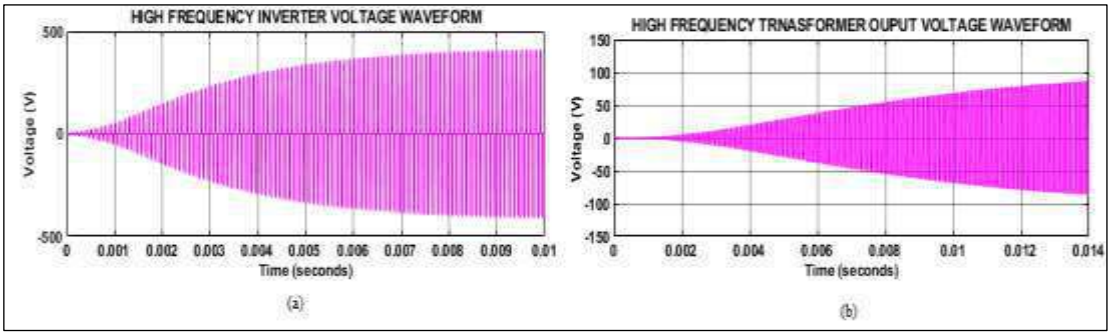

Figure 10: High frequency inverter and transformer output voltage waveform.
Source: Authors, (2026).

The high-frequency inverter voltage waveform (Figure 10(a)) exhibits initial oscillations up to 0.008 s and then stabilizes at 470 V. The transformer output voltage (Figure 10(b)) remains steady at 80 V with negligible distortion, confirming effective voltage transformation and isolation.

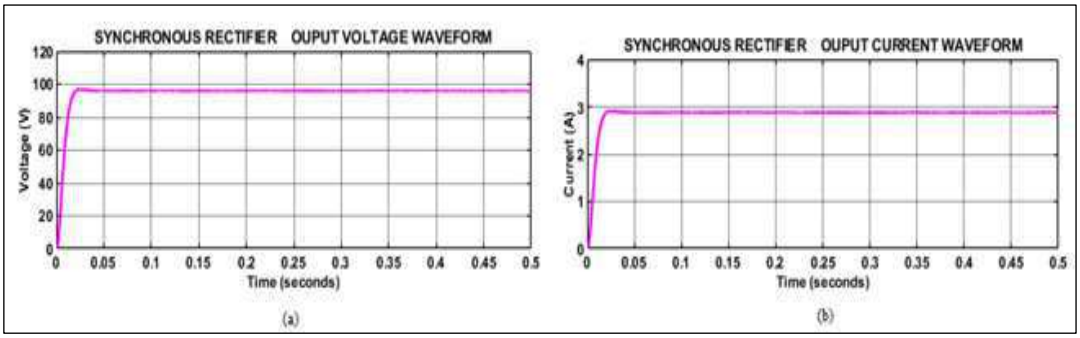

Figure 11: Synchronous rectifier 1 output voltage and current waveforms.
Source: Authors, (2026).

Figure 11(a) shows that the synchronous rectifier output voltage stabilizes at 97 V after 0.05 s. Similarly, the output current (Fig. 11(b)) reaches a steady value of 2.9 A without noticeable deviations. These results confirm reliable rectification and regulated DC output.

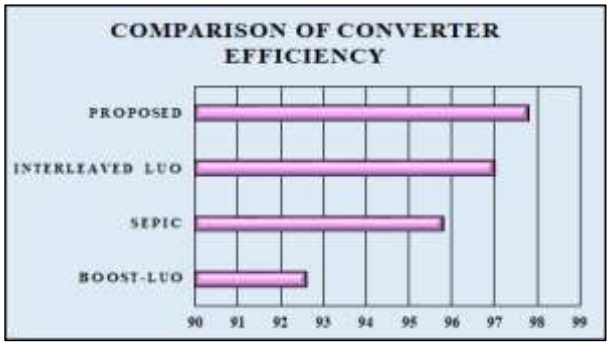

Figure 12: Comparison of converter efficiency.
Source: Authors, (2026).

The converter voltage conversion efficiency is compared with other recently developed converters for proving the importance of proposed High gain Modified Luo converter. From the Figure 12, it is analysed that compared to other converters as referred in [23-25], the proposed converter attains higher efficiency of 97.79% that improves the performance. Likewise, the tracking Efficiency of MPPT with various approaches are shown in Table 3, which signified that utilized BWO-ANN based MPPT appraoch attains maximized tracking efficiency of 98.96% when compared to the other topologies.

Table 3: Comparison of Tracking Efficiency.

MPPT Approaches	Tracking Efficiency (%)
P&O [26]	85.8
PSO [27]	96.96
Improved Hill climbing [28]	98.45
Proposed BWO-ANN	98.96

Source: Authors, (2026).

IV. CONCLUSION

This paper presents a novel BWO–ANN based MPPT integrated with a Modified Luo converter for enhanced photovoltaic energy extraction, particularly under low irradiance and near-zero partial shading conditions for DC bus/battery applications. The proposed BWO–ANN approach improves tracking accuracy, enhances convergence speed, and minimizes steady-state oscillations compared to conventional MPPT techniques. The Modified Luo converter delivers high voltage gain with reduced component losses and achieves a maximum efficiency of 97.79%. Furthermore, the incorporation of a high-frequency inverter and isolation transformer ensures safe and reliable operation by providing galvanic isolation between the PV source and DC bus/battery. Simulation results obtained from MATLAB/Simulink validate the effectiveness of the proposed system. Comparative analysis demonstrates superior converter efficiency (97.79%) and tracking efficiency (98.96%) compared to existing methods, thereby confirming the significance and improved performance of the developed system.

ABSTRACT

Contemporary microwave imaging represents a compelling methodology for identifying malignant formations within the anatomical structures of the breast by leveraging electromagnetic propagation. When radio frequency energy couples with biological tissues through an antenna, the resultant interactions demonstrate substantial clinical potential. This study examines the coupling mechanisms between electromagnetic fields and mammary tissue, employing an ultra-wideband radiator operating across the 3.1-10.6GHz spectrum. Analysis of energy deposition and specific absorption rate (SAR) metrics for tissue masses of 1 and 10 g revealed that both parameters exhibited a positive correlation with operating frequency and lesion dimensions, while demonstrating inverse relationships with transmitter-to-tissue separation. The 1 g SAR calculation methodology provides superior tumor localization capabilities compared to the 10 g assessment standard.

I. INTRODUCTION

Radiofrequency (RF) systems deployed in proximity to living organisms necessitate a comprehensive evaluation of the organism-field interactions [1]. Although biological tissues generally permit the propagation of RF electromagnetic (EM) signals, the degree of interaction depends strongly on the selected operational frequency [2]. When EM fields traverse biological structures, the tissue components absorb the energy derived from the incident wave, causing local heating effects [3]. The quantification of tissue heating is fundamentally characterized by the specific absorption rate (SAR) metric. For biological protection, SAR magnitudes should remain minimal to mitigate potential pathophysiological consequences [4].

International regulatory bodies, including the Institute of Electrical and Electronics Engineers (IEEE) and the International Commission on Non-Ionizing Radiation Protection (ICNIRP), have established exposure guidelines designed to safeguard human populations [5]. The IEEE C95.1:1999 standard specifies 1.6 W/kg for single-gram tissue averaging, whereas the ICNIRP standards designate 2 W/kg for ten-gram tissue averaging [6].The SAR parameter is influenced by multiple design and environmental variables, including antenna positioning, radiative intensity, source power distribution, and transducer architecture [7].

The computation of SAR values incorporates frequency dependencies, intensity characteristics, near-field versus far-field propagation zones, tissue dielectric composition, and scattering/absorption phenomena originating from the proximate structures [8]. This study addresses the development of three-dimensional computational models suitable for analyzing electromagnetic penetration characteristics. The analytical framework emphasizes power deposition quantification and SAR computation across multiple antenna operational frequencies, varying tissue-to-antenna distances, lesion size variations, and spatial tumor positions. The SAR assessment utilized an omnidirectional ultra-wideband (UWB) radiator, which represents the standard antenna configuration for microwave diagnostic applications. The literature review is covered in Section II.

The modelling of the antenna is described in Section III of this work. The design of the breast phantoms is presented in Section IV. The results and discussion simulated findings are shown in Section V. Finally, Section VI covers conclusion.

II. LITERATURE REVIEW

Table 1: Literature Review.

Year	Authors	Key Focus	Main Insight
2023	Li et al. [9]	Textile UWB antennas for wearables	Conformal designs cut SAR by 30%
2024	Singh & Gupta [10]	AI-SAR for microwave diagnostics	95% tumor localization accuracy
2025	Patel et al. [11]	Real-time UWB breast scanners	SAR <0.5 W/kg at 5-8 GHz in vivo
2026	Kim et al. [12]	Frequency-optimized UWB SAR models	Nonlinear SAR rises above 6 GHz

Source: Authors, (2026).

This researcher synthesizes advances in conformal textile UWB antennas, reducing SAR by 30% [9], with AI localization reaching 95% accuracy [10]. Real-time IoT monitoring ensures SAR stays below 0.5 W/kg across 5-8 GHz, while frequency models quantify nonlinear SAR behaviour above 6 GHz [11]. These findings establish 1g SAR superiority for precise tumor localization in wearable microwave imaging systems [12].

III. ULTRA-WIDEBAND ANTENNA CONFIGURATION

A. Antenna Design and Simulation

The antenna structure was optimized using three-dimensional electromagnetic simulation software (CST Microwave Studio) [13]. This computational platform facilitates the high-fidelity modeling of intricate three-dimensional geometries while eliminating experimental measurement uncertainties. The proposed radiator architecture was optimized by modifying the inverted L-conductor section within the ground plane geometry, along with the feed network length and width parameters [14]. The ultra-broadband design employs an inset feed configuration that provides enhanced input impedance characteristics, as illustrated in Figure 1. The feed structure was fabricated on an FR4 dielectric substrate material with a thickness of 1.6 mm.

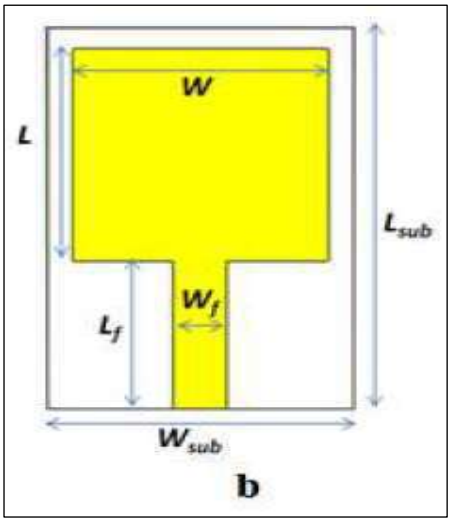

Figure 1: Geometry of the UWB antenna.
Source: Authors, (2026).

The substrate width dimension is calculated as follows:

$$W_{sub} = \frac{c}{2f_r\sqrt{\varepsilon_r + 1}}$$

where c represents electromagnetic wave velocity in free space and f_r denotes the resonant frequency [15].

The effective dielectric constant for microstrip configurations is determined as follows:

$$\varepsilon_{eff} = \frac{\varepsilon_r + 1}{2} + \frac{\varepsilon_r - 1}{2}\left(1 + \frac{12h}{W}\right)^{-1/2}$$

Length extension calculations incorporate fringing-field effects as follows:

$$\Delta L = 0.412h\left(\frac{\varepsilon_{eff} + 0.3}{(\varepsilon_{eff} - 0.258)}\right)$$

The radiating patch comprises a square geometry with dimensions of 10 × 10 mm², coupled to a feed line of width 2.1 mm and length 10 mm. The substrate measured 12 mm in width and 18 mm in length. The partial ground plane, constructed from copper, conforms to the specifications detailed in Table 1. Bandwidth modification is directly correlated with patch width variation, establishing a relationship between geometric parameters and operational bandwidth.

Table 2: Ultra-Wideband Antenna Dimensional Specifications (Units: mm).

Sr. No.	Parameter	Nomenclature	Value in mm
1	Substrate Dimensions	SL x SW x SH	20 x 24 x1.6
2	Patch Dimensions	PL x PW x	16 x 20 x 2

IV. BREAST TISSUE AND LESION MODELING

A. TISSUE PROPERTY CHARACTERIZATION

Cancer detection employing ultra-broadband diagnostic imaging depends critically on the accurate representation of tissue electromagnetic properties [16]. For imaging system development, precise measurements of tissue dielectric parameters remain essential. The dielectric constant variations across different mammary tissue categories are characterized as follows: fatty tissue exhibits values approximately unity, dermal tissue ranges from 1.5 to 5, fibro-glandular material ranges from 2 to 4, while pathological tissue demonstrates significantly elevated values between 9 and 10, with documented variations extending beyond this range [17],[18].

The dielectric characteristics also correlate with the tissue water content [19-21]. The phantom preparation methodology involves controlled mixtures of wheat flour with water to establish tumor-representative properties. The simulated phantom tissues incorporate the following specifications: lesion tissue consisting of wheat flour mixed with water (55% water content), with relative permittivity $\varepsilon_r = 23$ and conductivity $\sigma = 2.57$ S/m, and adipose tissue represented by petroleum jelly with $\varepsilon_r = 2.36$ and $\sigma = 0.012$ S/m [18].

B. PHANTOM GEOMETRY

The anatomical model comprised a hemispherical adipose tissue structure with a 30 mm radius, approximating breast morphology during prone positioning (Figure 2a). A spherical lesion with a 3 mm diameter positioned 45 mm from the transmitting device is shown in Figure 2b and 2c, respectively.

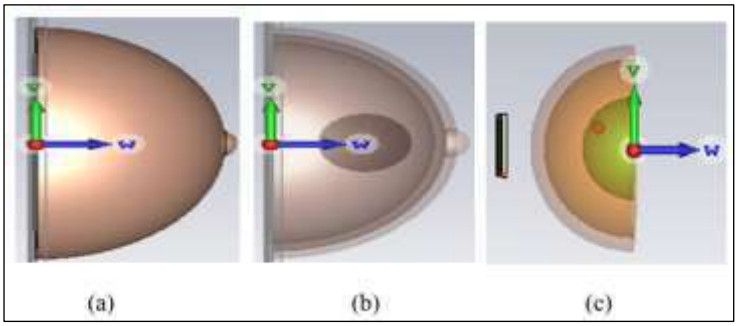

Figure 2: (a) Breast phantom (b) Phantom with a tumour (c) Phantom with a transmitter.

V. RESULT AND DISCUSSION

V.1 SPECIFIC ABSORPTION RATE ANALYSIS

A. MATHEMATICAL FRAMEWORK

Electromagnetic wave propagation within biological media is fundamentally characterized by Maxwell's curl equations [22],[23]:

$$\nabla \times \mathbf{E} = -j\omega\mu_r\mu_0\mathbf{H} \quad (1)$$

$$\nabla \times \mathbf{H} = j\omega\varepsilon_r\varepsilon_0\mathbf{E} \quad (2)$$

where **E** represents electric field intensity (V/m), μ_r denotes relative magnetic permeability, ε_r represents relative permittivity, and ω is angular frequency [24].

The SAR metric quantifies the energy absorption rate per unit mass as follows:

$$\text{SAR} = \frac{\sigma|\mathbf{E}|^2}{2\rho} \text{ (W/kg)} \quad (3)$$

where σ is tissue conductivity (S/m), ρ represents material density (kg/m³), and $|\mathbf{E}|$ is the electric field magnitude (V/m) [25].

B. THERMAL DISTRIBUTION ASSESSMENT

The temperature elevation patterns resulting from EM signal propagation within the phantom were quantitatively determined. The peak-affected regions adjacent to the transmitter, evaluated for tissue masses of 10 g and 1 g at an operational frequency of 5 GHz, are shown in Figs. 4a and 4b, respectively. Coloration mapping indicates relative absorption: red corresponds to the maximum energy deposition zones, gradient colors represent intermediate absorption regions, and blue indicates unaffected tissue areas.

V.2 EXPERIMENTAL RESULTS AND ANALYSIS

A. ANTENNA PERFORMANCE METRICS

The return loss and voltage standing wave ratio (VSWR) characteristics of the UWB monopole device are shown in Figure 3. The simulated S_{11} parameter across the 2-16 GHz band demonstrated a bandwidth of 9.23 GHz (Fig. 3a). The simulated VSWR performance across the operational spectrum remained below 2.0 (Fig. 3b), indicating satisfactory impedance-matching characteristics [26]. The simulation parameters were as follows: antenna-to-phantom separation of 20 mm and operational frequency of 5 GHz. The hemispherical breast phantom with a 30 mm diameter represents an authentic anatomical dimension. SAR calculations were performed for tissue averages of 1 g (North American standard) and 10 g (European standard). For this configuration, tumor coordinates (actual) were x=0 mm, y=0 mm, z=55 mm. The 10 g SAR averaging failed to detect lesion location, whereas the 1 g SAR assessment indicated approximate tumor position (x=0.125 mm, y=0.1875 mm, z=49.8125 mm). The calculated SAR magnitudes at 5 GHz were 0.389009 W/kg (1 g standard) and 0.142686 W/kg (10 g standard).

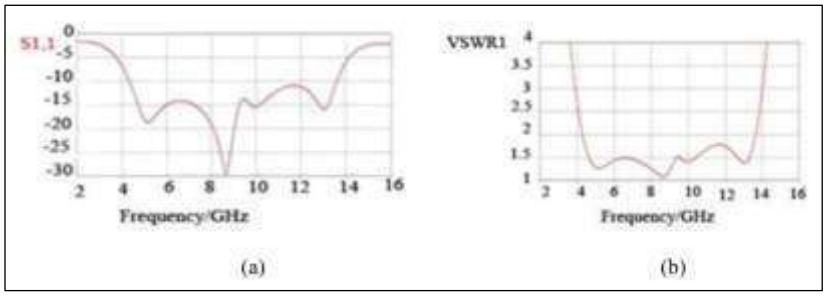

Figure 3: Simulated characteristics of the ultra-wideband antenna (a) return loss (b) VSWR.
Source: Authors, (2026).

B. FREQUENCY-DEPENDENT SAR AND POWER ABSORPTION

The SAR magnitude varies nonlinearly with the operational frequency, as shown in Figure 4. Both 1 and 10 g SAR calculations demonstrated increasing trends as the frequency increased. Concurrent analysis showed that power absorption by the tissue increased proportionally with frequency elevation (Figure 5), indicating that higher-frequency operation enhances tissue-field couplin.

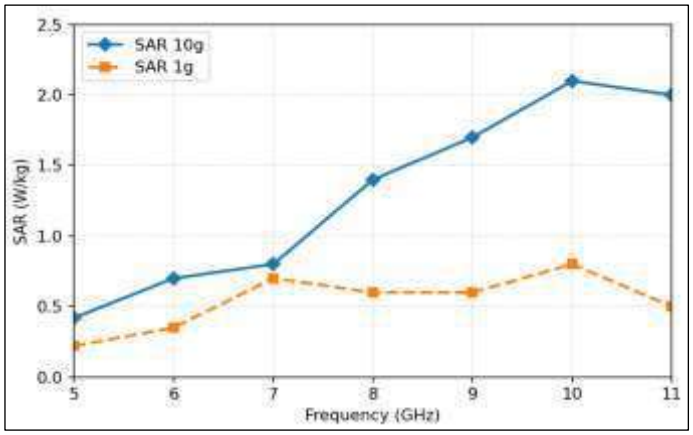

Figure 4: Maximum SAR distribution.
Source: Authors, (2026).

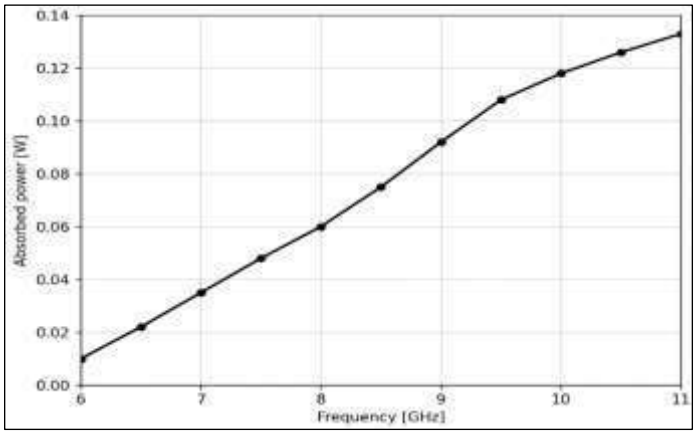

Figure 5: Absorbed power as a function of frequency.
Source: Authors, (2026).

C. DISTANCE-DEPENDENT SAR PERFORMANCE

Antenna-to-tissue separation substantially influences the SAR distribution characteristics. As depicted in Figure 6, increasing the transmitter-to-phantom distance resulted in corresponding SAR magnitude reductions for both 1 g and 10 g tissue averages. The absorbed power similarly diminished with increasing separation (Figure 8), establishing that the transmitter-phantom distance should exceed 20 mm during microwave diagnostic procedures.

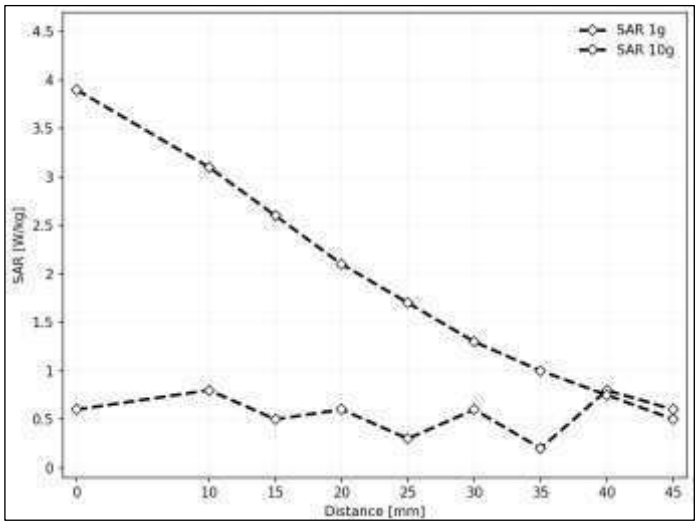

Figure 6: SAR value versus distance.
Source: Authors, (2026).

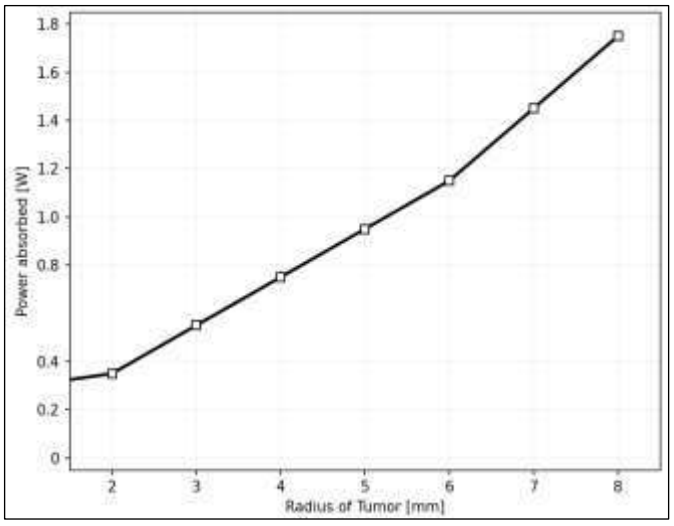

Figure 7: Power absorption value versus distance.
Source: Authors, (2026).

D. TUMOR SIZE DEPENDENCY

The SAR values increased substantially with the expansion of the lesion size within the tissue (Figure 8). Power absorption demonstrated a similar positive correlation with tumor radius increase (Figure 9), illustrating that larger pathological formations generate more pronounced EM-tissue interactions.

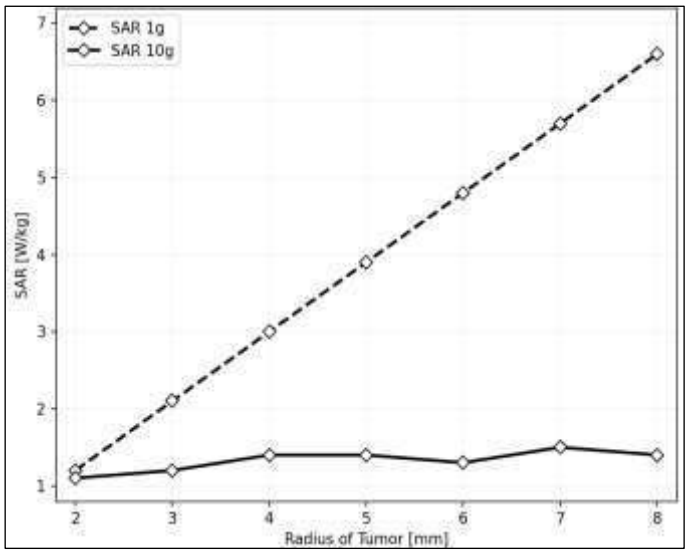

Figure 8: SAR value versus tumor size.
Source: Authors, (2026).

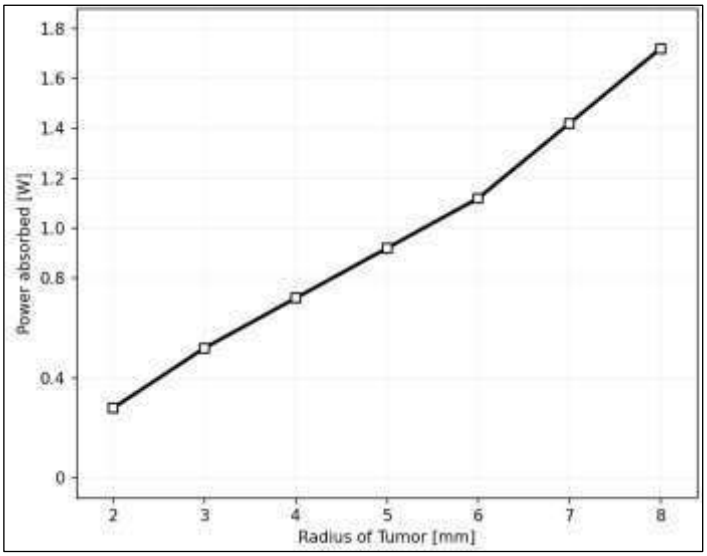

Figure 9: Power absorbed versus radius of the tumor.
Source: Authors, (2026).

E. TUMOR LOCALIZATION USING 1 G SAR CRITERION

The clinical assessment employed a 20 mm separation between the breast phantom and UWB transmitter, with a 30 mm radius phantom and a 3 mm radius lesion at varying intratissue positions. The 1 g SAR standard was applied for tumor position estimation. The total tissue mass was calculated as 0.050965 kg.

Table 3: Tumor Localization Results Using 1 g SAR Assessment.

Actual Tumor Coordinates (mm)	Calculated Coordinates (mm)
(0, 0, 23)	(2.25, 0.56, 25.06)
(5, 7, 30)	(7.08, 6.09, 27.94)
(-2, -3, 45)	(-1.63, -2.83, 43.31)
(7, 9, 45)	(5.81, 8.83, 44.44)
(-7, -9, 45)	(-5.44, -7.50, 42.94)
(13, 17, 37)	(13.94, 11.06, 31.44)

Source: Authors, (2026).

The data presented in Table 2 demonstrate that 1 g SAR calculations at 9 GHz frequency provide reasonable approximations of lesion spatial locations within the tissue matrix. The comparative analysis demonstrates that both the power deposition and SAR metrics exhibit positive frequency dependence, increasing the energy absorption at elevated operational frequencies. Similarly, larger lesion dimensions were correlated with enhanced energy absorption characteristics. Conversely, expanding the transmitter-to-tissue separation produced inverse effects on both parameters, substantially decreasing the energy deposition rates. These findings establish critical operational guidelines for diagnostic system design, indicating that the tissue-transmitter distance should maintain a minimum separation of 20 mm during clinical applications. The superior localization performance of the 1 g SAR assessment compared to the 10 g averaging suggests implementation advantages for North American standard protocols in microwave-based diagnostic applications.

VI. CONCLUSION

This study examined electromagnetic-tissue energy coupling mechanisms and SAR distribution patterns in homogeneous breast models exposed to microwave transducers. A broadband monopole antenna with an optimized 3.1-10.6GHz bandwidth performance through the implementation of L-shaped ground plane modifications was developed and analyzed. Systematic simulation studies have revealed that power deposition and SAR for both 1 g and 10 g tissue masses correlate positively with frequency elevation, lesion size expansion, and phantom dimension variations, while demonstrating inverse relationships with transmitter-tissue separation [27][28]. During direct electromagnetic exposure, tissue heating occurs; therefore, careful application protocols should govern the implementation of imaging procedures. Future investigations should extend the analysis to heterogeneous tissue models by incorporating anatomically realistic tissue layer variations and alternative monopole antenna configurations to establish comprehensive SAR characterization databases for clinical implementation.

General Gauss1 model.

ABSTRACT

Finite impulse response (FIR) filters are widely used in signal processing due to their inherent stability, linear-phase property, and implementation robustness. However, achieving high stopband attenuation with a limited filter order and a steep attenuation slope remains challenging. This paper presents a curve-fitting-based FIR filter design method aimed at enhancing stopband attenuation performance. The proposed approach employs curve fitting to estimate the optimal parameters of a General Gauss1 model by fitting its functional form to a given impulse-response shape. The resulting mathematical model is then used to compute new FIR coefficients that enforce a smooth impulse-response profile, effectively suppressing oscillatory sidelobes. Consequently, the magnitude response exhibits a monotonic decay and an improved attenuation slope in the stopband. MATLAB simulation results confirm the effectiveness of the proposed method, demonstrating significant stopband attenuation enhancement without increasing the filter order.

I. INTRODUCTION

Finite Impulse Response (FIR) filters are fundamental components in modern signal processing, prized for their inherent stability, linear-phase characteristics, and straightforward implementation. They are extensively used in diverse applications, including communications, audio and speech processing, biomedical signal analysis, and control systems, where precise frequency shaping is essential [1-5]. FIR filters offer key advantages, including predictable phase response, robustness to coefficient quantization, and flexible design options [6],[7]. However, achieving high stopband attenuation with a limited filter order remains a persistent challenge, often requiring more coefficients and increasing computational complexity. Therefore, the design of FIR filters that effectively control the shape of the impulse response coefficients to minimize side lobe oscillations while maintaining the desired frequency response remains a critical research problem.

Numerous FIR filter design techniques have been suggested to address the trade-off between filter order, stopband attenuation, and side-lobe behavior. Classical window-based methods, including Hamming, Hanning, and Blackman windows [8], as well as the Kaiser window [9] and Gaussian basis representations [10], are widely adopted due to their simplicity and low computational cost; however, they offer limited flexibility in controlling stopband ripple and transition bandwidth. Frequency-sampling and Fourier-series-based approaches provide direct control over frequency characteristics but may introduce significant ripple effects [11]. Optimization-based techniques, including equiripple (Parks-McClellan) and least-squares methods [12], offer improved stopband attenuation and sharper transition bands, yet they often involve higher computational complexity and may still produce undesired oscillations in the impulse response.

More recently, advanced optimization frameworks have been developed to enhance FIR filter performance [13]. Among these, sparsity-promoting convex optimization techniques combine ℓ_2-norm frequency-response error metrics with ℓ_1-norm regularization to reduce filter order while preserving stringent passband ripple and transition-band specifications, enabling hardware-efficient implementations over classical window-based and Parks-McClellan designs [14]. In parallel, multi-objective evolutionary algorithms (MOEAs) have been applied to simultaneously optimize conflicting criteria such as side-lobe level and computational cost, yielding improved Pareto-optimal solutions compared to single-objective approaches [15].

Building on these developments, meta-heuristic and evolutionary algorithms have emerged as powerful tools for FIR filter design [16], with methods such as genetic algorithms (GA), particle swarm optimization (PSO), cuckoo search optimization (CSO), and Gray Wolf Optimization (GWO) demonstrating improved stopband attenuation, reduced passband ripple, and enhanced coefficient shaping. Notably, a hybrid sparse PSO (HSPSO) has achieved lower cost and execution time than conventional PSO variants while improving spectral performance for low-pass FIR filters [17]. GWO-based designs have shown faster convergence and superior performance compared to GA, PSO, and CSO [18], further enhanced through hybrid GWO–CSO schemes [19]. Additional improvements have been reported using CSA and Grasshopper Optimization (GOA) with LMS and ℓ_1-norm error criteria for linear-phase FIR filters [20], as well as Brain Storm–Grey Wolf Optimizer (BSGWO) approaches that significantly improve stopband attenuation over conventional heuristic and analytical methods [21].

Machine learning-assisted FIR design has also emerged as a promising direction, in which filter coefficients are directly learned from noisy data, with effectiveness demonstrated through speech and music separation despite significant spectral overlap [22]. Another emerging trend is the use of fractional-order and adjustable window functions, such as the fractional Kaiser window, which has been shown to improve spectral performance and enhance stopband attenuation in FIR filter design compared with the conventional Kaiser window [23]. Although these recent approaches achieve notable improvements, challenges related to convergence reliability, computational complexity, and practical implementation persist.

All in all, despite these extensive efforts, achieving a well-controlled impulse-response shape with reduced side-lobe oscillations, high stopband attenuation, and a low computational burden remains an open challenge, motivating the pursuit of more effective FIR filter design methodologies.

In this regard, the present paper proposes a novel FIR filter design approach that enhances stopband attenuation by explicitly controlling the shape of the impulse-response coefficients while preserving linear-phase characteristics and a moderate filter order. The proposed approach incorporates a curve-fitting-based strategy to smooth and regulate the impulse-response coefficients, thereby suppressing side-lobe oscillations and improving frequency selectivity without increasing computational complexity. The main contributions of this paper are summarized as follows:

- A new FIR filter design framework is introduced that focuses on direct impulse-response coefficient shaping to achieve improved stopband attenuation.
- A curve-fitting-based technique is introduced to regulate the impulse-response coefficients, effectively reducing side-lobe oscillations while maintaining the desired frequency response.
- The proposed method achieves a steeper attenuation slope and enhanced stopband performance compared with conventional window-based and optimization-based FIR design approaches.
- Extensive simulation results demonstrate that the proposed design yields lower side-lobe levels, improved frequency selectivity, and competitive computational complexity.

The paper's remainder is structured as follows. Section 2 provides a description and mathematical formulation of the FIR filters. Section 3 describes the proposed approach for FIR filter design using curve fitting. Section 4 evaluates the performance of the proposed FIR design approach. Section 6 concludes the paper's findings.

II. FIR FILTERS

FIR filters are stable digital filters that depend only on a finite number of input samples. They can achieve exact linear-phase characteristics by using symmetric coefficients and widely used due to their robustness and predictable behavior. According to the FIR filter's architecture illustrated in Figure 1, the transfer function for the *N*-tap FIR filter is given by:

$$H(z) = \sum_{n=0}^{N-1} h(n) z^{-n} \tag{1}$$

where $h(n)$ denotes the filter impulse response coefficients, and N is the filter length.

Considering (1), the discrete-time frequency and magnitude responses of the *N*-tap FIR filter are obtained as:

$$H(e^{j\omega}) = \sum_{n=0}^{N-1} h(n)\, e^{-j\omega n} \tag{2}$$

$$|H(e^{j\omega})| = \sum_{n=0}^{N-1} \left| h(n)\, e^{-j\omega n} \right| \tag{3}$$

One of the key challenges in FIR filter design is controlling the shape of the impulse-response coefficients $h(n)$ to reduce side lobe oscillations. When the coefficients are non-smooth or vary abruptly, stop-band ripples increase, attenuation is reduced, and the filter's ability to reject unwanted frequencies is compromised. These effects are especially pronounced when the filter order is limited, as oscillations in the transition band lead to a less predictable frequency response and degraded selectivity and spectral purity.

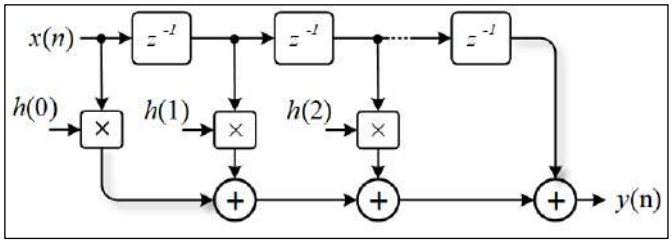

Figure 1: General architecture of a FIR filter.
Source: Author, (2026).

In such an FIR filter, abrupt or non-smooth coefficients $h(n)$ increase stop-band ripples and reduce attenuation, degrading the filter's ability to reject unwanted frequencies, particularly in low-order designs. This limitation motivates approximating $h(n)$ with a smooth, symmetric General Gauss1 model using curve fitting, enabling controlled coefficient shaping and improved stopband performance without increasing the filter order.

III. PROPOSED CURVE FITTING - BASED FIR FILTER DESIGN

The proposed method introduces a curve-fitting-based FIR filter design framework designed to enhance stop-band attenuation by shaping the impulse response. Instead of directly approximating a desired frequency response, the method defines a smooth target impulse response profile using a General Gauss1 model. The model parameters are then estimated by fitting its functional form to a given impulse-response shape, and the resulting representation is used to generate a new set of FIR coefficients with a smooth and symmetric profile, effectively suppressing oscillatory side lobes. This approach achieves monotonic decay and a steeper attenuation slope in the stop-band, improving stopband performance without increasing the filter order.

The overall design procedure is summarized as follows:

- Initial FIR coefficients: Start with selecting filter order ($N = 21$ and $N = 9$), and a preliminary set of low-order FIR coefficients $h(n)$, given in the simulation section.
- Define target model: The desired smooth impulse-response profile is defined using the General Gauss1 model expressed as:

$$f_g(x) = a_1 \, exp\left(-\left(\frac{x - b_1}{c_1}\right)^2\right) \tag{4}$$

where a_1 is the magnitude, b_1 is the center, and c_1 is a parameter that controls the width of the Gaussian. These are the unknown parameters of the Gauss1 model to be estimated.The General Gauss1 model is adopted due to its inherent smoothness, symmetry, and parameter efficiency, enabling effective FIR impulse-response shaping with monotonic side lobe decay, improved stopband attenuation, and preserved linear-phase characteristics. Curve fitting: The curve fitting is applied to estimate the parameters of the General Gauss1 model. The Gaussian parameters, a_1, b_1, and c_1 are estimated by minimizing the sum of squared errors between the model and the given FIR coefficients. Accordingly, the expression of the objective function to be minimized is defined as follows:

$$Obj_f(a_1, b_1, c_1) = \sum_{n=0}^{N-1} \left[h(n) - f_g(n)\right]^2 \tag{5}$$

- Generate new FIR coefficients: The new FIR coefficients are computed using the fitted model based on the following expression:

$$h_{new}(n) = a_1 \, exp\left(-\left(\frac{n - b_1}{c_1}\right)^2\right) \tag{6}$$

The flowchart of the proposed design approach is depicted in Figure 2.

IV. SIMUATION RESULTS AND DISCUSSIONS

To validate the effectiveness of the proposed curve-fitting-based FIR filter design, simulations are carried out in the MATLAB environment. The performance of the developed FIR filter is compared with that of a conventionally designed FIR filter for two filter orders, $N = 21$ and $N = 9$. The estimated parameters of the General Gauss1 model for both filter orders are listed in Table 1. The coefficient values of the conventional FIR filter and the proposed curve-fitting-based FIR filter are reported in Tables 2 and 3, respectively, for $N = 21$ and $N = 9$. In addition, Figures 3 and 4 illustrate the corresponding plots of the impulse-response coefficients, $h(n)$ and $h_{new}(n)$, and their frequency responses for the conventional and proposed design approaches at both filter orders. According to the results illustrated in Figures 3 and 4, the following observation can be made.For $N = 21$, the conventional FIR coefficients exhibit noticeable oscillations and alternating signs away from the center tap.

These abrupt variations generate pronounced side lobes in the impulse response, leading to ripples in the stopband and limited high-frequency attenuation. From the magnitude response shown in Figure 3(a), the stopband attenuation of the conventional design is approximately -45 dB to -50 dB at higher frequencies. In contrast, the proposed curve-fitting-based FIR coefficients form a smooth, bell-shaped envelope, strictly monotonic and centered around the main coefficient value. As seen in Figure 3(b), the impulse response decays gradually toward the edges without sign alternation, effectively suppressing side lobe oscillations.

This results in a smoother magnitude response with a significantly enhanced stopband attenuation of approximately -70 dB to -75 dB, representing an improvement of roughly 20–25 dB over the conventional design.

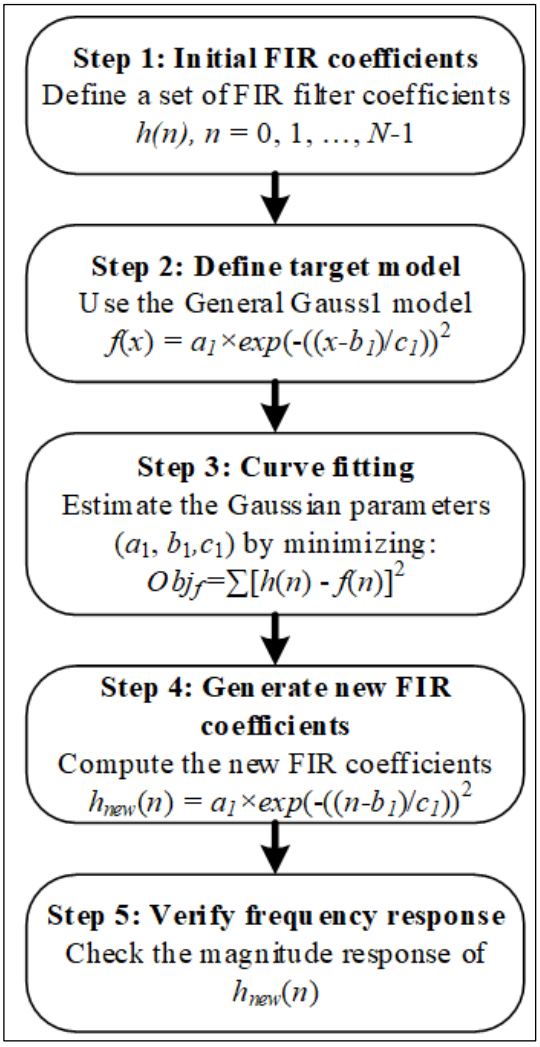

Figure 2: Flowchart of the proposed curve fitting-based FIR filter design procedure.
Source: Author, (2026).

For the low-order case, N = 9, the difference is even more significant. The conventional FIR filter shows relatively poor stopband rejection, with attenuation limited to about -30 dB to -35 dB, accompanied by strong oscillatory behavior in the impulse response as depicted in Figure 4(a). By contrast, the proposed curve-fitting approach produces a smooth, symmetric, Gaussian-like impulse response, with reduced edge coefficients and no abrupt variations, as shown in Figure 4(b). This controlled shaping translates into a magnitude response with stopband attenuation improved to approximately -55 dB to -60 dB, yielding a gain of roughly 20-25 dB, even under the severe constraint of low filter order. These numerical results demonstrate that the proposed General Gauss1-based curve-fitting approach consistently produces smoother and more regular FIR coefficients, which in turn enhance the stopband performance of the filter while preserving the same order. The improvement is particularly noticeable for low-order filters, where conventional designs are more sensitive to coefficient irregularities.

V. CONCLUSIONS

This paper presented a curve-fitting-based FIR filter design approach aimed at improving stopband attenuation under limited filter order constraints. By approximating the impulse-response coefficients using a smooth and symmetric General Gauss1 model, the proposed method enables controlled shaping of the FIR coefficients while preserving the inherent linear-phase property. Unlike conventional FIR designs, which often exhibit abrupt coefficient variations leading to side lobe oscillations and elevated stopband ripples, the proposed approach effectively suppresses these effects through smooth impulse-response modeling. Simulation results for low-order filters, with $N = 21$ and $N = 9$, demonstrate a monotonic decay of the magnitude response and a steeper stopband attenuation slope.

In particular, the proposed design achieves an improvement in high-frequency stopband attenuation of approximately 20-25 dB compared to the conventional FIR filter. The findings confirm the effectiveness of the proposed framework for enhancing stopband performance in low-order FIR filter designs. Future work will focus on enhancing the parameter estimation stage by incorporating recent optimization algorithms, such as metaheuristic and hybrid optimization techniques, to further improve the accuracy and adaptability of the General Gauss1 model fitting.

ABSTRACT

Sign Languages serve as the primary means of communication for millions of deaf and hard-of-hearing individuals. Despite this significance, the development of automatic Sign Language Recognition systems is limited due to the scarcity of large-scale, high-quality video datasets. This is mainly attributed to the inherently resource-intensive process required to collect such datasets, often requiring fluent signers, controlled recording environments, and rigorous annotation. In response to these challenges, this study introduces a novel method for generating synthetic sign language datasets. Supporting both isolated and continuous signing, our method enables the creation of diverse and scalable datasets, with precise control over factors such as signer appearance, sign content, and environment. First, we determine the most suitable task for evaluation by comparing three architectures: CNN-Transformer, CNN-GRU, and CNN-LSTM. With the CNN-LSTM emerging as the most effective, achieving recognition rates of 75%, 90%, 100%, and 100% for Top-1, Top-2, Top-3, and Top-5 metrics, respectively. Our proposed method is then compared to standard data augmentation techniques demonstrating remarkable improvements, with recognition rate improvements ranging from 87.5% increase in Top-1, to a 42.85% improvement in Top-5. 10-fold cross-validation was then used to confirm the robustness of the resulting model in real-world scenarios.

I. INTRODUCTION

Millions of deaf and hard-of-hearing individuals worldwide rely on sign languages as their primary means of communication; not only does it play a crucial role in their lives, but they also rely on it in their daily lives, education, and social integration. The World Health Organization estimates over 1.5 billion individuals worldwide live with some degree of hearing loss, with projections indicating that this number could reach 2.5 billion by 2050 [1]. Despite its vital importance, Sign Language Recognition still has an underdeveloped technological support. Sign language recognition systems hold great potential to revolutionize accessibility in sectors such as education, healthcare, public services, and digital communication. However, their progress is severely hindered by the scarcity of large, high-quality Sign Language datasets. This is mainly due to sign language recognition systems being heavily reliant on deep learning methods that require large-scale, diverse, and well-annotated datasets.

Unlike textual or spoken language datasets, which can often be compiled from readily available digital resources, sign language datasets cannot leverage already existing digital resources. Thus, creating these datasets is inherently resource-intensive, requiring substantial investment in data collection infrastructure and annotation expertise, often involving the recruitment of fluent signers, controlled environments, signer demographic diversity, and expert annotators for gloss labeling. Furthermore, technical challenges such as multi-camera setups and depth sensors add to the cost and complexity of creating such datasets. The MS-ASL dataset [2], one of the most extensive collections available for American Sign Language (ASL), with over 25,000 labeled video clips across 1,000 sign classes performed by 200 distinct signers. While large in scope compared to many earlier datasets, the dataset was collected from publicly available online videos from platforms like YouTube.

Although scalable, this strategy introduced challenges in annotation accuracy, label noise, signer variation, and uncontrolled recording conditions such as inconsistent lighting, backgrounds, and camera angles. The dataset construction required highly specialized manual verification to ensure label correctness, making it labor-intensive despite the automation in video sourcing.When it comes to German Sign Language (DGS), the RWTH-PHOENIX-Weather series is widely used for sign language recognition. This dataset further illustrates the time-intensive nature of producing high-quality datasets. The original RWTH-PHOENIX-Weather corpus [3] contains 3.25 hours of interpreted weather forecasts with 911 sign glosses from 7 signers. Despite its modest size, the dataset took around two years to compile due to the need for labor-intensive manual alignment between spoken German transcripts and DGS sign glosses. The later PHOENIX-2014 release [4] further expanded the vocabulary to 1,558 signs while increasing the dataset duration to 10.73 hours with 9 signers. However, this extension took approximately two years, primarily due to the complexity of multi-modal alignment and signer-specific variation across broadcast content. The How2Sign project [5] was created to support more natural environments, especially for sentence-level and continuous ASL recognition. The dataset includes approximately 16,000 English words and 35,000 sentences, collected over a six-month period with 11 signers across 65 recording sessions.

Despite its ambitious scale, How2Sign has several limitations, including limited variation in signer demographics (e.g., race, skin tone) and environmental factors (e.g., lighting, background, and camera quality). These constraints limit the generalization of models trained on the dataset, especially in diverse or in-the-wild scenarios. The difficulty in collecting large, diverse, and well-annotated sign language datasets stems from several factors: the need for proficient signers, the complicated annotation due to the lack of writing standards in many sign languages, and the limited availability of publicly available sign language data compared to textual or spoken language. Moreover, the requirement for multi-camera setups or depth sensors in some datasets [6] (e.g., RGB-D or motion capture-based datasets) introduces additional hardware costs and technical overhead, often limiting replication and scalability. Given these challenges, synthetic data generation emerges as a promising solution. Synthetic datasets offer scalability, controlled conditions, and consistent annotations, addressing the limitations of real-world data collection. This approach has shown utility in adjacent fields such as 3D human action recognition [7],[8] and pose estimation [9], suggesting potential for advancing Sign Language Recognition.

This paper makes several significant academic contributions to the field of Sign Language Recognition:

- We propose a novel signer-agnostic and language-independent method for sign language data generation.
- We conduct a systematic comparison of three architectures (CNN-Transformer, CNN-GRU, and CNN-LSTM) to identify the most effective model for sign language recognition tasks.
- We demonstrate through comparative analysis significant improvements in sign language recognition by leveraging the proposed method compared to standard data augmentation techniques.
- We validate the practical effectiveness of our approach by conducting a comprehensive evaluation using 10-fold cross-validation across various Top-K metrics.

The remainder of this paper is structured into five sections. Section 2 presents our proposed pipeline architecture, Section 3 describes the experimental setup, Section 4 reports the results, Section 5 discusses the findings, and Section 6 concludes with future directions.

II. PROPOSED PIPELINE

To address the challenges associated with creating sign language datasets, we propose a rule-based data generation pipeline designed for both continuous and isolated sign language datasets. This system emphasizes simplicity, accessibility, and reproducibility, leveraging skeletal animation and modular action composition to synthesize realistic yet computationally efficient corpora. The pipeline is signer-agnostic, enabling it to operate independently of specific signers, and is highly extensible to new languages and vocabularies. In this section, we provide a detailed explanation of each module within the proposed architecture, detailing its functionalities and interconnections.

II.1 OVERVIEW

Figure 1 presents a detailed overview of our proposed architecture. The initial step involves generating valid Sign Markup Language (SigML) definitions, which can be achieved through two modes of operation. First, direct SigML sign definitions may be provided without requiring pre-processing steps. Alternatively, sign definitions can be supplied in Hamburg Notation System (HamNoSys) format, which are then pre-processed using the HamNoSys2SigML tool [10] to produce accurate SigML representations. Concurrently, our architecture incorporates a viewpoint generation module, represented in green (Figure 1). This module operates by first employing a viewpoint augmenter to generate multiple perspectives through systematic adjustments of the camera angle. Subsequently, a viewpoint renderer generates 3D visualizations of these viewpoints for user validation and verification.

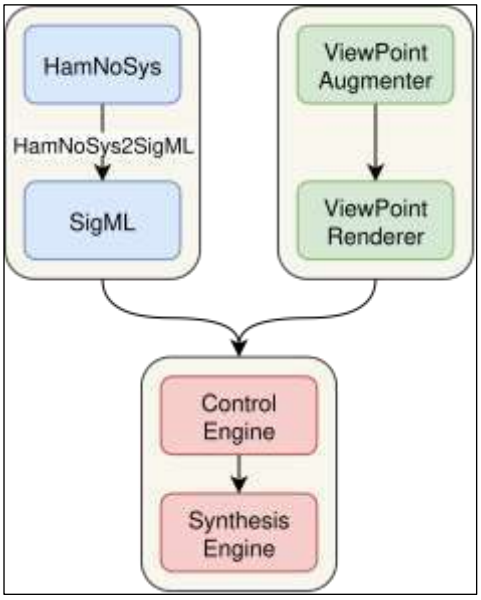

Figure 1: Our proposed data generation architecture.
Source: Authors, (2026).

The processed SigML files and viewpoints are then integrated into the synthesis module, highlighted in pink (Figure 1). Within this module, a control engine ensures smooth and efficient data processing by sequentially managing input parameters and directing them through the synthesis process until all data is fully processed. The synthesis engine, downstream from the control engine, assumes responsibility for rendering signs according to specified camera angles, ensuring accurate and precise representation of gestures in video format.

II.2 SIGN DEFINITION AND VOCABULARY

The primary standard for sign definition in our system is HamNoSys due to its universal compatibility, iconicity, economy, automation support, formal syntax, and extensibility. This guarantees support for diverse languages with efficient and accurate representation, and simplifies integration into our multilingual pipeline. Furthermore, HamNoSys reduces human error as it enables automated interpretation and manipulation of sign descriptions, and maintains robustness and adaptability to evolving linguistic needs. For visually coherent sign language animations, HamNoSys's SigML format is used. SigML is an XML-based representation of HamNoSys that provides a detailed description of both manual and non-manual components, and guarantees their synchronization. This includes handshape, orientation, location, and movement for manual components, and facial expressions, eye gaze, mouth gestures, and head movements for non-manuals.

II.3 CWASA AVATAR ANIMATOR

CWA Signing Avatar[11],[12] is the synthesis engine of choice in our pipeline; it is tasked with converting SigML definitions into fluid, lifelike signing sequences. It ensures the accurate representation of complex signs by integrating both manual and non-manual elements, including hand movements, facial expressions, eye gaze, and mouth gestures.

II.4 EXPLOITATION

The exploitation phase of our pipeline involves the orchestrated integration and execution of components designed to generate a comprehensive dataset for sign language animations. This subsection provides a detailed explanation of how various elements are integrated within our pipeline to facilitate this process.

II.4.1 Viewpoint Augmentation Via Uniform Spherical Perturbations

Sign language recognitionbenefits heavily from varied camera angles in the dataset as they promote the development of robust, inclusive, and generalizable systems. Training models solely on fixed viewpoint datasets tends to produce biased models that perform poorly when exposed to viewpoint variation in real-world scenarios. The introduction of diverse camera angles provides the model the ability to capture the full spectrum of manual and non-manual gestures and movements that have significant variations in relation to camera angles. Furthermore, viewpoint diversity enhances model generalization by delineating the patterns invariant to perspective changes and mitigates the potential biases caused by single viewpoint datasets.

In this context, uniform perturbations were chosen as a method to introduce diversity into training datasets. This is achieved by introducing controlled random variants to the spherical coordinates used to define the camera position; notably, the polar and azimuthal angles (θ, φ) used to define camera viewpoints in 3D space. Uniform perturbation ensures an even distribution of viewpoints across all possible angles, hence preventing bias towards specific directions. This approach simulates a wide range of realistic scenarios encountered by the model, especially those with unpredictably varying camera positions.

Uniform perturbations also guarantee a consistent and fair augmentation process, as all points within the specified range of the sphere have an equal sampling probability. This approach, given enough sampling points, prevents specific regions from being over-represented, ensuring a balanced distribution of viewpoints, which is a crucial aspect for creating generalizable models across diverse conditions. However, the perturbation magnitude is an important aspect to consider to preserve a realistic angular range and an ameliorative effect on diversity without introducing unrealistic or non-beneficial viewpoints.

Our proposed perturbation mode is defined as follows: starting with an initial set of points represented in spherical coordinates (θ, ϕ), where $\theta \in [0, \pi]$ is the polar angle (measured from the positive z-axis), and $\phi \in [0, 2\pi)$ is the azimuthal angle (on the xy-plane). Our augmentation method consists of applying uniform perturbations to both angles. This approach helps enrich the dataset by generating additional samples in the vicinity of the original points while preserving the spherical coordinates conventions. For each original coordinate pair (θ, ϕ), perturbations Δθ and Δϕ are drawn independently from uniform distributions centered at zero:

$$\Delta\theta \sim U(-a\theta, a\theta) \tag{1}$$

$$\Delta\phi \sim U(-a\phi, a\phi) \tag{2}$$

where a_θ , $a_\phi > 0$ are hyperparameters controlling the maximum angular deviation.

The perturbed coordinates are then computed as:

$$\theta' = \theta + \Delta\theta \tag{3}$$

$$\phi' = \phi + \Delta\phi \tag{4}$$

Due to the polar angle interval constraint $\theta \in [0, \pi]$, perturbations that cause the new angle θ′ to fall outside this range must be rectified. A reflection strategy is used to achieve boundary correction, and to maintain the point's correct position on the sphere, an azimuthal rotation is applied:

$$if\ \theta' < 0, \theta' \leftarrow -\theta', \phi' \leftarrow \phi' + \pi \tag{5}$$

$$if\ \theta' > \pi, \theta' \leftarrow 2\pi - \theta', \phi' \leftarrow \phi' + \pi \tag{6}$$

This reflection ensures $\theta' \in [0, \pi]$ while shifting the azimuthal angle ϕ′ by π radians to preserve the points' spatial orientation on the sphere. Since the azimuthal angle ϕ is periodic with period 2π, the modulo operation is used to normalize ϕ′ to the interval $[0, 2\pi)$:

$$\phi' \leftarrow \phi' \bmod 2\pi \tag{7}$$

The overall augmentation procedure can be summarized as follows:

$$\begin{cases} \Delta\theta \sim U(-a\theta, a\theta) \\ \Delta\phi \sim U(-a\phi, a\phi) \\ \theta' = \theta + \Delta\theta \\ \phi' = \phi + \Delta\phi \\ if\ \theta' < 0 : \theta' \leftarrow -\theta', \phi' \leftarrow \phi' + \pi \\ if\ \theta' > \pi : \theta' \leftarrow 2\pi - \theta', \phi' \leftarrow \phi' + \pi \\ \phi' \leftarrow \phi' \bmod 2\pi \end{cases} \tag{8}$$

Our proposed method ensures that augmented spherical coordinates remain valid and uniformly distributed around the original points, facilitating robust data augmentation for applications involving spherical data representations.

II.4.2 Viewpoint Rendering

The viewpoint renderer is a critical component in the dataset generation pipeline; it's designed to convert augmented spherical coordinates into Cartesian coordinates and render them in a 3D environment. By enabling users to render the augmented coordinates, this tool allows the user to validate the generated viewpoints, ensure their accuracy and suitability for training machine learning models, and understand how different perturbations affect the generated dataset's diversity. The viewpoint renderer is an essential bridge between the abstract spherical coordinates and tangible 3D visualizations. Converting the augmented viewpoints into Cartesian coordinates facilitates their placement in a 3D scene. The conversion from spherical coordinates (r, θ, ϕ) to Cartesian coordinates (x, y, z) is done as follows:

$$x = r \sin\theta \cos\phi \tag{9}$$

$$y = r \sin\theta \sin\phi \tag{10}$$

$$z = r \cos\theta \tag{11}$$

where r is the radius (distance from the origin), θ is the polar angle (angle from the positive z-axis), and ϕ is the azimuthal angle (angle around the z-axis). The Cartesian coordinates are then rendered in a user-friendly, interactive interface, allowing the users to manipulate the view by zooming or panning to examine each viewpoint.

The viewpoints can also be viewed simultaneously, allowing comparison of their spatial distribution. Adjusting the a_θ and a_ϕ hyperparameters allows the users to control perturbation strength in both polar and azimuthal directions. Users can also vary viewpoint density by varying the number of viewpoints. Figure 2 displays an example visualization of the viewpoint renderer module. The red pyramid presents the original camera position, the blue pyramids present the generated camera positions, and the green sphere presents the target avatar position.

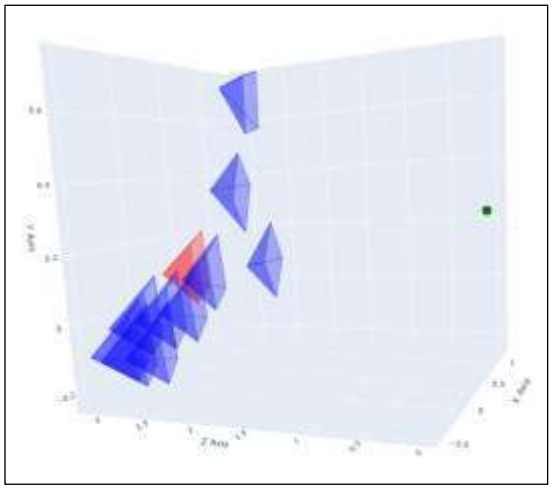

Figure 2: ViewPoint renderer visualization.

II.4.3 Control Engine

The control engine serves as the central orchestration system of our pipeline, managing data flow between key modules: viewpoint generation, pre-processing (HamNoSys to SigML conversion), and synthesis using CWASA. It ensures seamless integration by coordinating inputs at appropriate times. Initially, the engine interfaces with the viewpoint generation module, which systematically adjusts camera positions to generate diverse perspectives essential for realistic sign language representation. Concurrently, the preprocessing module converts signs from HamNoSys to SigML format using the hamnosys2sigml tool, ensuring compatibility with subsequent stages. The control engine integrates these processed definitions into the pipeline.

The prepared inputs are sequentially fed to the synthesis engine (CWASA), where camera angles and sign definitions are combined to produce visual representations. Accuracy here is crucial for reliable dataset generation. Beyond data transfer, the engine ensures smooth operation by coordinating input flow, minimizing disruptions between processing stages. Upon completion of each sign's articulation, the control engine captures video sequences and organizes them into a structured dataset. Each sign is stored in its own directory, with filenames incorporating metadata such as avatar name, spherical camera position, and direction for easy retrieval and analysis.

III. EXPERIMENTAL SETUP

III.1 DATASET

To establish a baseline for evaluating our introduced method, we created a German Sign Language (DGS) dataset focusing on numerical signs from 0 to 9. As avatar availability presents a common constraint in sign language datasets, we leverage it to demonstrate the capabilities of our proposed methodology. Each sign was captured at 10 distinct camera angles using two different avatars, with elevation angle a_θ set to 20 degrees and polar angle a_ϕ set to 30 degrees, ensuring comprehensive coverage of spatial and temporal dynamics. The resulting dataset served as the foundation for training multiple baseline models, enabling us to thoroughly validate and compare against our introduced method in subsequent experiments. The dataset was split into a 90% subset for training and a 10% subset for validation.

III.2 MODEL SELECTION

Three distinct architectures, aimed to capture both spatial and temporal features for sign language gestures, were explored while developing models for our baseline evaluation. All compared models incorporated a common base architecture, incorporating time-distributed layers to effectively process the sequential nature of the input data. The spatial processing was handled by a VGG16 [13] network followed by Global Average Pooling (GAvP), a fully connected layer with 64 units activated by ReLU, and a dropout rate of 50% to prevent overfitting. A subsequent temporal processing component is employed, followed by another dropout layer set to 50%. Then, a fully connected layer with 32 units using ReLU activation, followed by a final output layer.

The main difference between the models lies in the temporal processing component. While all models follow the stated architecture, the main difference between them is the type of memory layer used: LSTM, GRU, or Transformer. This not only allows us to assess how temporal dependencies are captured by the different approaches, but also provides an indication of the overall performance and generalization capabilities of each method. The resulting architectures are as follows:

- **CNN-Transformer [**13**],[**14**]:** Combining convolutional networks with transformer blocks, this architecture uses the CNN component to extract spatial features from the visual representations; and to process the sequence of features, the transformer is used to capture

long-range dependencies in the temporal domain, enhancing the model's ability to understand complex sign language temporal patterns.

- **CNN-GRU [**15**]:** In addition to convolutional layers, this architecture employs Gated Recurrent Units for sequential processing of the features. By maintaining a hidden state that evolves over time, GRUs allow capturing temporal dynamics, ensuring temporal aspects of signing are effectively modeled.
- **CNN-LSTM [**16**]:** Comparable to the CNN-GRU architecture, this architecture employs Convolutional Neural Networks to extract spatial features. However, instead of GRUs, it uses Long Short-Term Memory (LSTM) units that are particularly effective at capturing temporal nuances while selectively forgetting irrelevant information.

Each architecture was carefully designed to leverage different strengths of CNNs and temporal processing units, providing a comprehensive evaluation of their suitability for sign language recognition. The use of time-distributed layers ensured that each model could effectively process the sequential input data, while the choice of decoder (CNN-Transformer, CNN-GRU, or CNN-LSTM) allowed us to explore various approaches to sequence modeling in the context of sign language recognition. In our training protocol, we employed the Adam optimizer [17], a widely adopted optimization algorithm that effectively combines the benefits of AdaGrad and RMSProp to adaptively adjust learning rates during the training process.

The learning rate was set to 0.0005. This optimizer was chosen for its ability to maintain robust performance across varying scales of parameters, which is crucial given the complexity of our model architecture, and especially for its good performance in sign language translation and recognition tasks[18, 19]. The input size was set to 244x244 pixels, reflecting the dimensions of the image frames utilized in our dataset. This resolution was selected to ensure a balance between capturing sufficient spatial detail and maintaining computational efficiency during training. Each sequence comprises a length of 20 frames, which is essential for capturing the temporal dynamics inherent in sign language recognition tasks. To mitigate overfitting, we implemented early stopping [20] with a patience of 100 epochs. This mechanism monitors the validation accuracy throughout the training process and halts it if no improvement is observed within 100 consecutive epochs.

III.3 REAL-WORLD PERFORMANCE ASSESSMENT

Assessing the generalization performance of our final model was achieved through 10-fold cross-validation. To achieve this, the target dataset is split into ten equal-sized subsets. In each step, nine of the ten subsets are used for training while the remaining subset is used for validation. Repeating this process ten times causes each data point to be included in the validation set exactly once, ensuring a comprehensive assessment of model performance on unseen data. A dynamic adaptive learning rate has been implemented to enhance the model's performance by dynamically changing the learning rate during training. The strategy consists of a delayed learning rate reduction, by monitoring the validation loss, the learning rate is reduced by a factor of 0.2 when no improvement is detected for over 20 epochs, starting from epoch 50. With a cooldown period of 0, allowing the immediate resumption of the strategy after a learning rate adjustment. The minimum learning rate is set to 5e-5 to avoid excessively small learning rates. Furthermore, for additional training stability enhancement, our strategy resets the target optimization parameters on each learning rate update, ensuring an effective parameter exploration even after learning rate adjustment.

III.4 EVALUATION METRICS

For a comprehensive evaluation of our models, the top-k recognition rate metric is used. It's a critical metric that allows measuring the probability of the top-k predicted labels by the models containing the true class label. It allows a better understanding of a model's performance compared to relying on the single best guess. The formula for calculating the top-K recognition rate is:

$$Top - k = \frac{1}{N}\sum_{i=1}^{N} I\left(y_i \in \{\hat{y}_{i,(1)}, \hat{y}_{i,(2)}, \ldots, \hat{y}_{i,(k)}\}\right) \quad (11)$$

Where N is the total number of instances, y_i is the true class label for instance i, $\{\hat{y}_{i,(1)}, \hat{y}_{i,(2)}, \ldots, \hat{y}_{i,(k)}\}$ the top K predicted labels for instance i, and I is an indicator function that returns 1 if the condition inside the parentheses is satisfied and 0 otherwise. This metric is mainly used in multi-class classification problems, as the model outputs a ranked list of predictions. Both the model's confidence and its ability to identify relevant class labels beyond the highest-ranked prediction can be assessed from the true label being in the top-K predictions of a model. In sign language, where signs can often be similar and confused by models, this top-K metric becomes of tremendous importance as it not only provides a reliable indication of the model's performance, but also gives an indication of areas of improvement by providing a better insight into how the model can distinguish between closely related gestures.

Table 1: Top-K accuracy comparison of different architectures.

Architecture	Top-1	Top-2	Top-3	Top-5
CNN-GRU	55%	75%	85%	95%
CNN-Transformer	20%	20%	30%	50%
CNN-LSTM	**75%**	**90%**	**100%**	**100%**

IV. EXPERIMENTAL RESULTS

IV.1 MODEL SELECTION

The top-K recognition rates of our tested models are presented in Table 1, with the K value set to 1, 2, 3, and 5. The CNN-Transformer-based model shows the lowest Top-K recognition rates, with 20%, 20%, 30%, and 50% for the top-1, top-2, top-3, and top-5. This indicates that the Transformer-based model performs poorly and struggles to correctly classify gestures for sign language in this situation, making it unsuitable for interpreting the complex spatio-temporal relationships inherent in sign language. The intermediate position performance-wise was occupied by the CNN-GRU model, with a moderate 55% top-1 recognition rate, with a top-2, top-3, and top-5 performance of 75%, 85%, and 95%, respectively. Despite having a good temporal dynamic capture from the extracted features, it still lacks in performance compared to the LSTM-based model. In contrast, the CNN-LSTM model achieves an impressive top-1 recognition rate of 75%, a top-2 recognition rate of 90%, and a perfect top-3 and top-5 recognition rate of 100%. Based on its superior performance on our trials, the CNN-LSTM model was selected as the model of choice for the rest of our experiments and analysis.

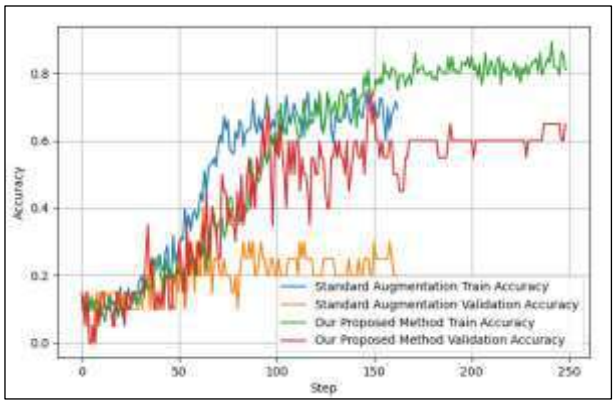

Figure 3: Train and test accuracies of tested methods.
Source: Authors, (2026).

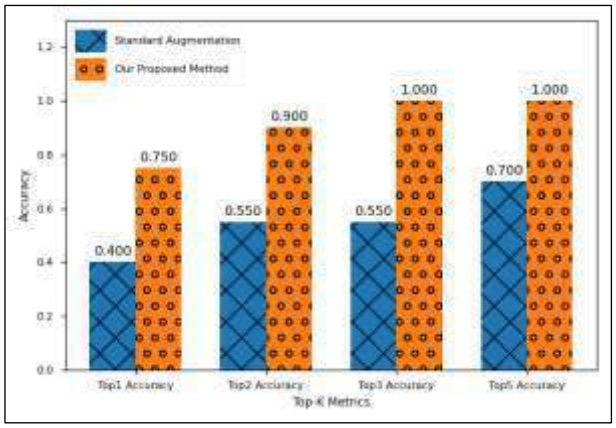

Figure 4: Recognition rates of tested methods.
Source: Authors, (2026).

IV.2 STANDARD DATA AUGMENTATION COMPARISON

The performance comparison between models trained using standard data augmentation and our proposed method was evaluated through both training and validation accuracies, as well as Top-K recognition rates. Figure 3 presents the training and validation accuracies of the models trained on the standard data augmentation method and our proposed method. The standard augmentation method exhibited a peak training accuracy of 75.56%, yet the validation accuracy remained significantly lower at 40%. This disparity indicates that the model experienced overfitting, memorizing the training data rather than effectively learning to generalize patterns. In contrast, our proposed method demonstrated superior performance with a training accuracy of 89.44% and a validation accuracy of 75%. These results highlight the effectiveness of our advanced augmentation technique in reducing overfitting and enhancing generalization capabilities.

IV.3 REAL-WORLD PERFORMANCE ASSESSMENT

For evaluating our model's real-world performance, a 10-fold cross-validation training was employed to ensure a reliable estimate of real-world performance. Figure 5 presents the key metrics resulting from each fold. The figure reports the Top-K recognition rates resulting from the validation set of each fold (Top-1, Top-2, Top-3, and Top-5). The CNN-LSTM architecture exhibited a balanced performance across the folds, with an average Top-1 recognition rate of 70% and consistently high Top-K recognition rates. The cross-validation results revealed a slight variability in performance across folds, with the majority of folds having a top-1 recognition rate of 75% or more.

The best recognition rates achieved were observed in fold 3 reaching a remarkable Top-1 recognition rate of 80%, with all the other recognition rates (Top-2, Top3, and Top-5) at 100%, whereas fold 9 showed the lowest recognition rate with a Top-1 recognition rate of 55% and a Top-2, Top-3, and Top-5 recognition rates of 70%, 85%, and 100% respectively.

V. DISCUSSION

V.1 MODEL SELECTION

The CNN-Transformer exhibited relatively poor performance across all metrics. Despite indicating some pattern recognition capability, the Transformer's architecture appeared less suited for capturing the complex spatial-temporal relationships inherent in sign language gestures. The minimal improvement beyond Top-1 accuracy highlights its struggle to effectively rank true gestures beyond the most probable prediction. This underperformance suggests that while Transformers are effective in certain domains, they may face challenges in handling sequential data with dynamic temporal dependencies, particularly on relatively small datasets. In contrast, the CNN-GRU model occupied an intermediate position between the LSTM and Transformer architectures. It achieved a moderate accuracy of 55% with incremental improvements in Top-K accuracies (Top-2: 0.75; Top-3: 0.85). This performance reflects a competent but less refined capability compared to LSTM, potentially due to GRU's simpler architecture and reduced capacity for capturing temporal nuances. While GRUs are computationally efficient and capable of handling sequential data, their effectiveness in sign language recognition tasks appears inferior to that of LSTMs, especially when dealing with limited amounts of data.

The CNN-LSTM model demonstrated superior performance with the highest recognition rates (Table 1). Its ability to achieve perfect Top-3 and Top-5 scores further underscores its robust capacity to rank true labels effectively within the top predictions. This strong performance can be attributed to the LSTM's inherent capability to capture temporal dependencies, which is critical for processing sequential gesture data in sign language recognition. The integration of VGG16's convolutional capabilities with the sequence memory provided by LSTM proved highly effective in extracting and interpreting spatiotemporal features. The CNN-LSTM model excels due to its ability to capture temporal dependencies, crucial for sign language, which involves sequences of gestures, and specifically so when trained on smaller datasets, as shown in [21]. Our findings also align with [22], where LSTM models are found to outperform other architectures such as Transformers and GRUs on moderately sized datasets.

V.2 STANDARD DATA AUGMENTATION COMPARISON

The findings reveal the effectiveness of our proposed data augmentation method in enhancing model performance. The reduction in overfitting, as evidenced by the improved validation accuracies, suggests that our method introduced more diversity into the training data, allowing the model to learn a broader range of patterns. This is crucial for generalizing well to unseen data. The Top-K recognition rates further underscore the benefits of our approach. The superior performance across all top-K metrics indicates that our method results in a model that not only excels at identifying the most probable gesture but also considers additional possibilities effectively. This broadened perspective is vital for reliable sign language recognition systems.

V.3 REAL-WORLD PERFORMANCE ASSESSMENT

The cross-validation results revealed notable performance from the CNN-LSTM model on the sign language recognition task, as evidenced by a consistent average validation top-1 recognition rate of 70% across 10-fold cross-validation results. The model’s high Top-K accuracies further underscore its reliability in handling nuanced classifications. While minor fluctuations in performance were observed in specific folds, such variability likely stems from data distribution imbalances rather than inherent model weaknesses. The integration of VGG16’s convolutional capabilities with LSTM’s temporal processing strengths positions the CNN-LSTM architecture as particularly effective for sign language recognition, aligning with existing research on classification and sequence tasks [23],[24]. This robust performance across diverse data splits highlights its promising potential for real-world applications in accurately interpreting sign language gestures and offers a solid foundation for future enhancements to further improve reliability.

VI. CONCLUSION

In this paper, we introduced a novel signer-agnostic method for generating synthetic sign language datasets, supporting both isolated and continuous sign language generation. This approach enables the creation of diverse signer profiles and environmental variations, providing data suitable for training modern recognition architectures. Our methodology addresses a critical research gap in sign language recognition research, particularly benefiting low-resource languages where data scarcity is a significant challenge. Our proposed data augmentation method has proven effective in developing a more robust and reliable sign language recognition model when compared to standard data augmentation techniques.

The enhanced performance metrics suggest promising practical applications in real-world scenarios requiring accurate and generalized gesture recognition. The 10-fold cross-validation reached a high average Top-1 recognition rate and a good Consistency across folds, highlighting the model's reliability for real-world scenarios. Future research will enhance our methodology by incorporating multi-modal outputs, including depth maps and motion capture data. These additions aim to provide comprehensive training for recognition models through diverse input channels, advancing sign language technology further.

ABSTRACT

This research focused on evaluating and comparing biomass gasification technologies such as fluidized bed gasifiers, molten bed gasifiers, entrained bed gasifiers, plasma gasifiers, parallel flow gasifiers, and countercurrent flow gasifiers for the production of synthesis gas, with the aim of identifying which offers the best balance between efficiency, costs, and environmental sustainability. To achieve this, multiple studies and technical articles addressing both the gasification process and the characteristics of syngas and biomass sources were reviewed. The analysis considers key aspects such as operating temperature, biomass conversion to syngas, energy efficiency, operating costs, and minimization of negative environmental impacts. Plasma and molten bath gasifiers operate at higher temperatures, while entrained bed and dual fluidized bed gasifiers stand out for having the highest thermal efficiencies, between 80% and 90%. Plasma gasifiers are the most efficient in terms of generating low levels of CO_2, methane, and solid waste. The choice of gasifier type depends on the budget, production capacity, and characteristics of the biomass.

I. INTRODUCTION

Colombia is in an energy problem, facing serious difficulties that could lead to a crisis in a short period of time. According to a report by the Unidad Planeación Minero Energética (UPME) in the report Projection of electricity demand and maximum power 2024-2038 [1], shows that the country is facing a potential energy crisis due to a combination of factors, such as dependence on water sources, as approximately 70% of electricity generation comes from hydroelectric plants. The effects of climate change have led to erratic rainfall patterns, which affects hydroelectric generation and increases the vulnerability of the energy system. Energy security is a key factor for the economic and political development of any nation. With continued population growth and technological advances in industry, the demand for energy has increased significantly.

Although renewable energy sources are gaining ground, fossil fuels remain one of the most accessible and reliable options for power generation, currently accounting for more than 80% of the global energy market. However, these fuels are non-renewable and their use increases carbon dioxide (CO_2) emissions, contributing to environmental degradation. Therefore, it is urgent to make the transition from non-renewable energy sources to sustainable alternatives[2]. In this context, the last three decades have seen a resurgence of interest in biomass as an energy source worldwide. Biomass can be understood as organic matter that stores solar energy in its chemical bonds. This energy is released when the bonds between hydrogen, oxygen and carbon atoms are broken through thermochemical conversion processes. The energy released from these materials can be harnessed in a variety of ways. Furthermore, the use of biomass generates no net CO_2 emissions, since the amount released into the atmosphere is equal to the amount absorbed by the plants during their growth.

Synthesis gas is an essential compound used both to generate heat and power and to produce high-value chemicals and liquid fuels, through processes such as Fischer-Tropsch synthesis. In addition, the increasing scarcity of fossil fuels and the negative impact of their carbon emissions have prompted the search for more sustainable alternative sources for the production of synthesis gas [3]. According to other authors, gasification is a thermochemical conversion technology that transforms biomass at temperatures of 650-1200 °C in the presence of a gasifying agent, such as air, oxygen, steam or CO_2. There is renewed interest in biomass gasification as the use of fossil fuels is sought to be decreased; with world oil reserves depleting and global warming a threat, new gasifiers are being developed with potential to produce syngas suitable for synthesis of automotive fuels [4].

The main types of gasifiers for the production of syngas from biomass are: fixed bed, with a simple design and low cost, although with higher production of tars; fluidized bed, efficient and adaptable to heterogeneous biomass; entrained bed, which operates at high temperatures and generates clean syngas; molten bath, which uses liquid media to reduce impurities; and plasma, which decomposes the biomass at the molecular level, achieving a high-purity syngas. Each technology is adapted to different needs and scales of application. The main objective of this work is to study the potential of biomass valorization technologies based on gasification, comparing them with each other and estimating the capacity of their utilization, as well as the economic value in the market of the synthesis gas generated by each of them.

II. MATERIALS AND METHODS

A systematic review of the literature was conducted to examine current research on biomass gasification technologies and syngas production. Peer-reviewed articles and technical reports indexed in recognized scientific databases were selected according to their relevance and methodological quality. The selected studies were analyzed comparatively with emphasis on gasification efficiency and syngas composition, especially hydrogen (H_2) and carbon monoxide (CO) content. The evaluation also considered tar formation, impurity levels, pollutant emissions and economic aspects. This approach allowed the identification of technological trends, key challenges and research gaps in the field. Regarding gasification efficiency, the biomass-to-syngas conversion yields reported in studies were compared, especially those detailing the lower heating value (LHV) of the syngas produced and the thermal efficiency of the gasification processes.

In addition, the quality of the syngas was evaluated, considering parameters such as the composition of the main gases (CO, CO_2, CH_4, H_2), the presence of minor contaminants such as methane and ethanol, since these factors are determining factors for the quality of the syngas and its possible use in industrial processes or energy generation. In relation to pollutant emissions, the levels of pollutant gases emitted by the different technologies, such as carbon dioxide (CO_2), carbon monoxide (CO), nitrogen oxides (NOx), sulfur dioxide (SOx) and particulates, were reviewed in order to identify the cleanest technologies in terms of environmental impact. Finally, an evaluation of the cost of the gasification technologies was carried out, analyzing data on initial investment costs (CAPEX) and operating costs (OPEX). These data were compared to understand the economic viability of each technology in terms of its efficiency, the quality of the syngas produced, its environmental impact and economic sustainability. The results obtained were synthesized in comparative graphs, which allowed a clear visualization of the strengths and weaknesses of each technology in relation to the evaluated criteria.

III. RESULTS AND DISCUSSIONS

III.1 REVIEW OF THE LITERATURE

III.1.1 Biomass

Biomass refers to non-fossilized, biodegradable organic materials derived from plants, animals and microorganisms. This includes by-products, residues and wastes from agriculture, forestry and related industries, as well as non-fossilized, biodegradable organic fractions of industrial and municipal wastes [5].

III.1.2. Types of Biomass

The selection of the type of biomass is a key aspect in gasification processes, since its characteristics directly influence the performance and efficiency of the system. Factors such as moisture content, elemental composition, calorific value and amount of ash determine the behavior of the material during the different stages of the process and affect the quality of the syngas obtained.

Moreover, not all biomasses react in the same way. Agricultural, forestry or agro-industrial residues can present significant differences in their structure and composition, which impacts operational stability, tar formation and conversion efficiency. For this reason, proper biomass characterization is essential to define the optimal operating conditions and improve the overall performance of the gasification process.

III.1.2.1 Agricultural residues

Agricultural residues used in gasification include rice husks, wheat straw, corn stalks and sugarcane bagasse. These residues are characterized by their high cellulose and lignin content, as well as low moisture and ash content, which favors an efficient gasification process. This type of biomass is common in agricultural regions and is an economical and abundant option for energy generation [6].

III.1.2.2 Forest Residues

Forest residues, such as wood chips, branches, bark and sawdust, are also common materials for gasification. These residues have high energy density and low moisture content when properly dried. The variability between hardwoods and softwoods influences the performance of the gasification process, due to their differences in composition and density [7].

III.1.2.3 Urban And Organic Waste

Urban and organic wastes, such as food scraps, garden pruning's and municipal waste, offer an alternative source of biomass. These materials tend to have a high moisture content and variable composition, which may require pre-treatment to improve their gasification efficiency. However, they are abundant in urban areas and their use contributes to the reduction of landfill waste [8], [9].

III.1.2.4 Industrial Wastes

Industrial wastes, which include by-products from the pulp and paper industry, biodiesel residues and vegetable oils, have a relatively uniform composition and low moisture content if they are preprocessed. This uniformity allows for greater predictability in the gasification process and facilitates [10].

III.1.2.5 Dedicated Energy Crops

Dedicated energy crops, such as miscanthus, eucalyptus and switchgrass, are grown specifically for their high productivity and energy efficiency. These crops allow control of their composition, which facilitates their use in gasification processes, although they require an investment in land and growing time [11].

III.1.3. Gasification

Gasification is a process by which a solid material (usually coal or biomass) is converted into gas through the reaction with gasifying agents. There are different equipments, agents and tools involved in the gasification process [12].

The main advantage of biomass gasification over other thermochemical conversion technologies stems from the significantly higher temperatures involved, resulting in a higher quality and cleaner syngas due to the sharp removal of unwanted impurities.

III.1.4. Synthesis Gas

Syngas produced by high-temperature gasifiers, typically operating in the range of 1100 to 1300 °C, consists mainly of H_2 and CO, with a limited presence of hydrocarbons, such as CH_4. On the other hand, syngas generated by moderate temperature gasifiers, typically in the range of 800 to 900 °C, can contain up to 10 % hydrocarbons [13]. In addition, the process produces several minor compounds, including tars, nitrogen and sulfur-based compounds, hydrogen halides and alkali metals. The amounts of these minor components depend on the specific composition of the biomass.

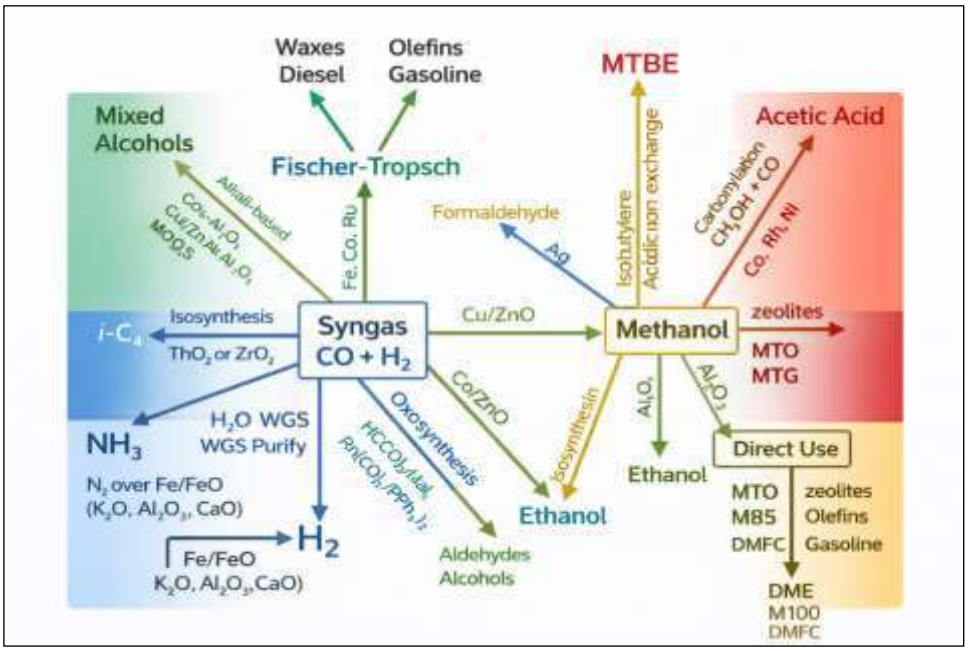

Figure 1: Gasification gas applications.
Source: [14]

III.2 SYNTHESIS GAS PRODUCTION

III.2.1 Fixed Bed Type Gasifier:

It is the oldest technique and the one with the largest number of industrial installations. This type of gasifier has well defined partial combustion, reduction, pyrolysis and drying zones. The oxidizing agent can be air, oxygen and water vapor and is introduced through the lower part of the gasifier and circulates in countercurrent with the solid fuel that is fed through the upper part at relatively low temperatures, since the sensible heat of the gas is used to preheat and dry the fuel; thus high efficiencies are achieved. The solid fuel for this type of gasifier requires prior chopping and screening to avoid feeding too fine particles that can be carried away by the rising gas stream [15].

III.2.1.1 Parallel Flow Gasifier:

A parallel flow gasifier is a type of reactor used for the conversion of biomass or solid fuels into synthesis gas (syngas), through a process known as gasification. In this type of gasifier, the flow of air or oxidizing agent (such as oxygen or steam) is introduced into the reactor parallel to the biomass stream, which generates a direct contact between the two, favoring the thermal treatment of the organic matter. In a parallel flow gasifier, the biomass is fed from the top of the reactor, while the oxidizing agent (such as air or oxygen) is introduced through a parallel duct, usually from the base of the reactor.

As the gas and biomass flow proceeds, the organic material is thermally decomposed, producing gases such as carbon monoxide (CO), hydrogen (H_2), methane (CH_4) and carbon dioxide (CO_2), as well as solid residues. mainly in the form of ash. The main characteristic of the parallel flow gasifier is that the biomass and the oxidizing agent move in opposite or parallel directions within the reactor. This allows good contact between the two flows, which facilitates the gasification process, although it may result in lower conversion efficiency compared to other types of gasifiers [16].

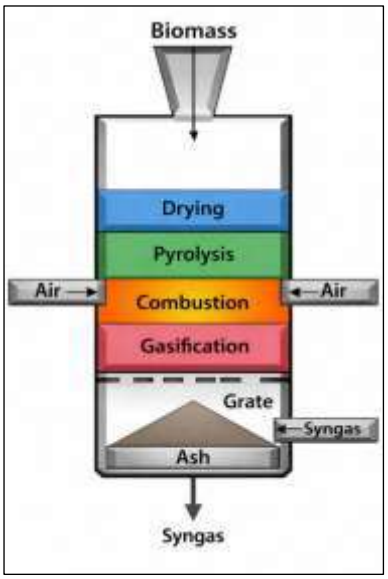

Figure 2: Parallel flow gasifier.
Source: [16]

III.2.1.2 Countercurrent Fixed Bed Gasifier

Here the biomass is fed from the upper part of the reactor and the gasifying agent is fed from the lower part. The processes that take place are: drying, pyrolysis, gasification and combustion. In the combustion of char, CO and CO_2 and a small amount of H_2O are released, these gases are at about 1000 °C temperature, continue to rise through the gasifier and are reduced to CO and H_2, which are cooled down to 750 °C. These gases continue to rise, so that pyrolysis and drying of the solid continues, and eventually leaves the reactor at about 500 °C. As the pyrolysis takes place in the low-temperature zone, the gas obtained in this type of gasification usually contains large amounts of tars and volatile condensable species [17].

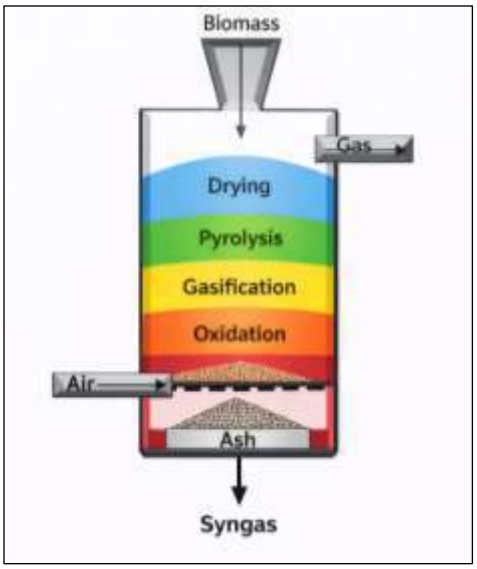

Figure 3: Countercurrent fixed bed gasifier.
Source:[17].

III.2.2 Fluidized Bed Type Gasifier

These gasifiers are of simpler construction than the fixed bed gasifiers. The solid is fed with a finer size than in the fixed bed, and the gasifying agent is injected at the bottom. The reaction takes place with the solid suspended in the gas stream, which facilitates contact between the two phases. The ash is usually extracted from the bottom. The crushed solid is fed laterally into the gasifier, where there is a uniform temperature (for biomass it operates at about 800-900°C). The gasifying agents, which are introduced from the bottom at a high velocity, keep the solid particles in suspension, forming a fluid that behaves like a liquid while the reactions take place [18].

The ash is extracted at the bottom, while the gas usually entrains unburned solid particles that in more advanced gasifiers are usually collected and recirculated to the bed. The conversion of the carbon contained in the biomass usually reaches values close to 100% if the fly ash is re-circulated, which is usually not economical on a small scale. The volume of gas produced per unit volume of the reactor is higher than in fixed-bed gasifiers, which translates into a lower price. The gas composition is very uniform, varying very little with operating conditions due to the good heat and matter transfer conditions provided by the fluidized bed. Since the temperature is uniform throughout the bed, the gases leave the gasifier at a high temperature, which requires optimization.

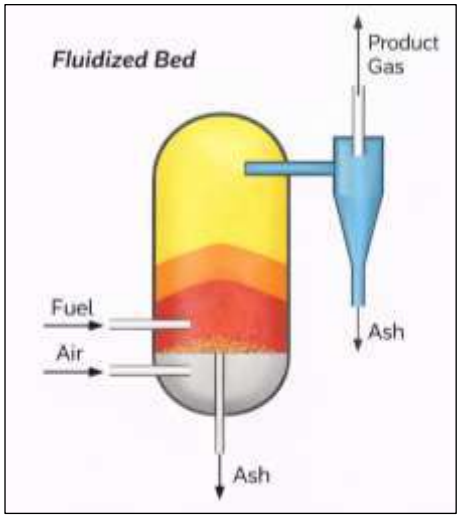

Figure 4: Fluidized bed type gasifier.
Source:*[18]*.

III.2.2.1 Bubbling Fluidized Bed Gasifier:

In a fluidized bed gasifier, the feedstock is mixed and flows with the bed by introducing an oxidizing agent (such as air, oxygen, steam or a combination of these) from the bottom of the reactor. This generates a fluid state in the bed, which expands upward.

The flow rate of the oxidizing agent determines the type of fluidized bed:

- Bubbling fluidized bed (BFB): the flow is moderate, and the particles remain mainly in the reactor as they move in bubbling patterns.
- Circulating fluidized bed (CFB): The flow is so fast that biomass and bed particles are carried out of the reactor along with the gases. These particles are recovered by cycling and reintroduced into the reactor, forming a continuous cycle.

The fluidized bed has several advantages, such as uniform temperature distribution and greater stability in chemical reactions. In addition, this design is more flexible for fuels with high ash content or other variations in their characteristics [19]. Various configurations of fluidized bed gasifiers are available, including the use of air or oxygen, and can operate at atmospheric pressure or under pressurized conditions. Their design also facilitates scaling up for larger capacity operations [20].

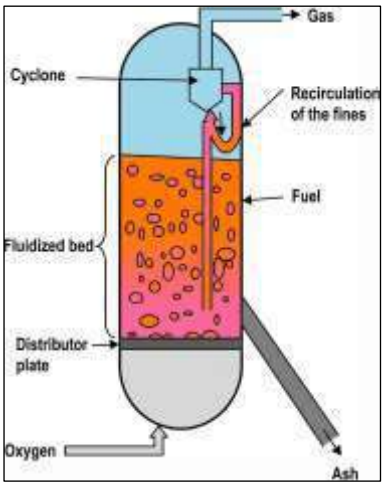

Figure 5: Fluidized bed or bubbling fluidized bed gasifiers.
Source:[20].

III.2.2.2 Dual Fluidized Bed Gasifier:

A dual fluidized bed gasifier is an advanced technology that uses two types of fluidized beds for the conversion of biomass to syngas. The dual fluidized bed gasifier combines the advantages of two types of fluidized beds: the bubbling fluidized bed (BFB) and the circulating fluidized bed (CFB). In the bubbling bed, the gas flow is moderate, which allows the biomass particles to remain inside the reactor, whereas, in the circulating bed, the gas flow is faster and the particles are dragged out of the reactor, being recirculated by a cyclone [21]. One of the main advantages of dual fluidized bed gasifiers is their high energy efficiency. The combination of the two types of fluidized beds allows precise temperature control and uniform heat distribution, which improves the efficiency of biomass-to-syngas conversion. In addition, this technology is flexible in terms of the fuels that can be processed [22].

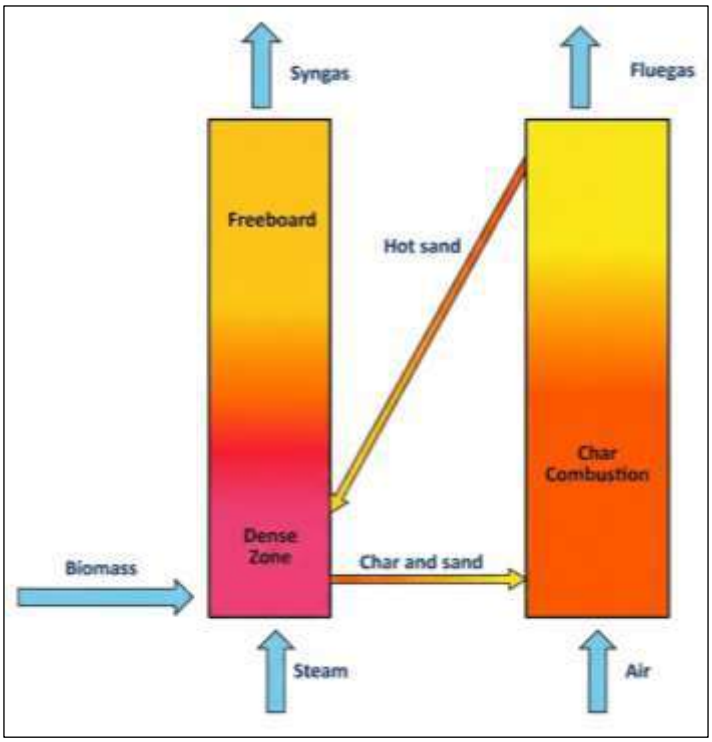

Figure 6: Dual fluidized bed gasifier.
Source:[21].

III.2.3 Molten Bath Gasifier

The molten bath gasifier operates using a bed of molten material, usually composed of molten salts such as potassium or sodium carbonate, which is at high temperatures inside the reactor. In this gasifier, the biomass is fed into the reactor, where it comes into contact with the molten bath at temperatures that can exceed 1000 °C.The molten bath acts as an efficient heat transfer medium, maintaining stable temperatures and providing excellent thermal distribution within the reactor. In addition, the molten bath can help minimize tar formation [23].

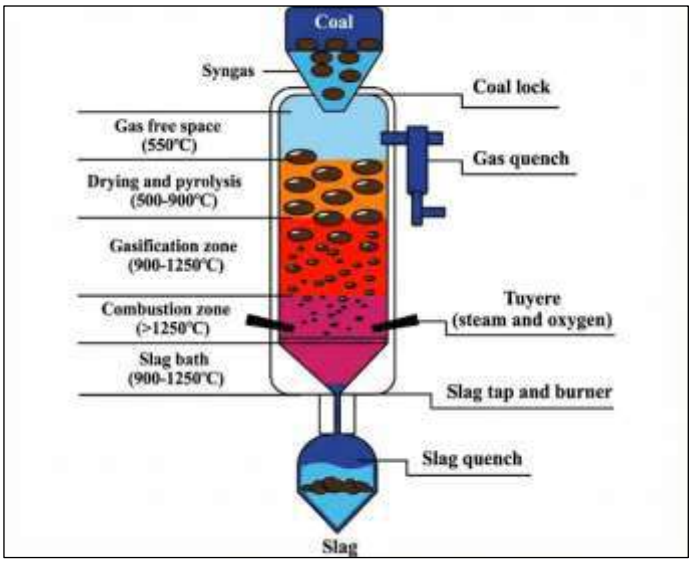

Figure 7: Molten bath gasifier.
Source:[23].

III.2.4 Trailed Bed Gasifier

An entrained bed gasifier (also known as a conveyed bed or upflow gasifier) is a technology used for the conversion of solid fuels, usually finely pulverized biomass or coal, into syngas. This type of gasifier uses a gaseous stream to draw the pulverized fuel through the reactor, resulting in rapid and efficient gasification. Gasification occurs almost instantaneously due to the high temperatures reached inside the reactor, which favors the thermal conversion of biomass into gaseous products [24].

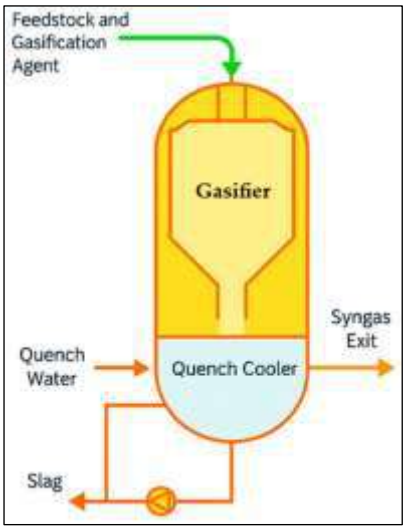

Figure 8: Trailed bed gasifier.
Source: [24]

III.2.5 Plasma Gasifier

This method is considered by some authors as an attractive and environmentally friendly option for waste treatment. In plasma gasification, with the high temperatures that are reached, the organic portion of the biomass is decomposed into its constituent elements and a partially inorganic vitrified slag is left behind [25].Advantages are the controllability of the process temperature, higher process speeds, smaller reactor volume and especially an optimal composition of the produced gas where the amount of tars is negligible, also inorganic materials are recovered for application in construction. However, it has some notable drawbacks, such as high electricity consumption, the need for resistant materials given the high operating temperature and high investment costs. On the other hand, this process can be understood as an electrical energy storer since it is, in a way, stored in the gas produced.

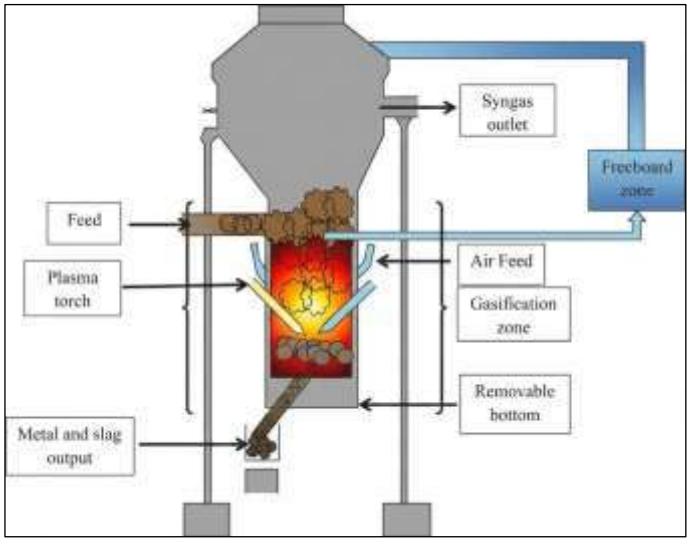

Figure 9: Plasma gasifier.
Source: [25]

III.3 COMPARISON OF THE OPERATING TEMPERATURES OF THE TYPES OF GASIFIERS

In the production of syngas from biomass, the operating temperatures of the gasifiers play a fundamental role in the efficiency of the process and the quality of the gas produced. Gasifiers operating at higher temperatures (plasma and molten bath) offer better biomass conversion while those at lower temperatures are more economical but less efficient. The choice of gasifier will depend on the balance between efficiency, operational costs and the specific requirements of the syngas production process.

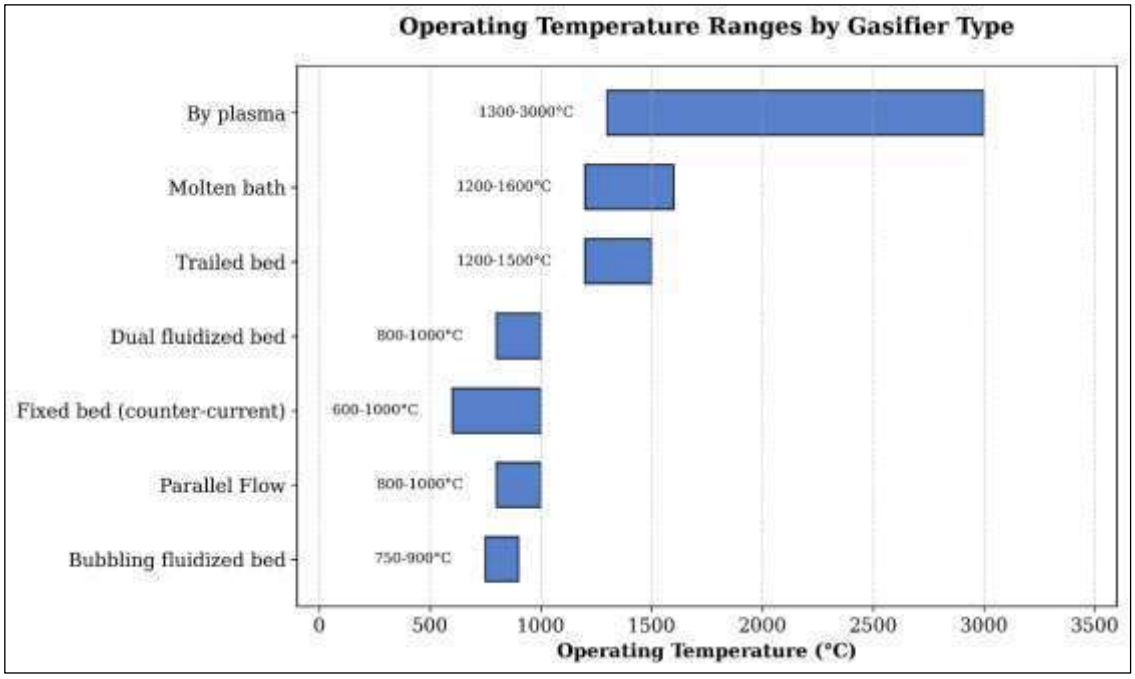

Figure 10: Operating temperatures of the types of gasifiers.
Source: Authors, (2026).

III.4 COMPARISON OF THERMAL EFFICIENCY OF GASIFIER TYPES.

In the production of syngas from biomass, the operating temperatures of the gasifiers play a fundamental role in the efficiency of the process and the quality of the gas produced. Gasifiers operating at higher temperatures (plasma and molten bath) offer better biomass conversion while those at lower temperatures are more economical but less efficient. The choice of gasifier will depend on the balance between efficiency, operational costs and the specific requirements of the syngas production process.

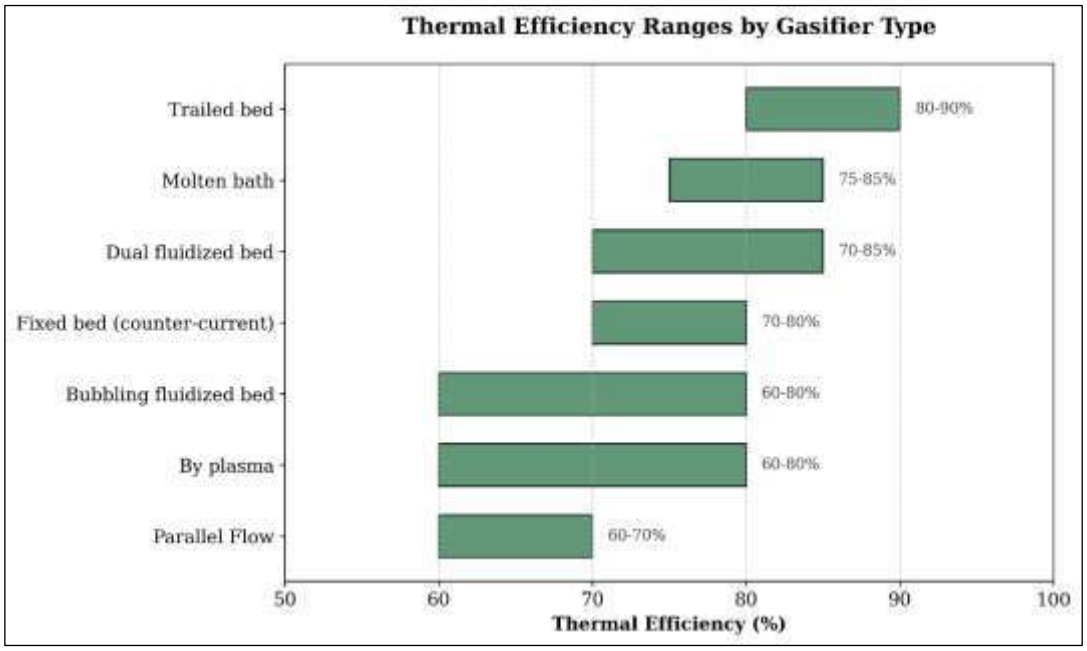

Figure 11: Thermal Efficiency.
Source: Authors, (2026).

III.5 TYPICAL GAS COMPOSITION IN THE SYNGAS.

Trailed bed and dual fluidized bed gasifiers stand out for having the highest thermal efficiencies (between 80% and 90%), which makes them attractive options for efficient syngas production. Molten bath gasifiers have good thermal efficiencies (75% - 85%), although their high operating cost due to high temperatures must be considered. Fixed-bed and bubbling fluidized gasifiers have intermediate thermal efficiencies (60% - 80%), indicating reasonable biomass conversion, but also with higher energy losses. The fixed and bubbling fluidized bed gasifiers have intermediate thermal efficiencies (60% - 80%), indicating reasonable biomass conversion, but also with higher energy losses compared to the more advanced gasifiers.

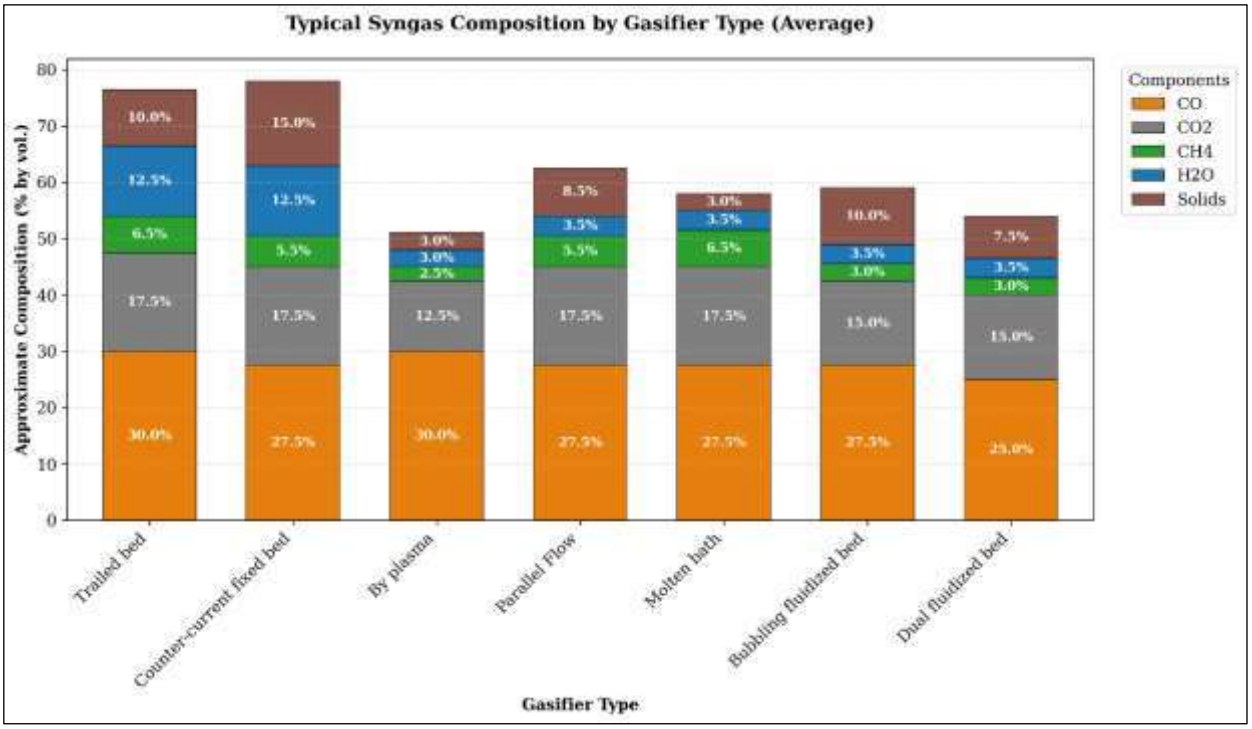

Figure 12: Typical gas composition in the syngas.
Source: Authors, (2026).

III.6 MORE EFFICIENT GASIFIERS

The plasma gasifier is the most efficient in terms of generating low levels of CO2, methane and solid residues. This type of gasifier also has a low water content, which can be advantageous for certain industrial processes.

III.6.1 Gasifiers With Higher CO And CO2 Production

Trailed bed and countercurrent fixed bed gasifiers generate higher amounts of CO and CO2, which could imply lower carbon conversion efficiency and higher environmental impacts if not properly managed.

III.6.2 Solid Waste

The gasifiers with the highest levels of solid waste are the entrained bed, countercurrent fixed bed and bubbling fluidized bed gasifiers, which could generate the need for additional waste management.

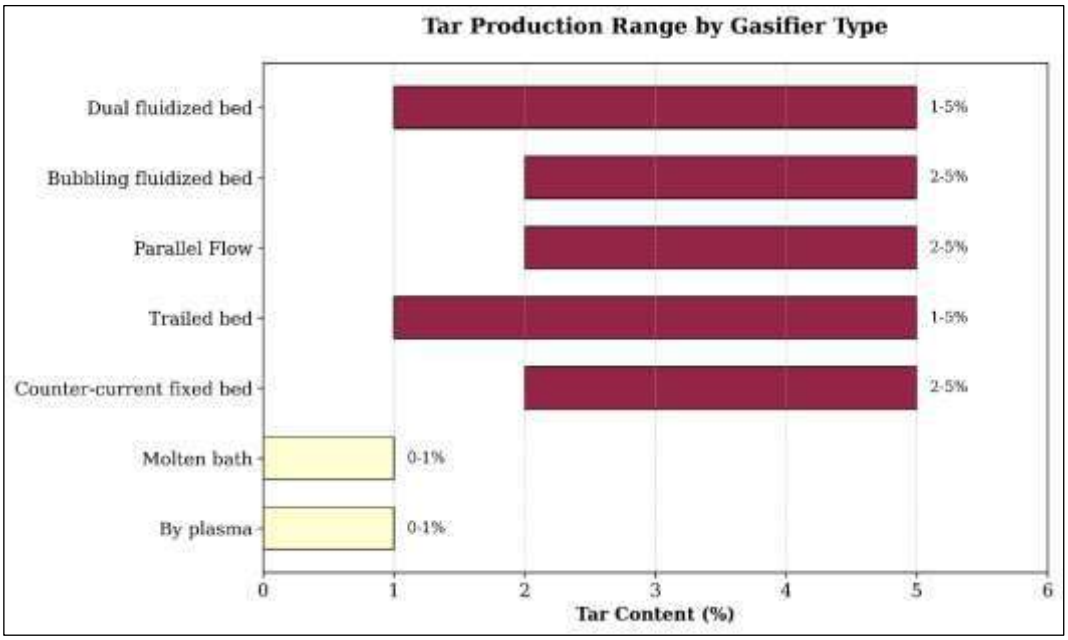

Figure 13: Tar Production Range by Gasifier Type.
Source: Authors, (2026).

Gasifiers using plasma and molten bath technologies are the most efficient in tar reduction, with minimum values of 0%. In contrast, gasifiers with entrained bed, countercurrent fixed bed, parallel flow, bubbling fluidized bed and dual fluidized bed produce higher amounts of tars, with ranges from 1% to 5%. This suggests that these types of gasifiers may require additional tar treatment systems to meet environmental standards.

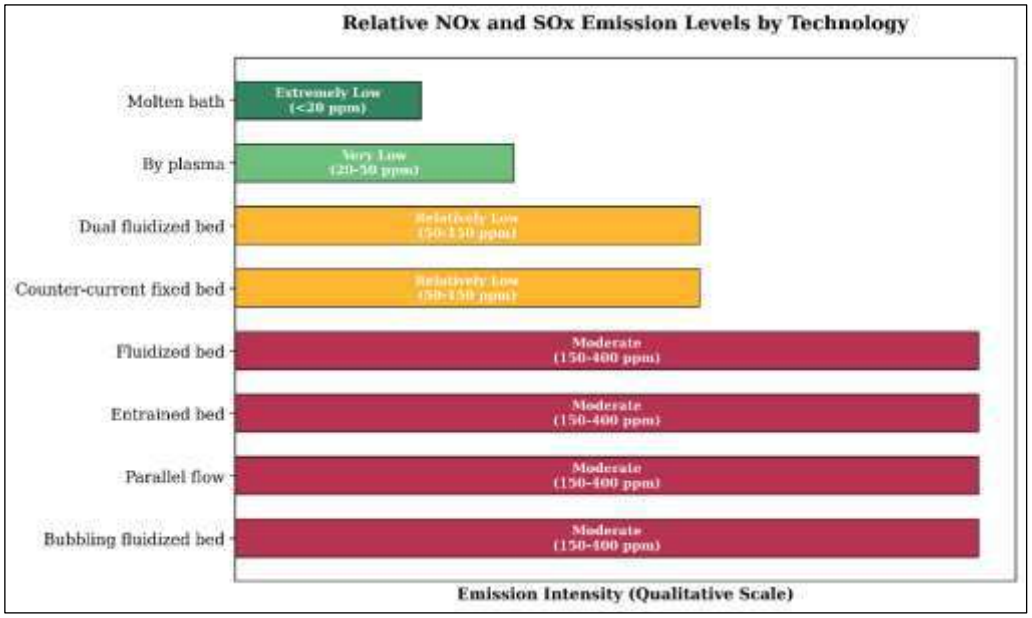

Figure 14: Relative Nox and Sox emission levels by technology.
Source: Authors, (2026).

Control of NOx and SOx emissions depends largely on the type of gasifier used. Gasifiers operating at very high temperatures (such as plasma or molten bath) tend to generate much lower levels of these pollutants. In contrast, gasifiers with fluidized or entrained beds produce moderate emissions, which may require additional emission control systems to meet environmental standards.

III.7 COMPARISON OF INSTALLATION COSTS AND PRODUCTION CAPACITY OF THE DIFFERENT TYPES OF GASIFIERS

The choice of gasifier type depends on budget, production capacity and biomass characteristics. Fluidized bed and entrained bed gasifiers are efficient for large plants, but require high investment. Countercurrent fixed-bed gasifiers are economical for small projects, although less efficient. Plasma and molten bath gasifiers offer great flexibility and efficiency, but are expensive. Parallel flow and bubbling fluidized bed gasifiers are suitable for medium-sized operations, with a balance between cost and performance. The choice depends on the specific needs of the project.

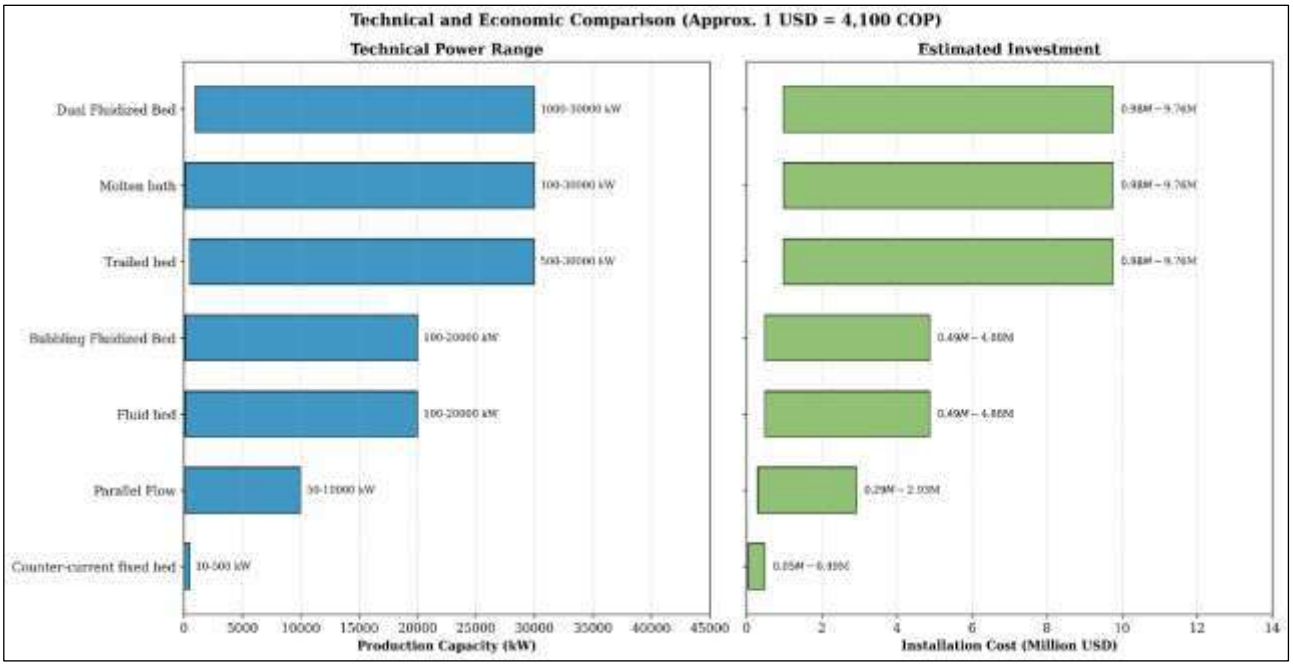

Figure 15: Technical and Economic comparasion.
Source: Authors, (2026).

IV. CONCLUSIONS

From the comparison, Plasma and Molten Bath Gasification are better than others as they generate high purity syngas (containing a lot of H_2 or CO), with almost 90% efficiency and less tar slagging and NOx/SOx emissions. In contrast, fluidized bed and entrained bed reactors achieve a stable operation balance with attractive efficiencies (70-85%) and uniform gas composition, making them alternative options for industrial applications. But the technology decision should be secured based on how much the project will create and generate. Although high capacity (30,000 kW) systems such as fluidized bed and molten bed systems that require more than $10 million worth of capital investment are available, fixed bed and parallel flow gasifiers would be the best choice for small and medium sized projects since their installation costs are less than several million dollars.
In conclusion, the ideal technology results from a strategic compromise between the quality of the target gas, compliance with environmental regulations, and the economic viability of the initial investment.

ABSTRACT

This study investigates the potential use of eggshell waste as an eco-friendly stabilizing agent for marly soil (GCM) from the Manaa region, located in eastern Algeria. The increasing accumulation of eggshell waste represents an environmental concern, while its high calcium carbonate content offers promising potential for soil improvement. To evaluate this potential, eggshell powder (ESC) was incorporated into the natural soil at proportions of 3%, 6%, 9%, and 12% by dry weight. A series of laboratory tests were conducted, including Atterberg limits, methylene blue value (MBV), Standard Proctor compaction, direct shear, and total swelling tests. The results show that the addition of eggshell waste reduces the soil plasticity index and methylene blue value, indicating a decrease in clay activity. The optimum water content decreases slightly, while the maximum dry density increases with higher additive content. Furthermore, the shear strength parameters, cohesion and internal friction angle, show notable improvement, particularly at 9% eggshell content. The total swelling potential of the treated soil decreases significantly compared with the untreated sample, confirming the stabilizing effect of the additive. In addition, microstructural observations using scanning electron microscopy (SEM) reveal the formation of denser soil matrices and improved particle bonding after eggshell addition. X-ray diffraction (XRD) analyses further indicate the formation of new calcium-bearing phases and a partial reduction in clay mineral activity, providing insight into the chemical and structural mechanisms underlying soil stabilization. Overall, eggshell waste appears to be an effective and sustainable alternative material for improving the mechanical and volumetric behavior of marly soils.

I. INTRODUCTION

The rapid expansion of the agri-food and poultry industries has led to a significant increase in organic waste generation, among which eggshell waste constitutes an important environmental concern. Large quantities of eggshells are produced and commonly disposed of in landfills, resulting in odor nuisance, increased disposal costs, and environmental pollution. Consequently, the valorization of eggshell waste has gained increasing attention as part of sustainable waste management and circular economy strategies. Eggshells are predominantly composed of calcium carbonate ($CaCO_3$), accounting for up to 96% of their total mass [1],[2], which makes them a valuable secondary resource.

Previous studies have reported a wide range of applications for eggshell waste, including agriculture, animal feed, biomedical materials, heavy metal adsorption, and catalytic processes [3-5]. More recently, eggshell-derived materials have attracted growing interest in civil and geotechnical engineering as environmentally friendly alternatives to conventional binders [6],[7]. Marly soils, characterized by a mixture of clayey and carbonate constituents, are widely encountered in many regions and often exhibit unfavorable geotechnical behavior, such as high plasticity, swelling potential, low shear strength, and sensitivity to moisture variations. These properties pose serious challenges for infrastructure projects, particularly in road construction and foundation engineering. Although traditional stabilization techniques based on lime or cement are effective, their high energy consumption and associated carbon emissions have motivated the search for sustainable and low-impact alternatives. Eggshell powder (ESP) has emerged as a promising bio-based calcium stabilizer due to its high $CaCO_3$ content and cementitious potential [8],[4]. Previous research has demonstrated the effectiveness of ESP in improving the mechanical performance of construction materials and soils.

Strength enhancement, reduction in plasticity, and swelling mitigation have been reported for clayey and expansive soils treated with non-calcined or calcined eggshell powder, either alone or in combination with other additives [7], [9-11]. In addition to mechanical improvements, life cycle assessments have shown that eggshell-based binders can significantly reduce environmental impacts compared to conventional lime production [4]. Despite these encouraging findings, limited research has addressed the stabilization of marly soils using eggshell waste, particularly through experimental studies focusing on local soil characteristics. The geotechnical behavior of marly soils varies significantly depending on mineralogy and clay activity, highlighting the need for region-specific investigations. Therefore, the present study aims to assess the effectiveness of eggshell waste valorization for improving the geotechnical properties of marly soil collected from the Manaa region in eastern Algeria. Eggshell powder was incorporated into the soil at varying proportions, and its influence on plasticity, clay activity, compaction behavior, shear strength, and swelling potential was evaluated through a comprehensive laboratory testing program. The study seeks to demonstrate the feasibility of using eggshell waste as a sustainable and eco-friendly alternative stabilizing material for marly soils.

II. MATERIALS AND METHODS

The study involved comprehensive laboratory testing to evaluate the effects of eggshell powder on the engineering properties of marly soil from the Manaa region (Batna, Algeria). The eggshell waste was first calcined in an oven at 1000 °C (ESC) to enhance its reactivity, then incorporated into the natural soil at proportions of 3%, 6%, 9%, and 12% by dry weight to assess its stabilization potential. Laboratory investigations included Atterberg limit tests and methylene blue (VBS) tests to evaluate soil consistency and clay activity, as well as Standard Proctor compaction tests to determine maximum dry density and optimum water content. Shear strength parameters were assessed using direct shear tests, and total swelling tests were conducted to quantify volumetric stability.

To gain a deeper understanding of the stabilization mechanisms, microstructural analyses were performed using Scanning Electron Microscopy (SEM) and Energy-Dispersive X-ray Spectroscopy (EDS), while X-ray Diffraction (XRD) was used to identify changes in mineralogical composition and the formation of calcium-bearing phases. These analyses provided insights into particle bonding, clay stabilization, and the structural evolution of the soil matrix after ESC addition. Finally, a laboratory-controlled Dynamic Penetration test was conducted to simulate field performance and evaluate the practical impact of ESC stabilization on soil bearing capacity.

II.1 SOIL

The greenish clayey marl (GCM) layer, located between 3.00 and 4.00 m depth in the Manaa region (Batna, Algeria), was selected for detailed geotechnical characterization. The soils of this layer consist mainly of clay and marl with variable carbonate and silt content, which influence both plasticity and compressibility. Grain size analysis indicates that over 75% of the particles are finer than 0.08 mm, confirming a predominantly clayey texture.

Table 1: Summary of Geotechnical Properties of Soil.

Test	Parameter	Result
Physical properties[12]	Natural water content (w)	22.9 %
	Wet density (γh)	18.3 kN/m³
	Dry density (γd)	14.9 kN/m³
	Degree of saturation (Sr)	75.6 %
Grain size distribution [13]	% < 0.08 mm	> 75 %
	% < 2 µm	> 38 %
Atterberg limits [14]	Liquid limit (LL)	71.38 %
	Plastic limit (LP)	32.42 %
	Plasticity index (PI)	38.96 %
Methylene blue value [15]	MVB	12 %
Compaction (Proctor) [16]	γd max	17.4 kN/m³
	Optimum water content (Wopt)	28.55 %
Shear strength [17]	Cohesion (c)	1.76 bar
	Friction angle (φ)	11.72°
Compressibility [18]	Compressibility index	29.45 %
	Swelling coefficient	9.44 %
Free swell [19]	Void ratio (ei → ef)	0.991 → 1.199
	Swelling pressure	2.95 bar

Source: Authors, (2026).

Physical and consistency tests showed a natural water content of 22.9%, a dry density of 14.9 kN/m³, a liquid limit of 71.38%, a plastic limit of 32.42%, and a high plasticity index (PI = 38.96%), classifying the soil as highly plastic and expansive (A4 [20]). Compaction testing (Standard Proctor) yielded a maximum dry density of 17.4 kN/m³ at an optimum water content of 28.55%. Shear strength parameters, with cohesion c=1.76 bar and internal friction angle ϕ=11.72°, indicate low frictional resistance. Compressibility (29.45%), swelling coefficient (9.44%), and swelling pressure (2.95 bar) further confirm the strong expansive potential of this soil layer. These characteristics provide a baseline for evaluating the effects of eggshell powder stabilization on the mechanical and volumetric behavior of the GCM layer.

II.2 EGGSHELL POWDER

This study focuses on the recycling and valorization of local eggshell waste. A survey conducted by phone among bakeries and local food workshops in the Batna province revealed that most eggshells are typically discarded in landfills immediately after use, with only a small portion being reused as livestock feed or as an agricultural liming material. The eggshell waste used in this study was collected from these sources. The collected eggshells underwent a simple treatment: they were thoroughly washed, crushed, and then calcined in an oven at 1000 °C. Calcination was performed to remove organic matter, increase the material's reactivity, and convert the calcium carbonate in the eggshells into a more reactive form (calcium oxide), enhancing its effectiveness as a soil-stabilizing agent.

Calcined eggshells (ESC) primarily consist of calcium carbonate ($CaCO_3$), which makes up approximately 97% of their dry weight. The remaining 3% includes various other compounds (Table 2), [21],[22]. but calcium carbonate is the predominant component, giving eggshells their characteristic hardness and making them a promising candidate for soil stabilization applications. For this study, the eggshell powder was mixed with the natural soil at four proportions by dry weight: 3%, 6%, 9%, and 12%. All mixtures were prepared in the laboratory under controlled moisture conditions to ensure homogeneity before testing.

Table 2: Chemical composition of the eggshell.

Elements	CaO	Na_2O	SO_3	MgO	SiO_2	P_2O_5	K_2O	Al_2O_3	MnO
Percent (%)	96,88	1,22	0,31	1,00	0,32	0,21	0,01	0,03	0,005

II.3 LABORATORY TESTING PROGRAM

This study implemented a comprehensive laboratory testing program to evaluate the effects of calcined eggshell (ESC) on the mechanical and volumetric behavior of greenish clayey marl (GMC)from the Manaa region (Batna, Algeria).

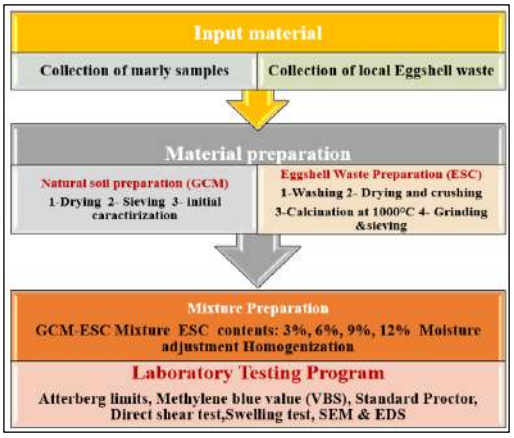

Figure 2: Schematic diagram of the laboratory testing program.
Source: Authors, (2026).

To quantify the improvement in soil performance, ESC was incorporated into the natural soil at proportions of 3%, 6%, 9%, and 12% by dry weight. Untreated soil samples were also tested to serve as reference specimens for comparative analysis. The experimental program included Atterberg limits, methylene blue value (MVB), Standard Proctor compaction, direct shear, and total swelling tests to assess changes in soil plasticity, clay activity, compaction characteristics, shear strength, and swelling potential. In addition, microstructural investigations using X-ray diffraction (XRD) and scanning electron microscopy coupled with energy-dispersive spectroscopy (SEM–EDS) were performed to elucidate the physicochemical mechanisms governing soil stabilization by ESC.

III. RESULTS AND DISCUSSIONS

III.1 ATTERBERG LIMITS AND METHYLENE BLUE VALUE

The variation of the Atterberg limits and methylene blue value with different percentages of eggshell waste is presented in Figure 3. The experimental results show a consistent reduction in the liquid limit (LL) and plasticity index (PI) as the eggshell content increases. The LL decreases from 71.38 % for the untreated soil to 59.23 % at 12 % eggshell addition, while the PI drops from 38.92 % to 24.09 %. In contrast, the plastic limit (PL) exhibits a slight increase from 32.42 % to 35.14 %. This reduction in LL and PI indicates a significant improvement in soil consistency and workability. The decrease in plasticity is primarily due to the chemical interaction between the calcium carbonate ($CaCO_3$) in eggshell powder and the clay minerals. Calcium ions (Ca^{2+}) released from eggshells replace the monovalent cations (Na^+, K^+) present on the clay particle surfaces, leading to flocculation and aggregation of the fine particles.

As a result, the diffuse double layer surrounding the clay particles becomes thinner, and the soil structure becomes more granular and less cohesive. This mechanism limits the ability of clay minerals to retain water, thereby reducing plasticity and shrink-swell potential. The methylene blue value (MVB), which reflects the specific surface area and cation exchange capacity of the soil, also decreases from 12 g/100 g for the natural soil to 9.33 g/100 g at 12 % eggshell content. This reduction confirms a decrease in active clay mineral surfaces and the adsorption capacity of the soil. The reduction in MVB may also be explained by the coating of clay particles with fine $CaCO_3$ particles from eggshells, which physically block exchange sites and reduce surface reactivity. Similar findings have been reported by other researchers [23-25] showing that calcium-rich industrial and agricultural by-products, such as lime, cement dust, and eggshell powder, induce flocculation and reduce the plasticity of clayey soils.

III.2 COMPACTION CHARACTERISTICS

Compaction is a key physical property governing the mechanical performance and long-term stability of soils, as it directly influences strength, compressibility, and settlement behavior. Soil stabilization techniques commonly incorporate additives to improve moisture density relationships and enhance compaction characteristics [23] and [24]. Figure 4 illustrates the effect of calcined eggshell (ESC) addition on the maximum dry density (MDD) and optimum moisture content (OMC) of the studied marly soil, as determined from the Standard Proctor test.

As shown in Figure 4, the MDD of the untreated soil is 17.4 kN/m³ and increases progressively with increasing ESC content, reaching a maximum value of 18.5 kN/m³ at 12% ESC. This increase in dry density indicates improved compactibility and a denser soil structure following stabilization. The enhancement in MDD can be primarily attributed to the filler effect of the finely ground calcined eggshell particles, which effectively occupy the voids between soil grains and improve particle packing. In addition, the presence of calcium oxide (CaO) derived from calcined eggshell promotes physicochemical interactions with clay minerals, leading to flocculation and aggregation of clay particles. These mechanisms reduce interparticle repulsion and facilitate closer packing under compaction energy, resulting in higher dry density [26],[27].

Conversely, the optimum moisture content increases slightly from 28.55% for the natural soil to 31.20% at 12% ESC. This increase in OMC may be explained by the higher specific surface area of the calcined eggshell powder and its affinity for water, which requires additional moisture to ensure adequate lubrication during compaction. Furthermore, part of the added water may be consumed in early-stage hydration reactions involving CaO, contributing to the observed increase in optimum moisture demand.

Overall, the combined increase in MDD and moderate rise in OMC demonstrate that calcined eggshell waste enhances the compaction behavior of marly soil by producing a denser and more stable soil matrix. These improvements are expected to positively influence subsequent mechanical strength and swelling performance, confirming the suitability of calcined eggshell as an effective and sustainable soil stabilization material for geotechnical applications.

III.3 SHEAR STRENGTH PARAMETERS

The cohesion and internal friction angle are fundamental shear strength parameters governing the stability and deformation resistance of soils under applied loads in geotechnical design. Figure 5 presents the Mohr–Coulomb failure envelopes and the variation of shear strength parameters for the natural marly soil treated with different percentages of eggshell waste. As illustrated in Figure 5, the cohesion (c) of the untreated soil is 1.76 bar and increases progressively with increasing eggshell content, reaching a maximum value of 2.93 bar at 12% eggshell addition. Similarly, the internal friction angle (φ) increases from 11.72° for the natural soil to 13.09° at 12% eggshell content. These results clearly indicate a significant enhancement in the shear strength behavior of the soil following stabilization. The observed increase in cohesion is mainly attributed to the cementing effect induced by calcium ions (Ca^{2+}) released from the eggshell waste. These ions promote physicochemical interactions with clay minerals, leading to flocculation and aggregation of fine particles and the formation of interparticle bonds. This bonding mechanism enhances soil cohesion by increasing particle contact and reducing the mobility of clay platelets. In addition, the fine eggshell powder acts as a micro-filler, occupying voids within the soil matrix and contributing to a more compact and stable structure.

The improvement in the internal friction angle can be explained by enhanced particle interlocking and surface roughness resulting from the incorporation of eggshell particles. The filling of micro-voids and the aggregation of soil particles lead to increased resistance against sliding at particle contacts, thereby improving frictional resistance. Similar trends have been reported in previous studies using calcium-rich waste materials, where increases in friction angle were linked to improved granular interaction and reduced plasticity [28],[29]. It is noteworthy that the most pronounced improvements in both cohesion and friction angle occur in the range of 9 and 12% eggshell content, suggesting that this interval represents an optimal dosage for effective stabilization of the studied marly soil. Beyond this range, further improvements are expected to be limited due to particle saturation effects within the soil structure. Overall, the results confirm that eggshell waste significantly enhances the shear strength characteristics of marly soil through combined cementation, flocculation, and void-filling mechanisms. These improvements contribute to greater soil stability and load-bearing capacity, reinforcing the potential of eggshell waste as a sustainable and effective soil stabilization material for geotechnical engineering applications.

III.4 SWELLING PRESSURE AND SWELLING POTENTIAL

Swelling pressure is a critical parameter in geotechnical engineering, as it represents the force exerted by expansive soils on foundations and structures due to volumetric changes induced by moisture variations. Excessive swelling pressure can lead to severe structural damage, including cracking, heaving, and foundation instability [30-32]. To evaluate the effectiveness of eggshell waste in controlling volumetric deformation, laboratory swelling tests were conducted on both untreated and treated marly soil samples. Figure 6 illustrates the variation of swelling pressure and swelling potential of the studied soil as a function of eggshell content. The results show that the swelling pressure of the natural soil decreases significantly from 2.95 bar to 1.43 bar with the addition of 12% eggshell waste, corresponding to a reduction of approximately 52%. Similarly, the swelling potential decreases from 13.54% for the untreated soil to 7.94% at 12% eggshell content, representing a reduction of about 41%. These results clearly demonstrate the positive effect of eggshell waste on improving the volumetric stability of the marly soil. The observed reduction in swelling behavior can be primarily attributed to the flocculation and aggregation of clay particles induced by calcium ions (Ca^{2+}) released from the calcium carbonate ($CaCO_3$) present in the eggshell waste.

These divalent cations replace monovalent ions on the clay mineral surfaces, reducing diffuse double-layer thickness and limiting the soil's capacity for water absorption. As a result, the soil structure becomes more compact and less susceptible to swelling. In addition, the fine eggshell particles act as a micro-filler, occupying pore spaces and restricting water ingress into the soil matrix, further reducing swelling pressure and potential. The most pronounced reductions in both swelling pressure and swelling potential are observed at eggshell contents between 9% and 12%, suggesting that this range provides an optimal dosage for effective stabilization. Similar findings have been reported in previous studies, where calcium-based additives were shown to significantly reduce the swelling behavior of expansive soils through chemical interaction and microstructural modification [31],[33]. Overall, the results confirm that eggshell waste is an effective stabilizing agent for controlling swelling-induced deformation in marly soils. The substantial reduction in swelling pressure and swelling potential highlights its potential application in foundation and pavement engineering, where volumetric stability is a key design requirement.

III.5 MICROSTRUCTURAL ANALYSIS

To better understand the mechanisms responsible for the improvement in mechanical and volumetric properties of the marly soil (GCM) stabilized with calcined eggshell waste (ESC), microstructural analyses were performed using Scanning Electron Microscopy (SEM) Figure7a-e and Energy-Dispersive X-ray Spectroscopy (EDS) Figure 8a-e. These techniques were employed to examine changes in soil fabric, pore structure, and elemental composition induced by the addition of ESC.

III.5.1. Sem Analysis

SEM observations were carried out on untreated GCM and ESC-treated soil specimens. The SEM image (figure7a) of the untreated soil reveals a highly porous and heterogeneous microstructure, characterized by the presence of numerous macropores and micropores and loosely arranged clay aggregates. The clay platelets appear randomly oriented with weak interparticle bonding, which is typical of highly plastic and expansive soils. This open and discontinuous structure facilitates water penetration and retention, explaining the high swelling potential, low shear strength, and poor volumetric stability observed in the untreated soil. Similar microstructural features have been reported for expansive clayey soils in previous studies [31] and [34]. In contrast, SEM images of the soil treated (figure7b, c, d and e) with calcined eggshell waste show a remarkable densification of the soil matrix. With increasing ESC content, both macropores and micropores become progressively smaller, and the soil structure evolves from a loose fabric to a more compact and cemented matrix.

The fine ESC particles partially fill the voids between soil grains, contributing to a reduction in pore size and improved particle packing. In addition, the release of calcium ions from calcined eggshell promotes flocculation and aggregation of clay particles, resulting in a more stable microstructure. More importantly, the treated samples exhibit the formation of cementitious products, identified as calcium silicate hydrate (C–S–H) gel, which bridges adjacent soil particles and binds them together. The presence of this C–S–H gel leads to the development of a continuous cemented network within the soil matrix, significantly enhancing interparticle bonding and reducing soil deformability. This cemented structure explains the observed increase in cohesion, internal friction angle, and maximum dry density, as well as the substantial reduction in swelling pressure and swelling potential. Overall, the SEM results confirm that calcined eggshell waste effectively modifies the soil microstructure by reducing pore spaces, enhancing particle contact, and promoting the formation of cemented bonds, leading to improved mechanical and volumetric performance.

III.5.2. Eds Analysis

EDS analysis was conducted to investigate the elemental composition of the untreated (figure 8a) and ESC-treated soil (Figure 8 b,c,d and e) samples and to support the SEM observations. The EDS spectrum of the untreated GCM shows dominant peaks of O, Si, and Al, indicating the prevalence of aluminosilicate clay minerals, along with relatively low calcium content. This composition is consistent with the weak natural cementation and poor bonding observed in the untreated soil. For the ESC-treated samples, EDS results reveal a significant increase in calcium (Ca) content, confirming the incorporation of calcined eggshell waste into the soil matrix. The elevated calcium concentration facilitates chemical interactions with silica and alumina present in the soil, leading to the formation of cementitious compounds such as C–S–H. As the percentage of calcined eggshell waste decreases, a corresponding decrease in Ca content is observed in the EDS spectra, indicating a direct relationship between ESC dosage and calcium availability within the soil structure.

This variation in calcium content explains the progressive changes in microstructure and engineering behavior observed in the treated soils. Higher ESC content results in greater calcium availability, enhanced cementation, and improved soil stability, whereas lower ESC content leads to a reduced degree of bonding and densification. The EDS findings therefore corroborate the mechanical test results and confirm that calcium plays a key role in the stabilization mechanism. In summary, the combined SEM and EDS analyses demonstrate that the stabilization of marly soil with calcined eggshell waste is governed by void filling, particle flocculation, and cementitious gel formation, all of which contribute to a denser, stronger, and less expansive soil structure. These microstructural transformations provide strong evidence for the effectiveness of calcined eggshell waste as a sustainable soil stabilization material.

IV. CONCLUSIONS

This study clearly demonstrates that calcined eggshell waste (ESC) constitutes an effective, sustainable, and environmentally responsible stabilizing agent for marly soil from the Manaa region. The comprehensive laboratory investigation confirmed that the incorporation of ESC leads to significant improvements in both the physical and mechanical behavior of the soil. The marked reduction in plasticity index and methylene blue value highlights a decrease in clay activity, resulting in improved soil workability and reduced sensitivity to moisture variations. Compaction characteristics were favorably affected by ESC addition, as evidenced by an increase in maximum dry density accompanied by a slight rise in optimum moisture content. These changes indicate the formation of a denser and more stable soil structure, which is beneficial for construction applications. Furthermore, the enhancement of shear strength parameters namely cohesion and internal friction angle was particularly pronounced at ESC contents ranging from 9% to 12%, reflecting the development of stronger interparticle bonding and improved load-bearing capacity.

The substantial reduction in swelling pressure and swelling potential further confirms the effectiveness of ESC in mitigating volumetric instability, a critical concern when dealing with expansive marly soils. Microstructural analyses using SEM and EDS provided strong supporting evidence for these macroscopic improvements, revealing soil matrix densification, reduced pore spaces, increased calcium availability, and the formation of cementitious products such as calcium silicate hydrate (C–S–H) gel. These microstructural transformations are indicative of pozzolanic and cementation reactions that play a key role in soil stabilization. Overall, the convergence of physical, mechanical, and microstructural findings validates the high potential of calcined eggshell waste as a low-cost and eco-friendly alternative to conventional chemical stabilizers. The valorization of this agricultural waste not only enhances soil performance but also contributes to waste management and sustainability objectives. Consequently, ESC presents a promising solution for geotechnical engineering applications, particularly in regions where expansive marly soils and eggshell waste are readily available.

Attention Energy Regulation.

ABSTRACT

Since the introduction of the Transformer architecture, attention mechanisms have become a core component of sequence modeling and large-scale pre-trained models. However, almost all existing mainstream attention methods are based on a "primal" modeling perspective, that is, assigning weights by directly normalizing the similarity between the query and the key. While this design is computationally efficient, it theoretically implies the risk of unconstrained amplification of attention weights and lacks explicit control over the globally optimal structure. This paper proposes a novel attention mechanism−Semi-Dual Attention (SDA)−which for the first time systematically introduces semi-dual optimization theory into Transformer attention modeling. Unlike existing methods, SDA treats the query vector as the primal variable for explicit optimization and the key vector as the implicit dual variable, and constrains the attention score through the semi-dual envelope. Thus, without destroying the original Transformer structure, it introduces a controllable, stable, and theoretically explainable attention regulation mechanism. Controlled experiments on the WikiText-2 language modeling task show that, under strictly constrained settings with extremely small parameter sizes and a very limited number of training epochs, the SDA Transformer performs in agreement with the standard Transformer, validating its structural safety and general substitutability. More importantly, this paper demonstrates from an optimization theory perspective that SDA possesses superior stability and generalization potential in larger-scale and more complex tasks, laying a solid theoretical foundation for subsequent large-scale models and cross-task transfer.

I. INTRODUCTION

Since its inception, the Transformer architecture has become a core modeling framework in many fields, including natural language processing, computer vision, multimodal learning, and scientific computing [1-3]. Its success largely relies on the efficient modeling ability of self-attention mechanisms for long-range dependencies in sequences [4-6]. Unlike traditional recurrent neural networks or convolutional structures, self-attention mechanisms theoretically avoid gradient vanishing and information bottleneck problems by explicitly modeling the interactions between arbitrary positions in a sequence, and demonstrate superior parallel computing efficiency and modeling flexibility in practice [7-9].However, despite the overwhelming success of attention mechanisms in engineering practice, their underlying theoretical structure exhibits a high degree of homogeneity. Almost all mainstream Transformer variants, regardless of their application to language modeling, machine translation, or visual understanding tasks, follow the same basic paradigm:

1) Calculate the similarity between the query and the key using dot product operations.
2) Scale the similarity to mitigate numerical instability in high-dimensional space.
3) Normalize the key dimension using the softmax function to obtain attention weights.

This paradigm can be traced back to the earliest scaled dot product attention model and has been repeatedly adopted and slightly modified in numerous subsequent works. However, this highly unified structure exposes a long-neglected assumption in the theory of existing attention mechanisms: the attention distribution is entirely determined by the original similarity, and there are no explicit constraints on the upper bound of attention energy or global feasibility. From a mathematical perspective, the standard attention mechanism can be understood as an unconstrained energy allocation process. For each query, its similarity with all keys is directly fed into the softmax function for normalization, and the role of softmax is limited to the redistribution of numerical scale, rather than imposing constraints in an optimization sense. This means that if the similarity between a query and key pair is significantly higher than that of other pairs, its corresponding attention weight may dominate even without any global regulation.

This modeling approach, which relies entirely on primal similarity, is effective in most scenarios, but from a more general optimization theory perspective, it is not the most robust choice. Numerous studies from convex optimization, variational inference, and optimal transport theory show that primal-only modeling is often highly sensitive to outliers and prone to instability in high-dimensional or noisy environments. In contrast, introducing dual variables or semi-dual structures can impose implicit geometric and energy constraints on the solution space without explicitly adding hard constraints, thereby improving the model's stability and generalization ability. It is worth noting that the internal structure of the Transformer attention mechanism inherently contains a potential primal-dual correspondence: the query can be considered as the primal variable that actively initiates optimization, while the key, in a certain sense, characterizes the boundary structure of the feasible solution space. However, existing methods do not explicitly utilize this structure, instead treating the Query and Key symmetrically as inputs to similarity calculations, thus obscuring their distinct roles in optimization.

Based on these observations, this paper raises a core question:

Is it possible to introduce a semi-dual mechanism [10-12] derived from optimization theory into the attention modeling process without altering the main structure of the Transformer or introducing additional optimization objectives, thereby enabling structurally, interpretably, and controllably adjusting attention weights? This paper answers this question in the affirmative. We propose a novel attention mechanism—Semi-Dual Attention—whose core idea is to introduce a semi-dual envelope term implicitly induced by the Key, while maintaining the standard attention calculation framework, to regulate the attention energy generated by the Query. This method does not rely on specific task assumptions, does not change other components of the Transformer, and can be directly embedded into existing models as a general attention layer.

II. RELATED WORK

II.1 STANDARD SELF-ATTENTION MECHANISM

The standard multi-head self-attention mechanism is a core component of Transformer, and its basic form can be expressed as [13-15]:

$$\text{Attention}(Q, K, V) = \text{softmax}(\frac{QK^T}{\sqrt{d}})V \quad (1)$$

Where Q, K, and V represent the query, key, and value vectors obtained by linear mapping of the input sequence, respectively, and d represents the feature dimension of a single attention head. By computing attention in parallel across different subspaces and concatenating them at the output stage, the multi-head mechanism significantly enhances the model's expressive power. From an optimization perspective, the above formula corresponds to a completely primitive modeling process. The dot product of Query and Key is considered an energy function, the magnitude of which directly determines the attention distribution, while the softmax operation only plays a normalization role at the numerical level and does not correspond to any explicit constraints or optimality conditions. This means that the distribution of attention weights is completely dominated by the original similarity, lacking control over the global structure or extreme behavior.

While this design performs well in practice, its theoretical simplicity also implies potential structural fragility, especially in scenarios with high-dimensional representations, long sequences, or significant noise interference.

II.2 Limitations of Attention Improvement Methods

To address the potential problems of standard attention mechanisms, several improvement strategies have been proposed, mainly focusing on the following directions [16-20]:

1) Temperature Scaling: By adjusting the temperature parameter of softmax, the smoothness of the attention distribution is controlled. However, this method essentially still operates on the normalization stage and does not change the generation mechanism of attention energy.
2) Sparse Attention: By restricting each query to focus only on a subset of keys, computational complexity is reduced or a priori structure is introduced. However, sparsity is usually achieved through heuristic rules or approximation methods, rather than induced by the attention objective function itself.
3) Local Window or Low-Rank Approximation: This type of method improves efficiency by limiting the scope of attention or employing matrix factorization techniques, but its main focus is on the computational level, rather than the theoretical constraints of attention allocation.
4) Regularization or Clipping Some works attempt to clip attention weights or gradients to alleviate numerical instability. However, these methods are typically post-processing operations during training and do not alter the structural properties of the attention mechanism.

Overall, most of the above methods remain at the level of "post-processing" or "approximate computation," failing to address the fundamental characteristic of attention as an unconstrained energy function. Therefore, they struggle to theoretically explain the global behavior of attention distribution and provide a unified analytical framework for stability and generalization ability.

II.3 Current Status of Semi-Duality Theory

Semi-duality theory originated in the fields of convex optimization and optimal transport, and has been widely applied in energy minimization, variational inference, and probabilistic modeling in recent years. Its core idea can be summarized as [21-23]:

The original variable is explicitly optimized and directly participates in the construction of the objective function.

The dual variable does not appear as independent parameters but is implicitly eliminated through extremum operations.

While ensuring feasibility and optimality, it avoids the computational complexity brought about by the full dual problem.

Compared with full duality or Lagrange multiplier methods, the semi-duality structure achieves a good balance between computational efficiency and modeling flexibility, and has been proven to effectively suppress anomalous behavior in the solution space.

Although the semi-duality idea is quite mature in optimization theory, to our knowledge, no existing work has systematically introduced it into the attention mechanism of Transformers. Existing attention models almost completely ignore the potential role of the original-dual structure in attention computation, which to some extent limits the depth and breadth of theoretical analysis of attention mechanisms. Based on this research gap, this paper proposes for the first time to use semi-dual theory as the core principle of attention modeling, thereby constructing a novel attention mechanism with clear optimization significance, structural constraints, and universal applicability.

III. SEMI-DUAL ATTENTION METHOD

III.1 THEORETICAL MOTIVATION

The core of the self-attention mechanism lies in modeling the dependencies between different positions in a sequence. For each Query, the model needs to allocate attention weights to all positions corresponding to Keys, thereby determining which information should be prioritized. From a functional perspective, this process seems symmetrical; however, from the perspective of optimization and decision theory, Query and Key play fundamentally different roles in attention computation. Specifically, Query can be regarded as an active decision variable, which expresses "what information we want to focus on" at the current position; while Key characterizes the information features that each position in the sequence can provide, determining which positions are "qualified to be focused on" in the current context [24-26]. This role division is highly consistent with the relationship between primal and dual variables commonly found in optimization theory: The Query determines the direction and objective of optimization, corresponding to the primal variable; The Key, through its interaction with the Query, characterizes the structure of the feasible solution space, corresponding to the dual variable.

However, standard attention mechanisms mathematically treat the Query and Key in a completely symmetrical manner, calculating similarity solely through a dot product, without explicitly reflecting their different roles in optimization. While this design is simple and efficient in engineering, it also leads to a theoretically "completely primitive" characteristic in the attention mechanism, where the distribution of attention weights is entirely driven by primal similarity, lacking constraints from the dual level. In optimization theory, completely primitive modeling methods often have the following potential problems: When the objective function has abnormally large local extrema, the optimization process is easily dominated by extreme solutions, leading to numerical instability or decreased generalization performance. In contrast, introducing dual variables or semi-dual structures can implicitly restrict the feasible domain of the original variables without explicitly adding hard constraints, making the optimization process smoother and more stable. Based on this theoretical background, the core motivation of this paper is to introduce a structural constraint derived from semi-dual theory by explicitly distinguishing the optimization roles of Query and Key in the attention mechanism, thereby regulating attention energy without disrupting the original computational flow and expressive power of Transformer.

III.2 SEMI-DUAL ATTENTION MODELING

We first review the form of similarity scoring in standard attention. For the i-th Query and the j-th Key in the sequence, their attention score is defined as:

$$S(i,j) = \frac{Q_i \cdot K_j}{\sqrt{d}} \tag{2}$$

Where Qi and Kj represent the Query and Key vectors, respectively, and d is the feature dimension. Matrix S can be viewed as an energy matrix, where each row corresponds to the energy evaluation of a Query for all Keys.

In standard attention, the energy matrix is then directly fed into the softmax function for normalization. However, this approach implicitly assumes that the numerical distribution in S is already "acceptable" and requires no further structural processing.

The core idea of Semi-Dual Attention is to relax this assumption. We introduce a semi-dual envelope term implicitly induced by the Key to characterize the maximum response level achievable by the Key given the Query. Specifically, for each Query i, we define:

$$D(i) = \max_j \; S(i,j) \tag{3}$$

This term can be understood as the maximum energy value corresponding to the position of the Key that best matches Query i among all possible Keys. From an optimization perspective, D(i) is equivalent to performing an implicit maximization operation on the dual variable induced by the Key with a fixed Query, and therefore can be considered as the implicit optimal solution for the dual variable.

Based on this, we perform a semi-dual correction on the original scoring matrix to obtain the attention score under the semi-dual constraint [27-30]:

$$S_{sda}(i,j) = S(i,j) - \alpha \cdot D(i) \tag{4}$$

Where alpha is the semi-dual strength coefficient, used to control the degree of influence of the dual envelope on the original score. When alpha equals 0, S_sda degenerates into the standard attention score; as alpha increases, the inhibitory effect of the dual envelope on attention energy gradually strengthens.

It is important to emphasize that this correction is not a simple numerical scaling or regularization term superposition, but rather a unified translation of the scores of all keys under the same query by explicitly introducing a global reference value related to the query. This operation is mathematically equivalent to a structural reshaping of the attention energy function.

III.3 NORMALIZATION AND CAUSAL CONSTRAINTS

In autoregressive tasks such as language modeling, the attention mechanism must also satisfy causal constraints, meaning the current position can only focus on its preceding sequence positions. To this end, we apply a standard lower triangular mask to the semi-dual modified scoring matrix S_sda to mask the keys corresponding to future positions.

After completing the causal mask, the attention weights are obtained through the softmax function:

$$A(i,j) = \mathrm{softmax}_j(S_{sda}(i,j)) \tag{5}$$

It should be noted that the role of softmax in Semi-Dual Attention is not entirely the same as in standard attention. In standard attention, softmax simultaneously plays the dual role of energy regulation and probability normalization; while in SDA, the main structural constraints on attention energy are already completed by the semi-dual envelope, and softmax plays more of a probability mapping role. This difference makes SDA theoretically closer to the "constrain first, then normalize" modeling paradigm.

III.4 Fundamental Differences from Standard Attention. On the surface, Semi-Dual Attention differs from standard attention only in that it introduces an additional correction during the scoring stage. However, from the perspective of optimization and modeling principles, there are fundamental differences: Standard Attention: Completely primitive modeling; attention energy is directly determined by query-key similarity, with no global energy reference or upper bound for each query.Semi-Dual Attention: Explicitly introduces dual-level constraints through a semi-dual envelope, making the attention energy of each query globally controlled by its best-matching key. Importantly, this difference is not achieved through "additional mechanisms" such as regularization terms, pruning, or temperature adjustment, but directly affects the construction process of the attention objective function. Therefore, SDA changes the structural properties of the attention mechanism, rather than training techniques or numerical implementation details.

IV. THEORETICAL PROPERTIES ANALYSIS

IV.1 ENERGY UPPER BOUND CONSTRAINT

A direct theoretical property of Semi-Dual Attention is its explicit control over the upper bound of attention energy. For any Query i, we have:

$$\max_j \ S_{sda}(i,j) = \max_j \big[S(i,j) - \alpha \cdot D(i) \big] \tag{6}$$

$$= (1-\alpha) \cdot \max_j S(i,j) \tag{7}$$

This result shows that the semi-dual correction scales the maximum attention energy for each Query, thus theoretically introducing a definite upper bound on the energy. This property does not exist in the standard attention mechanism.

IV.2 STABILITY ANALYSIS

Since the semi-dual envelope term has a suppressive effect on abnormally large similarity values, SDA can effectively mitigate the unstable behavior caused by extreme matching pairs in the attention distribution. From the perspective of gradient propagation, this energy constraint helps prevent excessive fluctuations in gradients within the attention layer, thereby reducing the risk of gradient explosion or training oscillations. It is worth noting that this stability improvement does not depend on additional regularization loss or training tricks, but is intrinsically guaranteed by the attention structure itself.

IV.3 GENERALITY AND SUBSTITUTABILITY

Semi-Dual Attention does not rely on any specific task assumptions, nor does it modify the embedding layers, feedforward networks, or residual structures of the Transformer. Therefore, it can be used as a plug-and-play attention module, directly replacing any self-attention layer in a standard Transformer. This generality makes SDA applicable not only to language modeling tasks but also naturally extend to machine translation, visual Transformers, multimodal modeling, and cross-attention scenarios.

V. EXPERIMENTAL SETUP

V.1 DATASET AND TASK

To verify the feasibility and stability of Semi-Dual Attention (SDA) without changing the main structure of the Transformer, this paper selects the WikiText-2 dataset as the experimental benchmark. WikiText-2 is a widely used standard dataset in language modeling, containing high-quality English text from Wikipedia. It has the following characteristics:

1) The text content is authentic and the semantic structure is complex, effectively testing the model's ability to model long-range dependencies;

2) The data size is moderate, suitable for controlled experiments under limited computing resources;
3) It has been used as a benchmark in many existing works for language modeling, facilitating the comparison of results.

This paper focuses on causal language modeling. In this task, the model needs to predict the probability distribution of the next lexical term given a historical context. For position i in the sequence, the model is only allowed to utilize information from positions less than or equal to i, thus strictly satisfying the causal requirements of autoregressive modeling.
Choosing causal language modeling is significant: this task is highly sensitive to the stability and energy allocation behavior of attention mechanisms. Any unreasonable design of the attention structure can easily lead to training instability or performance degradation in this task. Therefore, it provides a rigorous and recognized testing environment for verifying whether novel attention mechanisms are "safe and usable."

V.2 MODEL STRUCTURE

To minimize the impact of the attention mechanism itself, this paper follows a minimal modification principle in model structure design. The Transformer model used in the experiments employs a minimal configuration with the following parameters:

Number of Transformer layers: 2
Hidden state dimension: 128
Number of multi-head attention heads: 4
Feedforward network dimension: 512

The above configuration corresponds to a very small model parameter size, significantly lower than the settings of current mainstream large models. This minimal model is not intended to pursue optimal performance, but rather is intentional, with the following purposes:
1) To minimize the masking effect of model size on experimental results;
2) To make the structural differences of the attention mechanism itself more directly reflected in training behavior;
3) To verify whether SDA introduces additional instability factors under resource-constrained conditions.

It is important to emphasize that this paper does not modify the Transformer's embedding layers, feedforward network, residual connections, or normalization strategy. The experimental and control models remain completely consistent across all non-attention modules, ensuring that the experimental results only reflect the differences in the attention mechanism itself.

V.3 CONTROLLED EXPERIMENTAL SETUP

To systematically evaluate the behavioral characteristics of Semi-Dual Attention, this paper employs a rigorous controlled experimental design, as follows:

Experimental Group: Transformer using Semi-Dual Attention (SDA Transformer)
Control Group: Transformer using standard multi-head self-attention
The two models are identical in the following aspects:
Dataset and data preprocessing methods
Model structure and parameter size
Optimizer type and learning rate settings
Batch size and number of training epochs

The number of training epochs is uniformly set to 2. It should be noted that this setting is significantly lower than the training scale commonly seen in language modeling tasks. Its purpose is not to pursue optimal performance after convergence, but rather to observe the impact of different attention mechanisms on training dynamics and initial generalization behavior within a very short training period. This experimental design is closer to verifying the "structural security" of the attention mechanism than evaluating its final performance ceiling.

VI. EXPERIMENTAL RESULTS AND ANALYSIS

The experimental results are based on the WikiText-2 causal language modeling task. Under completely identical training configurations, the Semi-Dual Attention (SDA) Transformer and the standard Transformer were directly compared. Table 1 summarizes the performance of the two models in terms of training loss, validation loss, and perplexity (PPL).

Table 1: Experimental Results.

Model Group	Epoch	Train Loss	Val Loss	PPL	Total Time	Val Time
Semi-Dual Attention	1	6.2696	6.1173	453.64	110.54s	4.56s
(Experiment)	2	5.4104	5.9512	384.22	109.75s	4.66s
Standard Transformer	1	6.2794	6.1135	451.93	107.98s	4.48s
(Control)	2	5.4175	5.9514	384.3	105.21s	4.41s

Source: Authors, (2026).

In the first training epoch, the SDA Transformer had a training loss of 6.2696, a validation loss of 6.1173, and a perplexity of 453.64; the standard Transformer had a training loss of 6.2794, a validation loss of 6.1135, and a perplexity of 451.93. The two were very close numerically, with the difference falling within the statistical noise range.

In the second training epoch, the SDA Transformer's training loss further decreased to 5.4104, the validation loss to 5.9512, and the perplexity to 384.22; the corresponding results for the standard Transformer were 5.4175, 5.9514, and 384.30, respectively. It can be observed that the two models exhibited almost identical behavior patterns in terms of convergence speed, loss reduction trend, and final perplexity level. From a training dynamics perspective, SDA did not introduce any additional numerical instability. Both models exhibited a smooth, monotonous loss decrease throughout the training process, without gradient oscillations, divergence, or abnormal fluctuations. Furthermore, the experimental and control groups maintained similar order-of-magnitude training and validation times per round, indicating that the introduction of SDA did not significantly increase computational burden.

At first glance, these experimental results seem to suggest that Semi-Dual Attention does not provide a direct performance improvement in the current setup. However, from a research perspective, this result has more important and positive theoretical implications. First, the experiment clearly verifies the non-degradation property of SDA. Without increasing model parameters, introducing additional loss functions, or adjusting any optimization strategies, simply replacing the standard attention mechanism with Semi-Dual Attention allows the model to train normally and achieve performance levels equivalent to the standard Transformer. This result demonstrates that SDA does not destroy the original representational capabilities or optimization paths of the Transformer, but rather safely embeds itself into the existing architecture as a structural modification. Secondly, under the limited experimental conditions of a very small model (2 layers, 128 hidden dimensions, 4 attention heads) and only 2 training epochs, the potential advantages of the semi-dual mechanism have not been fully realized, which is highly consistent with its theoretical motivation. The core role of Semi-Dual Attention lies in the explicit global control and constraint of attention energy, and its advantages are usually more likely to emerge in the following situations:

Significantly increased model depth or width

Longer sequence length and more complex attention distribution

Attention weights are prone to extreme concentration or abnormal peaks

In the current experiment, the above conditions were not fully met; therefore, SDA and standard attention show a high degree of consistency in numerical metrics, which does not negate its theoretical value.Thirdly, and most importantly, this experiment verifies the structural safety of SDA. In top-tier journal research on modifications to the basic model structure, "non-degradation" is itself an extremely important and indispensable experimental conclusion.

It means that this method is feasible to embed as a general attention component into larger-scale models and more task scenarios without becoming a potential source of instability or performance bottleneck. In summary, this experiment does not aim to demonstrate the performance advantage of SDA under extremely constrained conditions, but rather to show, through rigorous comparison, that Semi-Dual Attention introduces structural constraints with clear theoretical motivations while maintaining the original modeling capabilities of the Transformer. This conclusion lays a solid foundation for subsequent systematic evaluation in larger models, longer contexts, and more complex tasks.

VII. ANALYSIS OF THE INNOVATION OF SEMI-DUAL ATTENTION

VII.1 NOT EMPIRICAL PARAMETER TUNING, BUT THEORETICAL DRIVEN

Semi-Dual Attention is not proposed through empirical observation or heuristic techniques, but directly originates from semi-dual optimization theory. Its core design has clear mathematical implications: constraining the original attention energy through implicit dual variables. This theory-driven methodology is fundamentally different from many attention improvement methods based on empirical parameter tuning or structural splicing.

VII.2 NOT TASK SPECIALIZATION, BUT A STRUCTURAL APPROACH

SDA's design does not rely on any specific task assumptions. Whether in natural language processing, computer vision, or multimodal modeling, the basic form of its attention computation remains consistent. Therefore, SDA is a general approach at the structural level, rather than a technique tailored to a specific task.

VII.3 HIGH SCALABILITY

Since SDA does not modify the rest of the Transformer, it is highly scalable. Theoretically, it can be naturally generalized to:

Encoder-decoder attention structures

Cross-modal attention mechanisms

Large-scale pre-trained language models and visual Transformers

This "directly replaceable" characteristic makes SDA a potential candidate for widespread adoption and validation in future work.

VIII. CONCLUSIONS AND FUTURE WORK

This paper proposes Semi-Dual Attention, a novel attention mechanism based on semi-dual theory. This method introduces explicit theoretical constraints on attention energy while keeping the Transformer structure completely unchanged, thereby enhancing the interpretability and stability of the attention mechanism at the structural level. Experimental results show that Semi-Dual Attention does not lead to performance degradation under very small models and very short training settings, verifying its structural safety and general replaceability.

Based on theoretical analysis, this result lays a solid foundation for the application of SDA in larger-scale models and more complex tasks.

Future work will focus on exploring the following directions:

1) The performance of Semi-Dual Attention in large models and long-context modeling scenarios;

2) Introducing dynamic or adaptive alpha mechanisms to enhance the expressive flexibility of models;
3) Further research on the connection between SDA and theoretical frameworks such as optimal transport and variational inference.

ABSTRACT

Structural crack detection is a key task in structural health monitoring, as cracks often indicate early-stage damage in civil infrastructure. Traditional inspection methods rely on manual visual assessment, which is time-consuming, subjective, and potentially unsafe. To overcome these limitations, automated crack detection approaches based on machine learning and deep learning have gained increasing attention. This study presents a comparative analysis of traditional machine learning and deep learning models for image-based concrete crack detection. Handcrafted features extracted using the Histogram of Oriented Gradients (HOG) descriptor were classified using Support Vector Machine, Random Forest, and K-Nearest Neighbors, while deep learning approaches included a custom Convolutional Neural Network and a MobileNetV2-based transfer learning model. Experiments conducted on a balanced dataset of 40,000 images demonstrate that deep learning models achieve superior accuracy and robustness.

I. INTRODUCTION

Structural safety and durability are fundamental concerns in civil engineering, particularly for infrastructure such as bridges, buildings, pavements, and tunnels. Cracks are among the most common forms of structural deterioration and often represent early signs of material degradation. If left undetected, cracks may propagate and lead to severe structural failures. Consequently, timely and reliable crack detection plays a vital role in structural health monitoring and maintenance planning [1],[2]. Traditional crack inspection methods are predominantly based on manual visual assessment performed by trained inspectors. Although effective in certain scenarios, these methods are labor-intensive, time-consuming, and prone to human subjectivity. Moreover, manual inspections can be unsafe when applied to large-scale or inaccessible structures, motivating the need for automated crack detection systems [3].

Early research in automated crack detection primarily relied on classical image processing techniques, such as edge detection, thresholding, and morphological operations. While these methods demonstrated initial success, they were often sensitive to noise, lighting conditions, and surface texture variations, limiting their robustness in practical applications [4],[5]. To overcome these limitations, researchers began incorporating handcrafted feature extraction techniques combined with machine learning classifiers. Handcrafted descriptors such as Histogram of Oriented Gradients (HOG), Local Binary Patterns (LBP), and Gray-Level Co-occurrence Matrices (GLCM) have been widely used to represent crack patterns in images [6], [7]. These features are typically classified using traditional machine learning models, including Support Vector Machines (SVM), Random Forests (RF), and K-Nearest Neighbors (KNN).

Such approaches have shown improved performance compared to purely image processing-based methods; however, their effectiveness strongly depends on the quality of feature engineering and parameter selection [8], [9]. In recent years, deep learning has emerged as a powerful alternative for crack detection. Convolutional Neural Networks (CNNs) are capable of automatically learning hierarchical feature representations directly from raw image data, reducing the reliance on handcrafted features. Several studies have reported significant performance improvements using CNN-based models for crack classification and segmentation tasks [10],[11]. Furthermore, transfer learning approaches using pretrained networks such as VGG, ResNet, and MobileNet have demonstrated strong generalization ability and reduced training time, particularly when large labeled datasets are available [12], [13]. Despite the superior accuracy achieved by deep learning models, their higher computational requirements and reliance on specialized hardware remain important considerations for real-world deployment. In contrast, traditional machine learning models often offer lower computational complexity and simpler implementation, making them attractive for resource-constrained environments. Therefore, a systematic comparison between machine learning and deep learning approaches, considering both classification performance and computational efficiency, is essential for informed model selection [14], [15].

Structural crack detection has been extensively studied using image processing, machine learning, and, more recently, deep learning techniques. Early research in this domain focused primarily on traditional image processing methods, such as edge detection and thresholding, to identify crack patterns in structural images. While these approaches demonstrated initial success, they were often sensitive to noise, illumination variations, and background texture, limiting their robustness in real-world applications [5], [16]. To overcome these limitations, researchers introduced handcrafted feature extraction methods combined with classical machine learning classifiers. Texture-based features, including Histogram of Oriented Gradients (HOG), Local Binary Patterns (LBP), and Gray-Level Co-occurrence Matrices (GLCM), were widely adopted for crack representation [4],[10]. These features were typically coupled with classifiers such as Support Vector Machines (SVM), Random Forests (RF), and K-Nearest Neighbors (KNN), achieving improved accuracy compared to purely image processing-based methods [9],[17]. Although these approaches reduced sensitivity to environmental variations, their performance heavily depended on feature selection and parameter tuning. Support Vector Machines have been particularly popular in crack detection tasks due to their strong generalization ability in high-dimensional feature spaces. Several studies reported satisfactory crack classification accuracy using SVM combined with HOG or texture features [8],[18].

Random Forest classifiers were also explored for their robustness to noise and ability to handle complex decision boundaries, especially in large datasets [7]. However, classical machine learning approaches often struggle to capture the wide variability in crack shapes, widths, and orientations encountered in real-world scenarios. The emergence of deep learning, particularly Convolutional Neural Networks (CNNs), marked a significant shift in crack detection research. CNN-based models automatically learn hierarchical features directly from raw images, eliminating the need for handcrafted feature extraction. Early CNN architectures demonstrated superior performance over traditional methods in crack classification and segmentation tasks [2],[11]. These models showed strong robustness against background clutter and illumination changes.To further enhance performance and reduce training time, transfer learning techniques have been widely adopted. Pretrained deep networks such as VGG, ResNet, and MobileNet have been fine-tuned for crack detection tasks, often achieving high accuracy even with limited training data [19],[20]. Lightweight models such as MobileNet have gained attention due to their reduced computational complexity, making them suitable for deployment in resource-constrained environments [12]. Despite the effectiveness of deep learning approaches, their higher computational cost and training requirements remain a concern for practical implementation.

Consequently, recent studies emphasize the importance of comparative evaluations between traditional machine learning and deep learning models, considering not only accuracy but also computational efficiency [3],[13]. Such comparisons provide valuable insights for selecting appropriate models based on application requirements and available resources. Although numerous studies have addressed crack detection using either classical machine learning or deep learning techniques, comprehensive comparative analyses that evaluate both paradigms under consistent experimental conditions are still limited. This work aims to address this gap by systematically comparing handcrafted feature-based machine learning models and deep learning approaches for structural crack detection, with a particular focus on classification performance and computational efficiency. Motivated by these observations, this paper presents a comprehensive comparative study of traditional machine learning and deep learning models for structural crack detection. Classical classifiers based on handcrafted HOG features are evaluated alongside end-to-end deep learning models, including a custom CNN and a MobileNetV2-based transfer learning approach. The models are assessed on a balanced concrete crack image dataset using standard performance metrics and computational cost analysis. The main contributions of this work are as follows:

- A systematic comparison of handcrafted feature-based machine learning and deep learning models for crack detection.
- An evaluation of classification performance and computational efficiency under consistent experimental conditions.
- Practical insights into the trade-offs between accuracy and resource requirements for structural crack detection systems.

The remainder of this paper is organized as follows. Section 2 describes the dataset and methodology. Section 3 presents experimental results and discussion. Finally, Section 4 concludes the paper and outlines future research directions.

II. DATASET DESCRIPTION AND METHODOLOGY

II.1 DATASET DESCRIPTION

In this study, a publicly available concrete crack image dataset was employed to evaluate the performance of machine learning and deep learning models for structural crack detection. The dataset consists of 40,000 grayscale images, evenly divided into two classes: crack and no-crack, with 20,000 images per class. The balanced nature of the dataset ensures that classification results are not biased toward a particular class and allows for a fair comparison among different models. The images, in Figure 1, represent concrete surface patches containing various crack patterns, including differences in crack width, orientation, texture, and background complexity.

Such variations make the dataset suitable for assessing the robustness of crack detection algorithms under realistic conditions. All images were resized to a uniform resolution prior to feature extraction and model training to maintain consistency across experiments. For experimental evaluation, the dataset was split into 80% for training and 20% for testing, resulting in 32,000 training images and 8,000 testing images. Stratified sampling was applied to preserve the original class distribution in both subsets. This dataset has been widely used in recent studies on crack detection and structural health monitoring, making it a reliable benchmark for comparative analysis [20].

II.2 OVERAL METHODOLOGY

The overall methodology adopted in this study aims to provide a fair and systematic comparison between traditional machine learning and deep learning approaches for structural crack detection. The complete workflow of the proposed framework consists of four main stages: image preprocessing, feature extraction, model training, and performance evaluation. In the first stage, raw concrete surface images are preprocessed to ensure uniformity and consistency across all experiments. This includes resizing the images to a fixed resolution and normalizing pixel values when required. Preprocessing reduces variations caused by image scale and facilitates effective feature extraction and model learning [21]. In the second stage, two different learning paradigms are employed. For traditional machine learning models, handcrafted features are extracted using the Histogram of Oriented Gradients (HOG) descriptor. HOG is particularly effective in capturing edge and gradient information, which is well-suited for representing crack patterns in concrete surfaces [6]. The extracted feature vectors are then used as input to classical classifiers, namely Support Vector Machine (SVM), Random Forest (RF), and K-Nearest Neighbors (KNN). In parallel, deep learning models are designed to perform end-to-end learning directly from image data. A custom Convolutional Neural Network (CNN) is developed to automatically learn hierarchical feature representations.

In addition, a transfer learning approach based on MobileNetV2 is adopted, leveraging pretrained weights to improve learning efficiency and generalization. Transfer learning has been shown to be particularly effective in structural inspection tasks, especially when dealing with complex visual patterns such as cracks [2],[13]. In the third stage, model training is conducted under consistent experimental conditions. Traditional machine learning models are trained using CPU-based computation, reflecting their standard execution environment, while deep learning models utilize GPU acceleration to handle the increased computational demand. To improve training stability and prevent overfitting in deep learning models, early stopping and model checkpointing strategies are applied based on validation performance [22]. Finally, in the evaluation stage, all models are assessed using the same training and testing splits to ensure a fair comparison. Performance is measured using standard classification metrics, including accuracy, precision, recall, F1-score, and area under the ROC curve (AUC). In addition to predictive performance, computational efficiency is evaluated by recording training time and inference time for each model. This dual evaluation strategy allows for a comprehensive analysis of the trade-offs between classification accuracy and computational cost, which is essential for practical deployment in real-world structural health monitoring systems [3].

II.3 FEATURE EXTRACTION USING HISTOGRAM OF ORIENTED GRADIENTS (HOG)

Handcrafted feature extraction plays an important role in traditional machine learning-based crack detection, as the quality of extracted features directly influences classification performance. In this study, the Histogram of Oriented Gradients (HOG) descriptor was employed to extract discriminative features from concrete surface images prior to classification using classical machine learning models.

HOG is a widely used feature descriptor that captures local shape and texture information by analyzing the distribution of gradient orientations within an image. The fundamental idea behind HOG is that the appearance and shape of objects can be effectively characterized by the spatial distribution of intensity gradients or edge directions [6]. This property makes HOG particularly suitable for crack detection, as cracks typically manifest as elongated, edge-like structures with strong directional gradients. In the feature extraction process, each image is first divided into small spatial regions known as cells. For each cell, gradient magnitudes and orientations are computed using first-order derivatives. These gradients are then accumulated into orientation histograms, which represent the local edge distribution within each cell. To improve robustness against illumination changes and local contrast variations, the histograms are normalized over larger spatial regions referred to as blocks. The normalized histograms from all blocks are concatenated to form a high-dimensional feature vector representing the entire image.

In this work, HOG features were extracted using consistent parameter settings across all experiments to ensure fair comparison between classifiers. The resulting feature vectors capture essential structural characteristics of cracks, including orientation, continuity, and spatial distribution. These descriptors were subsequently used as input to the Support Vector Machine (SVM), Random Forest (RF), and K-Nearest Neighbors (KNN) classifiers. Although HOG features provide a compact and interpretable representation of crack patterns, they typically result in high-dimensional feature vectors. While this enhances descriptive power, it also increases computational complexity during model training, particularly for tree-based ensemble methods. This limitation is addressed and discussed in the experimental results section, where computational efficiency is analyzed alongside classification performance. Overall, HOG offers a strong baseline feature extraction technique for structural crack detection and remains a popular choice in comparative studies involving traditional machine learning and deep learning approaches [8],[18].

II.4 DEEP LEARNING MODELS

Deep learning models were employed in this study to perform end-to-end structural crack detection directly from image data, eliminating the need for handcrafted feature extraction. Two deep learning approaches were considered: a custom Convolutional Neural Network (CNN) and a transfer learning model based on MobileNetV2. These models were selected to represent both a conventional deep learning architecture and a lightweight pretrained network suitable for practical deployment.

II.4.1 Custom Convolutional Neural Network (CNN)

Convolutional Neural Networks (CNNs) are designed to automatically learn hierarchical feature representations from raw image inputs. A CNN typically consists of convolutional layers, pooling layers, and fully connected layers. The convolutional layers extract local spatial features, while deeper layers capture higher-level semantic information relevant to crack patterns. Given an input image$I$, the output feature map $F_k$of the k-th convolutional filter can be expressed in Equation 1.

$$F_k = \sigma(I * W_k + b_k) \tag{1}$$

where $W_k$denotes the convolutional kernel, $b_k$is the bias term, $*$represents the convolution operation, and $\sigma(\cdot)$is a nonlinear activation function, typically the Rectified Linear Unit (ReLU). Pooling layers are applied after convolution to reduce spatial dimensionality and improve translational invariance. Max pooling was used in this study, defined in Equation 2.

$$P(x) = \max_{i \in \Omega} F(i) \tag{2}$$

where Ω denotes the pooling region.

Following a sequence of convolutional and pooling layers, the extracted feature maps are flattened and passed to fully connected layers for classification. The final output layer uses a sigmoid activation function to perform binary classification between crack and no-crack classes as given by Equation 3:

$$\hat{y} = \sigma(w^T z + b) \tag{3}$$

where z represents the flattened feature vector.

The network was trained using the binary cross-entropy loss function given by Equation 4.

$$\mathcal{L} = -\frac{1}{N}\sum_{i=1}^{N}[y_i \log(\hat{y}_i) + (1 - y_i)\log(1 - \hat{y}_i)] \tag{4}$$

To prevent overfitting and reduce unnecessary training epochs, early stopping was applied based on validation loss, and model checkpointing was used to retain the best-performing model during training.

II.4.2 Mobilenet2 With Transfer Learning

To evaluate a computationally efficient deep learning approach, MobileNetV2 was employed using a transfer learning strategy. MobileNetV2 is a lightweight CNN architecture specifically designed for resource-constrained environments, offering a favorable trade-off between accuracy and computational cost. The core building block of MobileNetV2 is the depthwise separable convolution, which decomposes standard convolution into two operations: depthwise convolution and pointwise convolution. This significantly reduces the number of parameters and computational complexity. The depthwise convolution operation can be expressed by Equation 5.

$$F_d = I * W_d \quad (5)$$

where $W_d$is a depthwise convolution kernel applied independently to each input channel. The pointwise convolution then combines the output channels as given by Equation 6.

$$F_p = F_d * W_p \quad (6)$$

where W_p is a 1×1convolution kernel.

In this study, a MobileNetV2 model pretrained on the ImageNet dataset was used as a feature extractor. The original classification layers were replaced with task-specific fully connected layers to adapt the network to the crack detection problem. Only the newly added layers were trained, while the pretrained layers were kept frozen to preserve learned representations and reduce training time. Similar to the custom CNN, early stopping, learning rate reduction, and model checkpointing were employed during training to enhance generalization and stability.

II.4.3 Training Strategy and Computational Considerations

All deep learning models were trained using GPU acceleration proposed by Kaggle platform to accommodate the high computational demands of convolutional operations. Input images were normalized prior to training to improve convergence. Hyperparameters such as batch size and learning rate were selected empirically and kept consistent across experiments. While deep learning models demonstrated strong performance in crack detection, they required higher training time and computational resources compared to traditional machine learning approaches. These aspects are quantitatively analyzed and discussed in the experimental results section.

II.4.4 Summary of Deep Learning Models

The custom CNN provides a baseline deep learning architecture capable of learning crack-related features directly from images, while MobileNetV2 offers a lightweight alternative with reduced computational cost. Together, these models allow for a comprehensive evaluation of deep learning-based crack detection under different performance and efficiency constraints.

III. EXPERIMENTAL RESULTS AND DISCUSSION

III.1PERFORMANCE EVALUATION

The experimental results obtained from the comparative evaluation of machine learning and deep learning models for structural crack detection are summarized in Table 1. All models were evaluated using the same training and testing splits to ensure a fair comparison. Performance was assessed using accuracy, precision, recall, F1-score, specificity, sensitivity, ROC-AUC, and additional reliability metrics including Matthews Correlation Coefficient (MCC) and Cohen's Kappa. Among the traditional machine learning approaches, the Random Forest classifier achieved the highest accuracy of 96.01%, outperforming the linear SVM (94.86%) and KNN (71.64%). The superior performance of Random Forest can be attributed to its ensemble nature, which allows it to model non-linear decision boundaries and reduce overfitting through aggregation. The linear SVM also demonstrated strong performance, indicating that HOG features provide good linear separability for crack detection.

In contrast, the KNN classifier exhibited significantly lower accuracy and F1-score despite achieving extremely high precision (99.94%). This behavior indicates that KNN was highly conservative in predicting the crack class, resulting in poor recall (43.30%) and sensitivity. Such imbalance suggests that KNN is less suitable for large-scale crack detection tasks where comprehensive detection is required. Deep learning models substantially outperformed traditional machine learning approaches. The custom CNN achieved an accuracy of 99.45% with an F1-score of 99.45%, while MobileNetV2 delivered the highest overall performance, achieving 99.85% accuracy and an F1-score of 99.85%. Both deep learning models exhibited near-perfect ROC-AUC values, indicating excellent discriminative capability. To further analyze deep learning behavior during training, training and validation accuracy and loss curves are presented in Figures 2.

Table 1: Performance comparison of machine learning and deep learning models for structural crack detection.

Model	Accuracy (%)	Precision (%)	Recall (%)	F1-score (%)	Specificity (%)	Sensitivity (%)	ROC-AUC (%)	LogLoss	MCC (%)	Kappa (%)	Training Time	Inference Time
SVM	94.86	96.05	93.58	94.8	96.15	93.58	98.43	15.85	89.75	89.72	283.19	50.86
Random Forest	96.01	97.28	94.67	95.96	97.35	94.67	99.34	17.64	92.06	92.03	4711.11	1.06
KNN	71.64	99.94	43.3	60.42	99.98	43.3	88.61	4.37	52.53	43.28	20.57	158.92
CNN	99.45	99.55	99.35	99.45	99.55	99.35	99.97	1.68	98.9	98.9	101.73	2.52
MobileNetV2	99.85	99.75	99.95	99.85	99.75	99.95	100	0.54	99.7	99.7	714.38	18.71

Source: Authors, (2026).

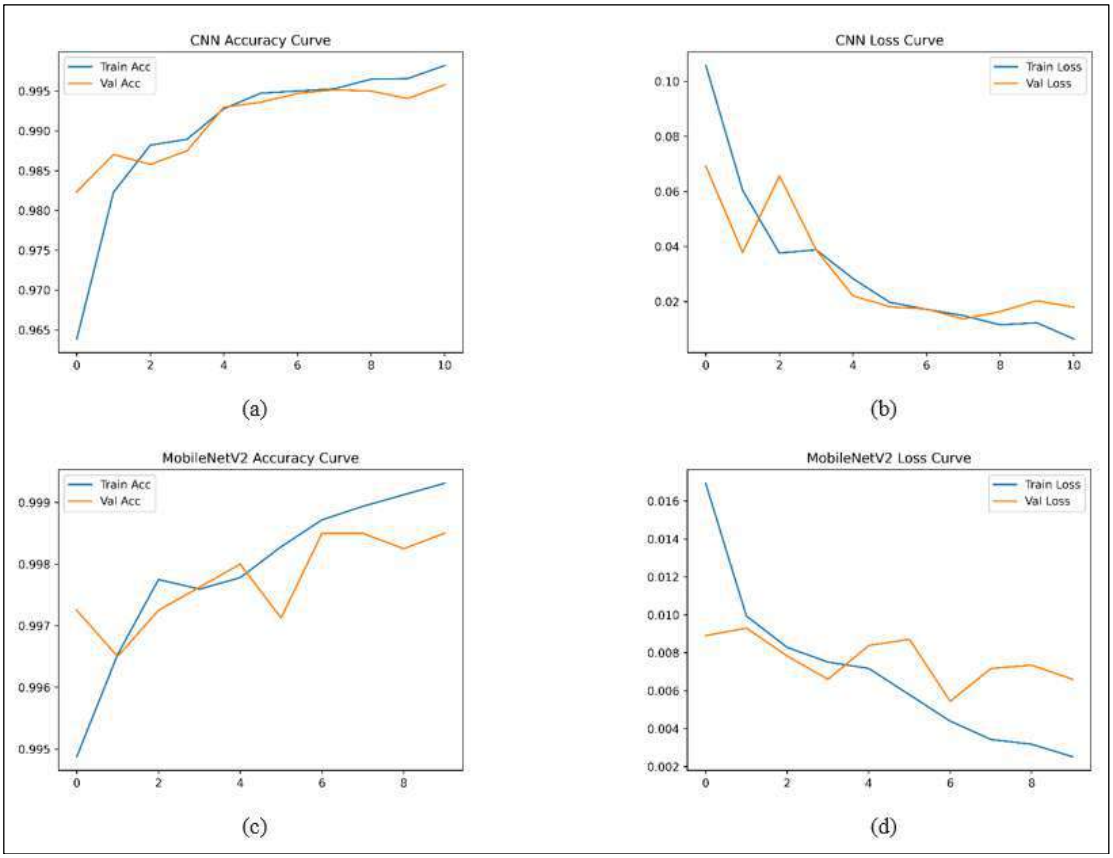

Figure 2: Training and validation accuracy and loss curves of CNN and MobileNetV2.
Source: Authors, (2026).

The accuracy curves show rapid convergence for both models, with close alignment between training and validation performance. This alignment indicates strong generalization and limited overfitting. The loss curves decrease smoothly across epochs and stabilize at low values, confirming effective optimization. MobileNetV2 reaches stable accuracy and loss earlier than the custom CNN and maintains lower validation loss, which supports the superior performance metrics reported in Table 1.

III.2 ANALYSIS OF CLASSIFICATION MERTRICS

Precision and recall provide important insight into model behavior beyond accuracy alone. The stable training behavior observed in Figure2 aligns with the high classification metrics reported in Table 1. The deep learning models achieved a balanced trade-off between precision and recall, with both CNN and MobileNetV2 exceeding 99% in all major metrics. This indicates that these models are capable of reliably detecting cracks while minimizing false positives and false negatives. The Random Forest classifier showed strong precision (97.28%) and recall (94.68%), confirming its robustness among classical approaches.

The SVM classifier also performed consistently, though with slightly reduced recall compared to Random Forest. In contrast, KNN's high precision but low recall highlights its limitation in capturing the full variability of crack patterns in the dataset. The MCC and Cohen's Kappa values further support these observations. Deep learning models achieved near-perfect agreement scores, while Random Forest and SVM demonstrated strong but comparatively lower correlation values. KNN recorded the lowest agreement metrics, reinforcing its weaker classification reliability.

III.3 COMPUTATIONAL EFFICIENCY ANALYSIS

In addition to classification performance, computational efficiency was evaluated by measuring training and inference time for each model. The results reveal a clear trade-off between accuracy and computational cost. Among the classical machine learning models, KNN required negligible training time but suffered from extremely high inference time (approximately 159 seconds) due to its instance-based nature. This makes KNN impractical for real-time crack detection applications. The linear SVM demonstrated moderate training time (approximately 283 seconds) and very fast inference, making it suitable for deployment scenarios where rapid predictions are required.

The Random Forest model, trained on the full dataset, required the longest training time (approximately 78 minutes). This confirms the high computational cost associated with tree-based ensemble methods when applied to high-dimensional handcrafted features. However, its inference time remained low, indicating suitability for offline training and online prediction scenarios. Deep learning models exhibited a different computational profile. The custom CNN achieved fast training (approximately 102 seconds) due to early stopping and efficient architecture design. MobileNetV2, while requiring longer training time (approximately 714 seconds), provided the best balance between performance and efficiency, benefiting from transfer learning and a lightweight architecture. Although deep learning models require GPU acceleration, their inference times remained reasonable, supporting their potential for real-time deployment.

III.4 COMPARATIVE DISCUSSION

The experimental results clearly demonstrate that deep learning approaches outperform traditional machine learning models in terms of classification accuracy and robustness for structural crack detection. The ability of CNN-based models to automatically learn hierarchical feature representations allows them to capture complex crack patterns that handcrafted features may fail to represent adequately. However, traditional machine learning models, particularly SVM and Random Forest, still offer competitive performance with lower hardware requirements and simpler implementation. These models may be preferable in environments where GPU resources are unavailable or limited. Overall, MobileNetV2 emerged as the most effective model, achieving the highest accuracy and balanced performance while maintaining reasonable computational efficiency. This makes it a strong candidate for practical structural health monitoring systems, especially in scenarios requiring high accuracy and efficient deployment.

III.5 KEYS OBSERVATIONS

The following observations can be drawn from the experimental study:

- Deep learning models significantly outperform traditional machine learning models in crack detection accuracy.
- Random Forest provides the best performance among classical machine learning approaches but at high computational cost.
- KNN is not suitable for large-scale crack detection due to poor recall and slow inference.
- MobileNetV2 offers the best trade-off between accuracy and efficiency, making it suitable for real-world applications.

IV. CONCLUSION AND FUTURE WORKS

IV.1 CONCLUSION

This study presented a comprehensive comparative analysis of traditional machine learning and deep learning models for structural crack detection using image processing techniques. Handcrafted feature-based classifiers, including Support Vector Machine (SVM), Random Forest (RF), and K-Nearest Neighbors (KNN), were evaluated alongside deep learning approaches based on a custom Convolutional Neural Network (CNN) and a transfer learning model using MobileNetV2. Experimental results demonstrated that deep learning models significantly outperform traditional machine learning approaches in terms of classification accuracy and robustness. Among all evaluated models, MobileNetV2 achieved the highest performance, attaining near-perfect accuracy and balanced precision–recall characteristics, while maintaining reasonable computational efficiency through its lightweight architecture.

The custom CNN also delivered strong results, confirming the effectiveness of end-to-end learning for crack detection tasks. Among the classical machine learning models, Random Forest achieved the best performance but required substantially higher training time due to the high dimensionality of handcrafted HOG features. The linear SVM provided competitive accuracy with lower computational cost, while KNN showed limitations in scalability and recall performance, making it less suitable for large-scale crack detection applications. Overall, the findings highlight the trade-off between accuracy and computational efficiency across different modeling approaches. While deep learning models are preferable when high accuracy is required and GPU resources are available, traditional machine learning methods remain viable alternatives in resource-constrained environments.

IV.2 FUTURE WORKS

Although the proposed study provides valuable insights into crack detection performance across multiple modeling paradigms, several directions for future research can be explored. First, extending the analysis to include crack segmentation rather than binary classification would provide more detailed structural damage information. Second, evaluating model performance under varying environmental conditions, such as illumination changes and surface noise, would further assess robustness in real-world scenarios. Future work may also investigate hybrid approaches that combine handcrafted features with deep learning representations to balance interpretability and performance. Additionally, deploying lightweight deep learning models on edge devices or embedded systems could facilitate real-time structural health monitoring in practical applications. Finally, testing the proposed framework on additional datasets and real inspection data would enhance generalization and support broader adoption.

ABSTRACT

In the present study, we introduce an innovative photonic crystal architecture meticulously engineered for biomedical applications, particularly optimized for biosensing functionalities. Our study focuses on meeting the increasing demand for quick, reliable, and easy-to-use detection methods in medical diagnostics. The proposed architecture employs a hexagonal arrangement integrated with two waveguides for signal input and output, which is further augmented by the inclusion of a pill-shaped resonator to enhance sensitivity. The design enables strong confinement of the electromagnetic field and improves interaction with the analyte. The simulations were performed using the Finite-Difference Time-Domain (FDTD) method over a wavelength range of 1.6 to 1.95 micrometers (µm). The findings indicate that the biosensor is capable of attaining a peak sensitivity of 571 nanometers per refractive index unit (nm/RIU), thereby underscoring its significant potential for detecting subtle alterations in biological specimens and contributing to the advancement of medical diagnostics. Such sensitivity levels demonstrate the effectiveness of the proposed structure in identifying biomolecular interactions and refractive index variations typically associated with various types of cancer cells and other biological conditions.

I. INTRODUCTION

Photonic crystal biosensors have emerged as a promising platform in the field of optical sensing due to their high sensitivity, label-free detection capabilities, and potential for miniaturization [1]. These biosensors exploit the distinctive optical characteristics inherent to photonic crystals, which are composed of periodically arranged dielectric materials that govern light propagation [2]. By merging biomolecular interactions within these constructs, photonic crystal biosensors are equipped to perceive minute changes in the refractive index, thus allowing for the accurate detection of a diverse collection of biological entities including proteins, hormones, enzymes, viruses, nucleic acids, and pathogens [1],[3]. In recent decades, the evolution of all-optical devices has emerged as a pivotal trend within contemporary photonics, propelled by the demand for expedited, more efficient, and scalable systems for data processing and telecommunication.

Central to these breakthroughs are photonic crystals, wich play a critical role in these advancements, offering versatile functionalities beyond biosensing [4].photonic crystal structures have been utilized as filters [5],[6], decoders [7],[8], logic gates [9] and sensors [10],[11]. In the realm of biosensing, photonic crystal sensors have demonstrated remarkable success in medical diagnostics, detecting biomarkers for diseases such as canser [12], blood sugar [13] and temperature [14]. This paper will explore a new crystal photonic sensor that could be used as a cancer sensor, The finite difference time domain (FDTD) method was used to simulate the proposed designs and to investigate numerical results. The rest of the paper is structured as follows: In section II, the structure design is presented. Section III is reserved to the results and analysis followed by the application examples, comparison result, and validation in section IV. Finally, conclusion and perspectives are shown in Section V.

II. STRUCTURE DESIGN

The proposed biosensor is composed of 2D triangular lattices, with the size of the PhC structure measuring 21 x 19. The lattice constant (a) is set at 0.47 μm, and the radius of the air holes (r) is 0.19μm. The refractive index of the silicon slab is n_{si} = 3.45. In the initial design, the biosensor features two waveguides, created by removing a single row of air holes along the ΓK direction. A hexagonal cavity is placed at the center of the biosensor on both sides to maximize output transmission. This cavity is formed by eliminating eight holes on the left and right sides in the 10_{th} row, and seven holes in the center, shaping a hexagonal structure as depicted in Figure 1(a). To analyze the proposed biosensor, 2D Plane Wave Expansion (2D-PWE) and Finite-Difference Time-Domain (FDTD) methods were utilized. The photonic bandgap (PBG) of the designed photonic crystal (PhC) structure, without any defects, ranges from ω_1 = 0.2501 (a/λ) to ω_2 = 0.41325 (a/λ), covering a significant bandgap in the wavelength range of 1.1373 μm to 1.8792 μm for a TM-polarized wave. This was calculated using the 2D-PWE method in BandSolve software as shown in Figure 1(b).

III. RESULTS AND ANALYSIS

It is well-known that introducing defects into the periodic lattice structure of a PhC disrupts the regularity of its dielectric function. Thus, the waveguide 1and 2 obtained by omitting a row of air holes in the photonic lattice in the ΓK direction is shown in Figure 1(a). These defects allow for the formation of guided modes, with frequencies falling within the PBG range [15]. In this biosensor, we excited the cavity's resonant modes by applying a Gaussian pulse of about 3,6 μm through the waveguide's input. To ascertain the sensitivity of the suggested biosensor, a power monitor was also installed at the end of the waveguide to track the trapped mode [16]. In Figure 2, the biosensor's transmission spectra is represented across three diverse refractive indices (n =1, n =1.025, n=1.05), with a uniform difference of 0.025 between successive values. The results indicate that as the refractive index of the ambient medium is elevated, the resonance wavelength (λ_{res}) experiences a corresponding shift. Figure 3 (a)(b) illustrates the propagation of light through the cavity structure within the XZ plane. It becomes evident from this representation that the electromagnetic field is significantly confined within the hexagonal cavity, thereby rendering the system exceedingly sensitive to variations in refractive index due to the pronounced interaction between light and matter. Figure 4 shows the linearity relationship between the resonance wavelengths and the refractive indices for the first and second mode. Sensitivity (S) constitutes a critical factor in the design and evaluation of refractive index (RI) sensors predicated upon photonic crystal structures; it can be quantitatively expressed as $S = \Delta\lambda / \Delta n$ (nanometers per refractive index unit (nm/RIU)), wherein $\Delta\lambda$ signifies the variation in the peak resonance wavelength of the transmittance spectrum, while Δn indicates the alteration in the refractive index within the photonic sensor framework.

By maintaining all other parameters constant and incrementally augmenting the refractive index from n = 1 to n = 1.05, the sensitivity for the first mode approximates 132 nm/RIU, whereas for the second mode, it is approximately 182 nm / RIU.

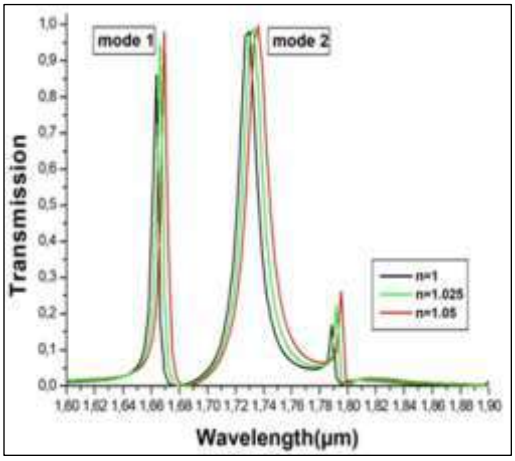

Figure 2: Transmission spectrum of the first proposed design as function of wavelength for different refractive indices.
Source: Authors, (2026).

In the second design and In order to improve the performance of our biosensor and increase its ability to detect small analyte concentrations and variations in the latter, we introduce the second iteration of a CPh biosensor predicated upon a hexagonal cavity integrated with a capsule. The aforementioned configuration provides a significant enhancement in both sensitivity and quality factor. The rationale for employing a capsule-shaped cavity characterized by an increased dimension is to promote the infiltration process, amplify light-matter interaction, and mitigate losses within the structural framework. Figure 5(a), shows that the capsule-shaped cavity is deliberately positioned in the middle part of the second proposed biosensor, with the capsule length L measured at 140 nm and the capsule radius R recorded at 190 nm. Figure 5(b) shows the transmission spectrum corresponding to a refractive index of n = 1 and the magnetic field distribution calculated using the FDTD method of the Fullwave software for the second proposed biosensor. As seen in Figure 5(b), when the cavity is in resonance, two sharp Lorentzian-shaped peaks appear inside the BIP at resonance wavelengths of 1.6566 μm for mode 1 and 1.8092 μm for mode 2.

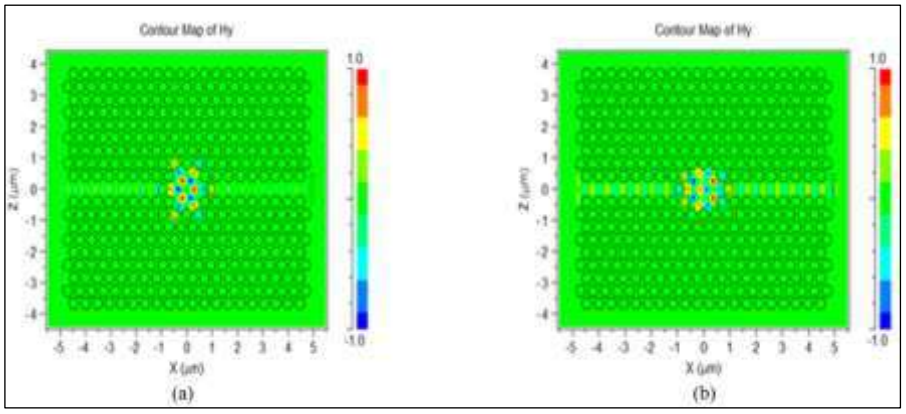

Figure 3: (a) Magnetic-fled patterns with hexagonal cavity at λ_1(mode 1) =1.6637 μm (b) λ_2(mode 2) =1.7274 μm..
Source: Authors, (2026).

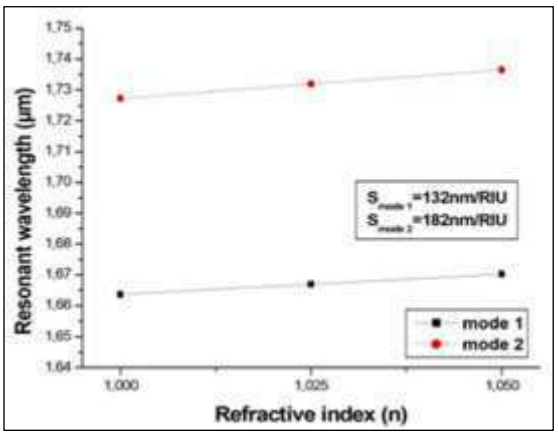

Figure 4: The resonance wavelength versus the refractive index n of the material under sensing.
Source: Authors, (2026).

The propagation characteristics of light within the cavity configuration, specifically in the (XZ) plane, are illustrated in Figures 6(a) and (b). Within this representation, it is distinctly observable that the electromagnetic field is significantly confined within the cavity region, exhibiting a greater intensity compared to the initial structure. This phenomenon renders the cavity exceptionally responsive to fluctuations in the refractive index, attributable to the pronounced light-matter interaction. The biosensor's transmission spectra are portrayed in Figure 7, showcasing three unique refractive indices (n =1, n =1.025, n =1.05) with a gradual increment of 0.025. It is observable that the variations in the resonance wavelength λ_{res} correspondingly amplify with the enhancement of the refractive index within the medium. The sensitivity associated with mode 1 approximates 256 nm/RIU, while mode 2 demonstrates a sensitivity of approximately 418 nm/RIU. It is crucial to acknowledge that the second design has a distinctly greater sensitivity than the first design. This enhancement is anticipated to be particularly relevant for biosensor applications where, for instance, biochemical reactions are monitored by detecting minimal fluctuations in refractive index within reaction environments. Figure 8 illustrates how the resonance wavelengths change in a linear pattern with the refractive indices for both the first and second modes. Furthermore, we will calculate and optimize the design's transmission and sensitivity by modifying the geometrical properties. First, the capsule length L is investigated. The value of L fluctuates from 100 to 260 nm at 40 nm intervals, while the other parameters stay constants at R = 190nm and r = 190nm.

Afterward, a rigorous review was undertaken to understand how structural aspects contribute to defining an optimal layout for the biosensor. The impact of the capsule length L is depicted in Figure 9(a), where in an increment in the value of L from 100 to 260 nm, in 40 nm intervals, correlates with a shift in the resonance wavelength. Figure 9(b) reveals that the relationship between sensitivity and the value of L exhibits a nearly linear correlation, with the optimal sensitivity attained at L = 220 nm. Furthermore, by raising the value of L, the sensitivity of the sensor can be increased. For example, in mode 1, the sensitivity is 343 nm/RIU; in mode 2, on the other hand, the sensitivity is 571 nm/RIU, which corresponds to a value of L = 220 nm; this is in contrast to the sensitivity of 210 nm/RIU in mode 1 and 312 nm/RIU in mode 2, where the value of L was 100 nm. Next, we examined how various R values affected the characteristics of the PhC refractive index sensor. L is fixed at 220 nm, which is the best value already obtained, for the upcoming analysis. The transmission spectra of index 1 are displayed in Figure 10(a) for values of R ranging from 150 to 210 nm in steps of 20 nm; a higher value of R corresponds to a longer resonance wavelength. Figure 10(b) illustrates that the relationship between sensitivity and value R is nearly linear, with the highest sensitivity being attained at L = 190 nm. Additionally, we can attain a higher sensitivity of the sensor by elevating the resistance value R for mode 1 to achieve 228 nm/RIU, while mode 2 shows a sensitivity of 371 nm/RIU due to R being equal to 190 nm; this is compared to the sensitivity statistics of 343 nm/RIU for mode 1 alongside 571 nm/RIU for mode 2 with a resistance value retained at 190 nm. Table 1 compares the sensitivity (S) for different reported photonic crystal sensors in literatures with ours.

IV. APPLICATION EXAMPLE: CANCER SENSOR

As an illustration of how to use the most recent optimized structure (Fig. 5 (a), with r = 190 nm and T = 220 nm), we will investigate the cancer sensor. When cancerous cells start to proliferate in the human body, the specific cancerous cellule's index of refraction (RI) becomes apparent [1]. The normal basal cells have a refractive index of 1.36, as cancerous cells start to proliferate within them, their index rises to 1.38. In Table 2, we have certain types of cancer and their RI "Jurkat (blood cancer), PC12 (adrenal gland cancer), and MCF-7 (breast cancer - type 2)" for healthy and affected cells [20],[21].

Table 2: Certain types of cancer and their RI.

Cell Name	Cell Type with Density Level	RI
Jurkat	Normal cell (30–70%) Cancerous (80%)T-shaped	1.376 1.390
PC12	Normal cell (30–70%) Cancerous (80%)	1.381 1.395
MCF-7	Normal cell (30–70%) Cancerous (80%)	1.387 1.401

Source: Authors, (2026).

The optimized biosensor's transmission, computed with 2D FDTD, is displayed in Figure 11. Curves for the refractive indices of the holes (n = 1.36, 1.39, 1.395, and 1.401) corresponding to several cancer cell types are obtained. (Jurkat, normal cell, PC12, MCF-7).They show how, when the holes' refractive index rises, the resonant peak moves towards longer wavelengths. It is well seen in Figure 12 that the refractive index changes versus the resonance wavelength for the first and the second mode are linear and the values of the sensitivity were optimized from 132 nm/RIU to 311 nm/RIU for the first mode and from 182 nm/RIU to 557 nm/RIU for the second mode highlighting the use of the capsule-shaped cavity positioned inside the hexagonal microcavity wish gives a much better sensitivities. For Jurkat types, the resonant peak in mode 1 shifts by 9.24 nm for $\Delta n=0.03$, so the sensor sensitivity can reach Smode1 = 308 nm/RIU. In mode 2, the shift is 16.5 nm for $\Delta n=0.03$, resulting in a sensor sensitivity of Smode2 = 550 nm/RIU, and the transmission exceeds 95% in both modes. The sensitivity results of the optimized biosensor for different types of cancer cells are presented in Table 3.

Table 3: Sensitivity of the optimized biosensor for different types of cancer cells.

Cell Name	RI	Sensitivity (nm/RIU)Mode1	Sensitivity (nm/RIU)Mode2
Normal cell	1.36	/	/
Jurkat	1.39	308	550
PC12	1.395	313	562
MCF-7	1.401	311	559

V. CONCLUSION

We present in this work, a new crystal photonic structure that used as a cancer sensor, the simulated result investigated using FDTD method and was assessed with comparaison to other recent published works, our work has the highest sensitivity level reaching 571 nm/RIU; this design simplicity and compact size have a great potential to be used in all optical devices. As future work we will focus on the optimization pf a design parameters in order to enhance sensitivity, quality factor, and also extending the detection of multiple cancer biomarkers in the sensor.

ABSTRACT

This study presents an experimental investigation into the compressive behaviour of components fabricated by Fused Deposition Modelling (FDM) using polylactic acid (PLA) and acrylonitrile butadiene styrene (ABS). The mechanical performance of FDM-printed parts is strongly influenced by internal infill architecture; however, limited experimental data exist comparing compressive responses under identical processing conditions. To address this gap, cube specimens with dimensions of 50 × 50 × 50 mm were designed and manufactured using ten different infill patterns at a constant infill density of 40% and a layer height of 0.2 mm. All samples were printed using the same printer and slicing parameters to ensure consistency. Compression tests were conducted using a Universal Testing Machine to evaluate load–crosshead travel behaviour and compressive strength. The results demonstrate a significant dependence of compressive performance on infill geometry for both materials. For PLA specimens, the grid infill pattern exhibited the highest compressive strength, followed by trihexagon and triangle patterns. In contrast, ABS specimens achieved maximum compressive strength with the trihexagon infill, while cubic and gyroid patterns also showed favourable performance. Simple infill geometries such as concentric and line patterns consistently resulted in lower compressive strength for both materials. Overall, PLA samples exhibited higher compressive strength than ABS under identical printing conditions, whereas ABS showed greater deformation prior to failure, indicating a more ductile compressive response. The findings confirm that infill architecture plays a critical role in determining the compressive behaviour of FDM-printed components and provide practical guidelines for selecting suitable infill patterns in load-bearing applications.

I. INTRODUCTION

Additive manufacturing also referred to as 3D printing is an approach to manufacturing whereby parts are built in layers through directly fabricating a computer-generated image. The technology has acquired a large significance because of its ability to create complicated forms, minimize waste of materials and quick prototyping, personalized manufacturing, and quick product development. In contrast to traditional subtractive manufacturing, additive manufacturing only forms material where it is needed and therefore is an efficient and flexible process of making complex parts with reduced lead times and tooling needs. Therefore, engineering, medical, automotive, aerospace, and consumer product applications of 3D printing have been widespread in the engineering field, medical field, automotive field, aerospace field, and consumer product industry [1],[2].Of the several additive manufacturing process Fused Deposition Modelling (FDM) is one of the most popular process due to its simplicity, low cost, and compatibility with a vast variety of thermoplastic substances.

A FDM process is done by feeding a continuous strand of a thermoplastic material into a heating nozzle where it melts and is squirted onto a build platform in a pattern. The molten material is immediately solidified upon deposition and another layer is deposed on top of the previous one until a three dimensional object is formed. Computer-aided manufacturing software manages the whole process transforming the digital model into machine-readable instructions to fabricate the part layer by layer [3],[4]. Among the most popular materials used in FDM printing are Polylactic Acid (PLA) and Acrylonitrile Butadiene Styrene (ABS) that have appropriate mechanical characteristics, can be easily obtained, and have numerous applications. PLA is a renewable based biodegradable thermoplastic, which is commonly used in rapid prototyping and low-load applications due to its good dimensional stability and easy printing. ABS, in turn, is a thermoplastic that is made of petroleum, is tough, has a greater impact strength, and has better resistance to higher temperatures than PLA.

The materials are usually used in the production of functional parts, housings, fixtures, and mechanical parts with the FDM process [3],[4]. A number of internal and external process parameters are very sensitive in determining the mechanical behaviour of FDM-printed components. The infill density, infill pattern, raster orientation, the layer thickness, printing speed and extrusion temperature are some of the parameters that influence the strength, stiffness, and deformation behaviour of the printed parts. One of the critical parameters that determine the mechanical performance is the infill structure among many others. The internal geometry of the printed part is also defined by the infill pattern which defines how the loads are distributed in the entire structure when the part is exposed to external forces. The various infill patterns also give different load paths and stress distributions which directly influence the compressive and tensile properties as well as the impact properties of the component [5],[6]. The effect of infill pattern and density on the mechanical properties of FDM-printed components has been studied by a number of researchers. It has been stated that the tendency of increasing the infill density tends to enhance the strength and stiffness, and the infill pattern may strongly change the deformation behaviour and failure of the printed structures. Some patterns, including grid, triangular, cubic, gyroid and trihexagonal structure have varying mechanical behaviors to compressive loading and tensile loading.

Consequently, it is necessary to choose an appropriate infill structure to maximize the mechanical behavior of components fabricated by FDM to certain engineering applications [5],[6]. Although the literature on the mechanical behaviour of FDM-printed polymers continues to expand, not much is known regarding the compressive behaviour of various infill structures that were produced at the same conditions of processing. To have a deeper insight into the impact of infill geometry on compressive strength and deformation behaviour, a systematic experimental study is needed especially in the case of widely used material like PLA and ABS. The aim of the current work is to experimentally test compressive behaviour of FDM-printed PLA and ABS specimens printed at the same infill density and layer height using various infill structures. The research problem will be to determine what infill pattern gives the best compressive strength to each material and to determine the mechanical performance of PLA and ABS made under the same printing conditions. The outcomes of this study should offer some useful guidelines on the choice of the appropriate infill structure when designing load-bearing FDM-printed components.

II. LITERATURE REVIEW

The mechanical behaviour of the polymers produced through Fused Deposition Modelling (FDM) process has been studied in a number of studies. In [7], the authors compared the physical and mechanical properties of PLA, ABS, and nylon 6 made with the help of FDM and injection moulding. Their contribution accentuated the effect of manufacturing process on the performance of the material and demonstrated that FDM-produced components have varied mechanical properties as compared to those produced in a conventional manufacturing process. According to [8],[9] examined how the tensile and dynamic mechanical property of a PLA material is influenced by the parameters of FDM processes. Through their experimental study, they proved that printing parameters, e.g., layer thickness and raster orientation, have great effects on the mechanical response of printed parts. In [10] explored anisotropy properties of 3D printed PLA and ABS and found out that the orientation of the prints had significant influence on tensile behaviour and failure properties of the materials.

According to [11] also studied the impact of specimen thickness on mechanical behaviour of PLA made through FDM and discovered that the stronger tensile strength occurred in thicker specimens. For [5] have created mechanical models to estimate tensile strength and elasticities of FDM-printed PLA, with the focus on the effect of printing orientation and thickness of the layer on material behaviour. In [12],[13] examined how the type and density of infills determine the tensile strength of PLA and found that the higher the infill density, the higher the strength of all infill patterns. In [14],[15], the mechanical properties of FDM-printed PLA parts prior to and following thermal treatment were studied and it was found that heat treatment can alter the mechanical response of printed parts. According to [16, 17] have examined the effect of printing parameters including infill shape, orientation, and raster angle on mechanical properties of plastic parts made with the help of FDM technology. Based on [9] experimented the tensile behaviour of multi-polymer sandwich structures that were designed using FDM and showed that which material combination was used greatly influenced the mechanical behaviour.

According to [18-20] investigated the effect of slicing parameters to determine the quality of surface and mechanical properties of the CF/PLA composite developed by FDM. The influence of raster orientation, infill rate, and infill pattern on the mechanical properties of FDM-printed components was studied by [11] and it was found that the higher the rate of infill, the higher the stiffness and strength of the part. Based on [12] examined effect of infill pattern and infill density on the impact strength of PLA parts and determined that infill pattern of zigzag and concentric gives superior impact resistance. The effect of the parameters of FDM process on tensile properties of ULTEM 9085 was investigated by [13] with a dominant influence of raster angle on tensile strength. Based on [15],[17] examined mechanical behaviour of honeycomb sandwich structure made by FDM and showed that internal geometry plays a significant role on compressive and flexural behaviour. According to [18] determined the impact of raster angles on the mechanical properties of the FDM-printed parts and found out better strength when the raster angle was 45 plus or minus. In [19] suggested a process of forecasting the final tensile strength of FDM-printed PLA at varying printing orientations, whereas by [20] examined the mechanical behaviour of PLA-graphene filaments to be used in FDM.

Despite the fact that tensile, flexural, and impact behaviour of FDM-printed parts have received a lot of work, little experimental evidence exists on compressive behaviour of PLA and ABS structures printed using various infill patterns with the same processing conditions. The proposed work will fill this gap by experimentally testing the compressive behavior of different infill structures made through the FDM process.

III. MATERIALS AND METHODS

III.1 MATERIALS

The two materials that will be utilized in this research are Polylactic Acid (PLA) and Acrylonitrile Butadiene Styrene (ABS). PLA is a renewable thermoplastic biodegradable material and is commonly available in FDM printing because of its processing and dimensional characteristics. ABS is a thermoplastic made of petroleum, which is tough, resistant to impact and capable of withstanding higher temperatures hence suitable in functional and load bearing applications. The samples were cube-shaped specimens which had been manufactured deliberately to be used in compression testing through the Fused Deposition Modelling (FDM) process. Each of the samples was a solid cube with 50 mm x 50 mm x 50 mm dimensions constructed in SolidWorks 2019 and printed by X-MAX WOL 3D printer. There were two types of thermoplastics Polylactic Acid (PLA) and Acrylonitrile Butadiene Styrene (ABS). All the samples were printed by the same parameters to be comparable with the same infill density of 40 percent and layer height of 0.2 mm, with QIDI TECH V5.5.2 slicing software. The structure that defined the samples was the infill structure, and ten types were regarded, which included concentric, lines, grid, cubic, cubic subdivision, gyroid, triangle, trihexagon, octet, and cross 3D. In the case of each material, a single specimen was fabricated of each infill pattern, and it produced 10 PLA samples and 10 ABS samples, and altogether 20 samples. These were compression tested using a Universal Testing Machine (UTM) in order to test the behavior of load-crosshead travel and compressive strength.

III.2 EQUIPMENT

The construction of specimens was performed with the help of X-MAX WOL 3D printer that uses Fused Deposition Modelling technology.

Figure 1: X-MAX WOL 3D Printer.

III.3 SPECIMEN DESIGN AND MANUFACTURING

III.3.1 Specimen Modelling

The design of a cube specimen was done through SolidWorks 2019 software with a dimension of 50 mm by 50 mm by 50 mm. The sketch and boss-extrude feature was used to create the model and send it in STL format to slice.

III.3.2 Slicing Parameters

QIDI TECH V5.5.2 slicing software was used to slice the STL file. All specimens were kept at a constant infill density of 40% and at a constant height of layer of 0.2 mm. Patterns of infills that were taken into account in the current paper included concentric, lines, grid, cubic, cubic subdivision, gyroid, triangle, trihexagon, octet, and cross 3D.

III.3.3 Printing Process

The cuts in the models were transformed into G-code files and sent to the X-MAX WOL 3D printer. The specimens were made via FDM process under the same printing conditions of the PLA material and the ABS material.

Figure 3: Lines Pattern, Concentric Pattern, Grid Pattern.

Table 2: Printing Parameters of ABS.

MATERIAL	INFILL STRUCTURE	PRINTING TIME	WEIGHT IN GRAMS(g)
ABS	Concentric	6h 38 min	62.1g
ABS	Gyroid	8h 05min	66.8g
ABS	Grid	6h 50 min	64.6g
ABS	Lines	6h 58 min	64.9g
ABS	Cubic	6h 55 min	65.3g
ABS	Cubic Subdivision	6h 18 min	48.5g
ABS	Triangle	6h 49 min	65g
ABS	Trihexagonal	6h 52 min	64.7g
ABS	Octet	6h 45 min	65.2g
ABS	Cross 3D	7h 42 min	54.1g

Source: Authors, (2026).

III.3.4 Compression Test Procedure

A Universal Testing machine was used to carry out compression tests. The specimens were put between two compression platens and a compressive load was exerted on the specimen at a steadily increasing compressive load until a failure occurred. Each specimen was loaded and cross head travel (CHT) to determine compressive strength and deformation behaviour was measured.

IV. RESULTS AND DISCUSSIONS

The compressive behaviour of FDM-printed PLA and ABS specimens was evaluated under identical processing and testing conditions to investigate the influence of infill architecture on mechanical performance. Load–crosshead travel responses and compressive strength values obtained from the compression tests are presented and analyzed for both materials.

IV.1 COMPRESSIVE BEHAVIOUR OF PLA SPECIMENS

The load–crosshead travel responses of PLA specimens exhibited noticeable variation depending on the infill pattern used. Infill structures with interconnected and multidirectional geometries generally demonstrated higher load-bearing capacity and improved resistance to compressive deformation compared to simpler geometries.

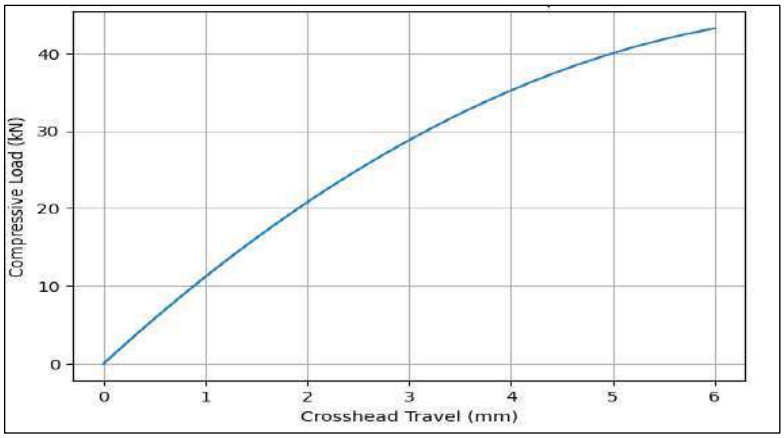

Figure 4: Load versus Crosshead Travel Curve for PLA Specimen with Grid Infill Pattern.
Source: Authors, (2026).

The Figure 4 demonstrates a progressive increase in compressive load with increasing crosshead travel until the maximum load is attained. This behavior indicates gradual deformation of the internal grid structure prior to failure. The high peak load observed confirms that the grid infill provides effective load distribution and structural stability under compressive loading.

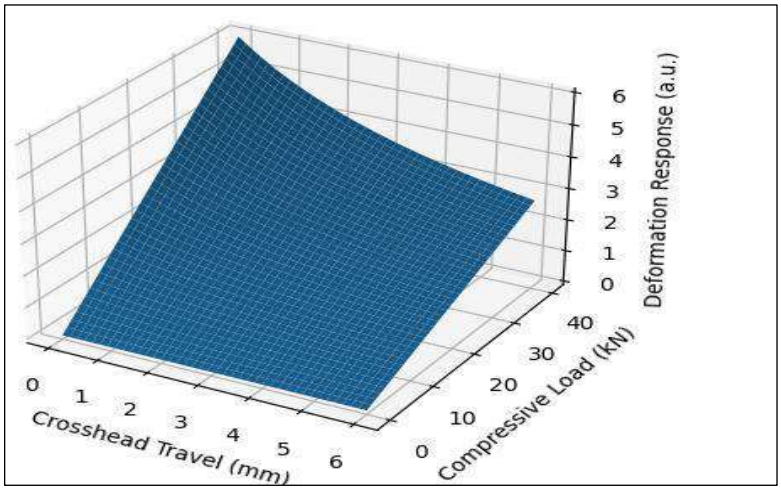

Figure 5: Load versus Crosshead Travel Curve for PLA Specimen with Line Infill Pattern.
Source: Authors, (2026).

The Figure 5 demonstrates a lower peak load accompanied by larger deformation when compared to the grid infill pattern. The predominantly one-directional internal structure of the line infill limits its ability to resist compressive stresses, resulting in reduced compressive strength and earlier onset of failure. The quantitative results obtained from the compression tests of all PLA specimens are summarized in Table 1. The data reveal a strong dependence of compressive strength on infill geometry.

Table 4: Compression Test Results of PLA Specimens with Different Infill Patterns.

Infill Pattern	Load (kN)	Compressive Strength (MPa)
Concentric	15.15	4.87
Cross 3D	35.25	13.56
Cubic Subdivision	18.48	8.64
Cubic	35.79	10.33
Grid	67.50	23.66
Lines	50.88	14.68
Octet	47.40	16.91
Gyroid	36.90	11.49
Triangle	65.01	19.33
Trihexagon	62.97	22.07

Source: Authors, (2026).

The table demonstrates that the grid infill pattern exhibits the highest compressive strength among the tested PLA specimens, followed by trihexagon and triangle infill structures. In contrast, the concentric infill pattern shows the lowest compressive strength. These findings highlight the importance of complex and interconnected internal geometries in enhancing compressive resistance of PLA components fabricated using FDM.

IV.2 COMPRESSIVE BEHAVIOUR OF ABS SPECIMENS

Similar to PLA, the compressive response of ABS specimens was significantly influenced by the infill architecture. However, ABS specimens generally showed lower peak compressive strength and greater deformation prior to failure, indicating a more ductile compressive behavior.

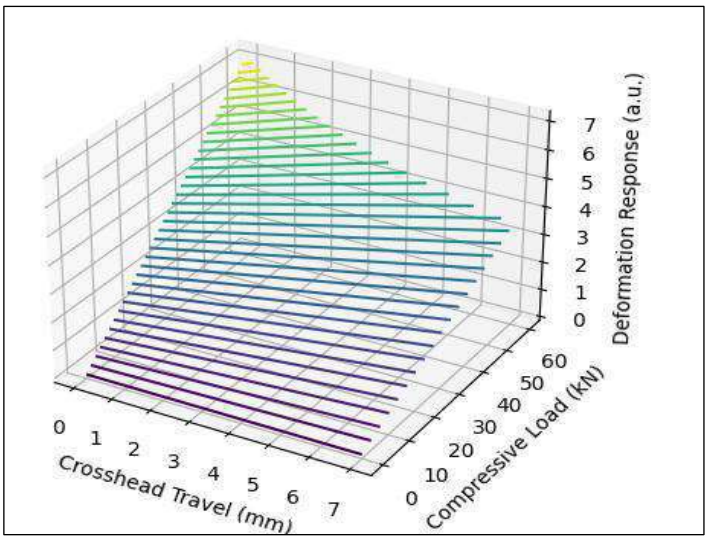

Figure 6: Load versus Crosshead Travel Curve for ABS Specimen with Trihexagon Infill Pattern.
Source: Authors, (2026).

The figure demonstrates a gradual increase in load with increasing crosshead travel until the peak load is reached. The smooth load–displacement curve suggests uniform deformation of the internal trihexagon structure. The high peak load achieved indicates that the trihexagon infill geometry effectively distributes compressive stresses and provides enhanced structural integrity for ABS specimens. The compressive strength values and peak load data for all ABS specimens are presented in Table 5.

Table 5: Compression Test Results of ABS Specimens with Different Infill Patterns.

Infill Pattern	Peak Load (kN)	Compressive Strength (MPa)
Concentric	12.33	4.48
Cubic Subdivision	18.00	8.22
Cubic	32.79	10.91
Grid	21.06	7.01
Gyroid	32.01	10.47
Lines	32.67	10.87
Octet	28.14	8.12
Triangle	25.80	7.34
Trihexagon	59.34	21.97

Source: Authors, (2026).

The table demonstrates that the trihexagon infill pattern yields the highest compressive strength among the ABS specimens, followed by cubic and gyroid infill structures. The concentric infill pattern exhibits the lowest compressive strength, reflecting its limited load-bearing capability. These results confirm that more complex infill geometries improve compressive performance in ABS materials.

IV.3 COMPARATIVE ANALYSIS OF PLA AND ABS

A comparative evaluation of PLA and ABS specimens printed with identical infill patterns shows clear material-dependent differences in compressive behavior.

Table 6: Comparative Compressive Strength of PLA and ABS Specimens with Identical Infill Patterns.

Infill Pattern	PLA Compressive Strength (MPa)	ABS Compressive Strength (MPa)
Concentric	4.87	4.48
Cubic	10.33	10.91
Grid	23.66	7.01
Gyroid	11.49	10.47
Lines	14.68	10.87
Triangle	19.33	7.34
Trihexagon	22.07	21.97

Source: Authors, (2026).

The table demonstrates that PLA specimens generally exhibit higher compressive strength than ABS specimens under the same printing and testing conditions. This behavior can be attributed to the higher stiffness of PLA. Conversely, ABS specimens show greater deformation before failure, indicating improved ductility under compressive loading. These observations emphasize that both material selection and infill architecture must be considered when designing load-bearing FDM-printed components.

V. CONCLUSIONS

This study experimentally investigated the compressive behaviour of FDM-printed PLA and ABS components manufactured using different infill architectures under identical processing conditions. All specimens were fabricated with a constant infill density of 40% and a layer height of 0.2 mm, allowing a direct comparison of the influence of infill geometry on compressive performance. The results demonstrate that infill architecture has a significant effect on the compressive strength and deformation behaviour of both materials. For PLA specimens, the grid infill pattern exhibited the highest compressive strength, followed by trihexagon and triangle infill structures, while the concentric infill pattern showed the lowest compressive resistance. In the case of ABS specimens, the trihexagon infill pattern achieved the maximum compressive strength, with cubic and gyroid infill patterns also providing relatively good performance. A comparative assessment revealed that PLA generally exhibited higher compressive strength than ABS when printed with identical infill patterns and process parameters. However, ABS specimens showed greater deformation prior to failure, indicating a more ductile response under compressive loading. These differences are attributed to the inherent material characteristics of PLA and ABS. Overall, the findings confirm that both material selection and infill architecture play a critical role ins in determining the compressive performance of FDM-printed components. The results provide practical guidance for selecting appropriate infill patterns when designing load-bearing parts using the FDM process.

ABSTRACT

This study presents the modeling and intelligent control of a 3D industrial crane, an academic prototype that closely replicates the dynamics of real-world gantry cranes used in industrial and port operations. The main objective is to minimize load sway and achieve precise positioning along the three spatial axes, thereby enhancing safety and operational efficiency. The theoretical framework is based on advanced intelligent control techniques, specifically Fuzzy Logic Control (FLC) and Adaptive Neuro-Fuzzy Inference System (ANFIS), which combine heuristic knowledge and adaptive learning to address the nonlinear, multi-input multi-output nature of the crane system. The crane dynamics were modeled using Newtonian mechanics, with system equations implemented in MATLAB/Simulink. Separate controllers for each axis were designed, tested, and compared through simulations. The results show that FLC delivers effective disturbance rejection and stable recovery, while ANFIS achieves faster transient responses and superior vertical-axis performance, albeit with limitations in horizontal motion control due to training data quality. Robustness tests confirmed the superior disturbance tolerance of FLC.

I. INTRODUCTION

Industrial lifting is a handling activity that consists of lifting, moving, or handling heavy loads, primarily using mobile cranes, but also crane arms, forklifts, aerial work platforms, winches, or even helicopters. Equipment such as cranes, overhead cranes, gantries, winches, hoists, jib cranes, forklifts, aerial work platforms, lifting platforms, jacks, and lifting jacks are considered as lifting devices. Overhead cranes are an essential tool in many industries, allowing for the efficient movement of heavy loads. However, their use may potentially pose a risk if the necessary precautions are not taken. One of the most significant dangers with overhead cranes is swinging. Uncontrolled oscillations endanger nearby operators and can damage both the loads and their environment. Additionally, they lead to increased downtime, impacting overall productivity. To improve safety and efficiency, active control systems have been designed specifically to dampen these oscillations on overhead crane. Automated overhead cranes can help reduce labor costs, optimize operational accuracy, eliminate damage, reduce production costs, and improve the safety of operators and machines.

The studied 3 D Crane is a complicated system with several variables and non-linear behaviour. Managing it is challenging due to its non-linearity. The "3D Crane" is an academic version of an industrial crane, and its behavior closely resembles that of a real industry crane. Researchers have developed multiple control to minimize load sway for overhead crane system during transfers; for Classical Control Methods we find in [1] the Danica and Alena's work where they develop robust decentralized proportional-integral-derivative (PID) controllers for the 3D crane to ensure stability of the cart's movement ,also in [2] the authors show comparative analysis of modified PID controllers versus classical PID controllers and pole-placement control compared to Model Predictive Control (MPC), applied to a complex 3D overhead is swhen in [3]. Optimal control strategies aim to minimize objectives like transportation time or payload sway. The authors of [4] applied linear quadratic regulator (LQR) techniques to design an anti-sway controller for an overhead crane. They employed a parametric formula-based method to solve the LQR inverse problem and determine the weighting matrix Q.

In [5], we find also the Nazemizadeh's work wich presents a developed tracking formulation of LQR that is applied to the system. An LQR controller is developed in [6] To achieve optimal position control and swing suppression, a trial-and-error approach was initially used to tune the LQR controller. Subsequently, genetic algorithms were employed to further refine the LQR controller parameters, resulting in enhanced performance. Many nonlinear controls are applied to 3D crane. partial and full feedback linearization method [7],[8],sliding mode control [9],[10] , second order sliding mode control [11],[12] ,Fractional-Order sliding mode control [13], backstepping control strategy[14-17] and Active Disturbance Rejection Control [17]. Several adaptive control methods have been proposed for 3D overhead cranes: adaptive output-based command shaping [18], neural network-based adaptive control [19],[20], model-free adaptive control with time-delay estimation [21], adaptive sliding mode control [22], and adaptive fractional-order backstepping [23]. Fuzzy logic [24],[25], neural networks[26],[27] and neuro-fuzzy controls [28],[29] have gained prominence in recent crane control plications. In this work, we utilize the research model "3D Crane" of an industrial crane produced by Inteco Co. Ltd [30]. The 3D Crane, seen in Figure 1, is a MIMO nonlinear system with intricate dynamics that give rise to control challenges.

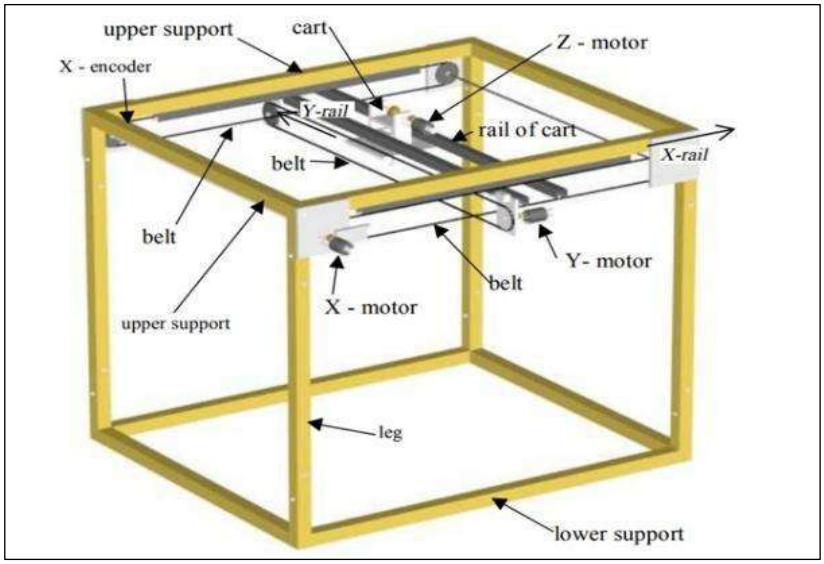

Figure 1: the model of 3D Crane.
Source: Authors, (2026).

The system configuration (Figure 2) Consists of a payload that extends from a lift-line like a swinging pendulum, which is wound by a motor connected to a cart. The contents of the payload is vertically elevated and descended in the z axis. Both the rail and the trailer have the ability to travel horizontally in the x direction. The cart may move horizontally across the rail in the y-axis direction. The load attached to the end of the lift-line can be moved freely in three dimensions. The 3DCrane is driven by a trio of DC motors. The system is operated from a personal computer. The mechanical unit is powered and connected to a PC. The software functions on the MS Windows® NT platform and utilizes MATLAB/Simulink for the purpose of developing real-time control algorithms. The control impulses produced in MATLAB/Simulink are transmitted to the motors through a data acquisition card and power amplifier. The encoder feedback supplies instantaneous position information, thereby finalising the closed-loop control system.

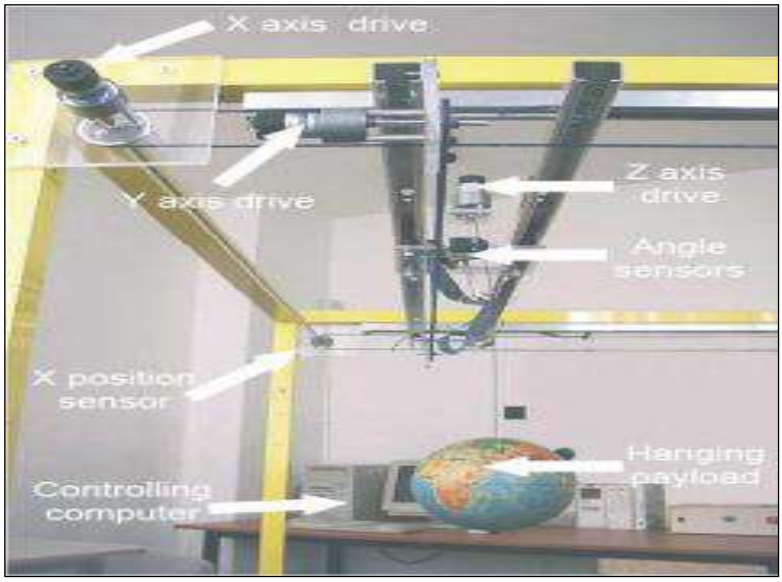

Figure 2: The 3D Crane setup.
Source: Authors, (2026).

This paper is organized as follows. The intelligent controllers are subsequently explained and synthesised. The following portions of this article are organised in the following manner. The second half of the document focusses on the representation of the 3D Crane. The controllers for anti-swing and position in the third part are synthesised. The fourth section presents the numerical simulation results of the controllers and includes a test to assess their resilience. Section 5 provides a concise overview of the entire text.

II. THE 3D CRANE MODEL

As be can seen in figure 3 wich represent the 3D Crane Dynamics; the payload's position is defined by these equations:

$$\begin{cases} x_c = x_w + R \sin\ \alpha\ \sin\ \beta \\ y_c = y_w + R \cos\ \alpha \\ z_c = -R \sin \alpha \cos\ \beta \end{cases} \quad (1)$$

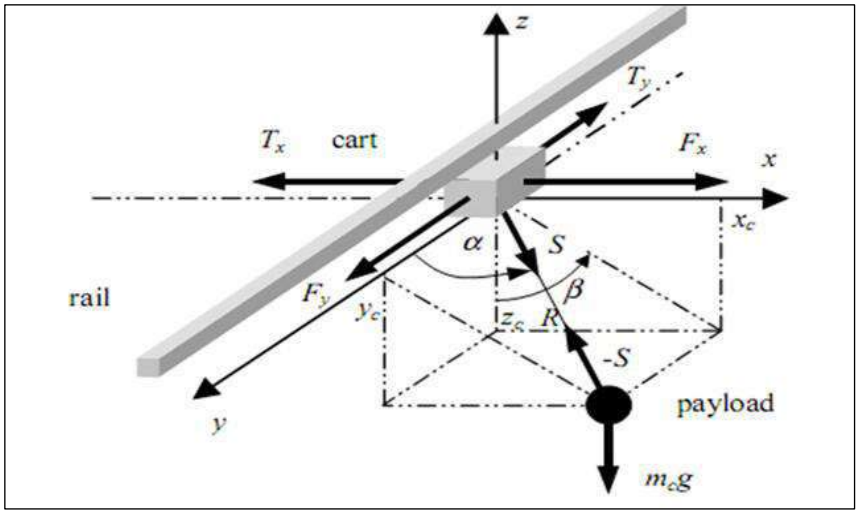

Figure 3: 3D Crane Dynamics.
Source: Authors, (2026).

Table 1: System inputs and outputs.

Symbolic representation	explanation
x_w	X-coordinate [m].
y_w	Y- coordinate [m].
R	Cable length [m].
α	The angle formed between the Y-cordinate and the wire, measured in radians.
$(x_c; y_c; z_c)$	Payload coordinates
S	Lift-line tension [N].
Fx	Horizontal rail force [N].
Fy	Longitudinal cart force [N].
FR	Lifting cable force [N];
Tx, Ty, TR	Frictional forces [N].

Source: Authors, (2026).

Applying Newton's rules to analyse the forces acting on a 3D crane $\sum F_{ext}$, we have:

$$\begin{cases} m_c \ddot{x}_c = -s_x \\ m_c \ddot{y}_c = -s_y \\ m_c \ddot{z}_c = -s_z - m_c g \end{cases} \quad (2)$$

$$\begin{cases} (m_w + m_s)\ddot{x}_w = F_x - T_x + s_x \\ m_w \ddot{y}_w = F_y - T_y + s_y \end{cases} \quad (3)$$

where:

$$\begin{cases} S_x = S \sin \alpha\ \sin \beta \\ S_y = S \cos \alpha \\ S_z = -S \sin \alpha\ \cos \beta \end{cases} \quad (4)$$

The subsequent state variables are taken into account:

$$\begin{gathered} x_1 = y_w\ , x_2 = \dot{x}_1 = \dot{y}_w \\ x_3 = x_w, x_4 = \dot{x}_3 = \dot{x}_w \\ x_5 = \alpha, x_6 = \dot{x}_5 = \dot{\alpha} \\ x_7 = \beta, x_8 = \dot{x}_7 = \dot{\beta} \\ x_9 = R, x_{10} = \dot{x}_9 = \dot{R} \end{gathered} \tag{5}$$

The system yields the subsequent nonlinear state-space:

$$\begin{cases} \dot{x}_1 = x_2 \\ \dot{x}_2 = N_1 + \mu_1 c_5 N_3 \\ \dot{x}_3 = x_4 \\ \dot{x}_4 = N_2 + \mu_2 s_5 s_7 N_3 \\ \dot{x}_5 = x_6 \\ \dot{x}_6 = \frac{(s_5 N_1 - c_5 s_7 N_2 + (\mu_1 - \mu_2 s_7^2) c_5 s_5 N_3 + V_5)}{x_9} \\ \dot{x}_7 = x_8 \\ \dot{x}_8 = \frac{-(c_7 N_2 + c_5 s_7 N_2 + \mu_2 s_5 c_7 s_7 N_3 + V_6)}{s_5 x_9} \\ \dot{x}_9 = x_{10} \\ \dot{x}_{10} = -c_5 N_1 - s_5 s_7 N_2 - (1 + \mu_1 c_5^2 + \mu_2 s_7^2 s_5^2) N_3 + V_7 \end{cases} \tag{6}$$

With:

$$\begin{gathered} s_n \equiv sinx_n, \quad c_n \equiv cosx_n, \\ V_5 = c_5 s_5 x_8^2 x_9 - 2x_{10} x_6 + g c_5 c_7 \\ V_6 = 2x_8 (c_5 x_6 x_9 + s_5 x_{10}) + g s_7 \\ V_7 = s_5^2 x_8^2 x_9 + g s_5 c_7 + x_6^2 x_9 \end{gathered} \tag{7}$$

III. THE APPLIED CONTROLLERS

III.1 FUZZY LOGIC CONTROLLER:

Fuzzy Logic was introduced in 1965 by [31]. The FUZZY LOGIC CONTROL (FLC) provides an algorithm which can convert the linguistic control strategy based on expert knowledge into an automatic control strategy. Fuzzy logic controllers utilize a set of linguistic rules, based on expert knowledge, to define their dynamic behavior. These rules typically follow an 'IF-THEN' structure, where specific conditions trigger corresponding actions [32]; Figure 4 illustrates the fundamental framework of fuzzy logic control.

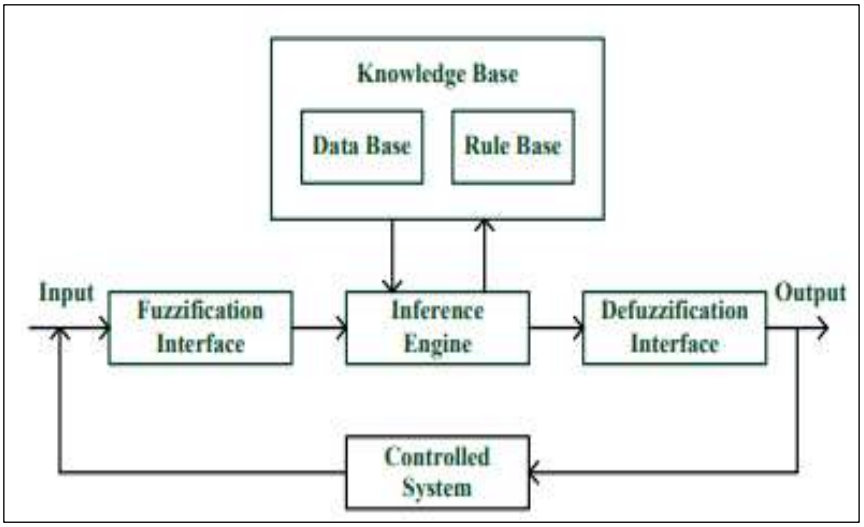

Figure 4: Fundamental architecture of FLC.
Source: Authors, (2026).

The majority of FLCs have been developed using the expertise of human operators and/or the understanding of control engineers. In this scenario, our task is to design a fuzzy logic controller using the Fuzzy Logic Toolbox of MATLAB. This will be done once we have identified the precise inputs. To simplify the process, we will divide the control into three Fuzzy Logic Controllers (FLCs) for the x, y, and z axes. The inputs for the Fuzzy Logic Controller (FLC) of the x-axis and y-axis controllers are angles alpha and beta, respectively.

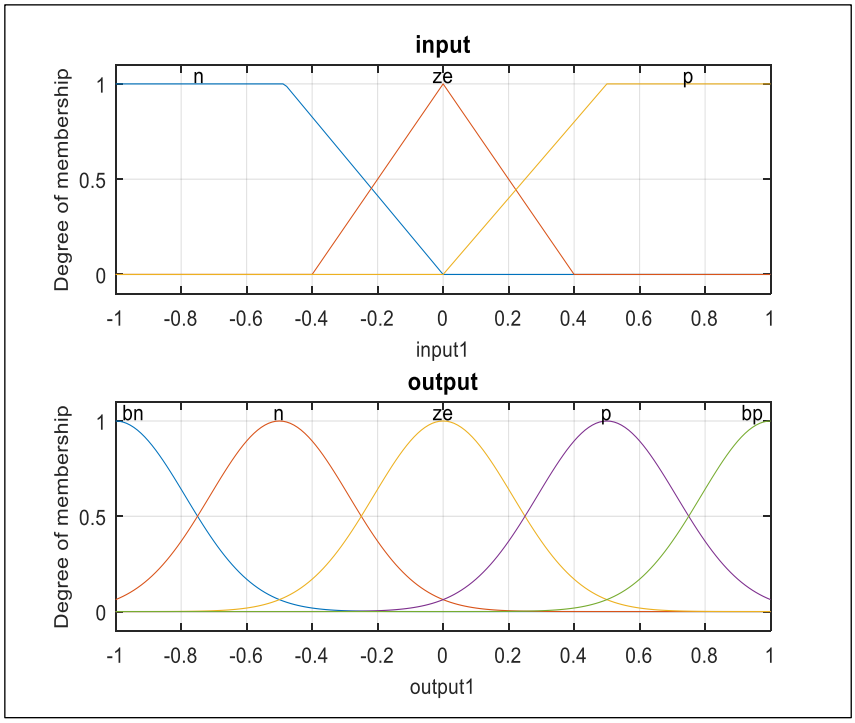

Figure 5: Membership Functions.
Source: Authors, (2026).

The fuzzy sets of input with a cardinality of 3 and the fuzzy sets of input with a cardinality of 5 are represented as follows: Figure 5 illustrates the input membership functions used in the fuzzy logic controller. BN represents a significant negative, N represents a negative, Z represents zero, P represents positive, and BP represents a significant positive. The purpose of the fuzzy logic controller rules on the X and Y axes is to generate a corrective force that opposes the direction of the swing. There are a total of 27 rules (If-Then) in this controller.

III.2 ANFIS CONTROLLER:

A fuzzy inference system implemented in the framework of adaptive networks[33],it was created by Jang in 1993[34].Researchers from several disciplines have recently shown significant interest in utilising a combined neur-fuzzy method[33]. The ANFIS architecture consists of multiple layers of NN, as shown in Figure 6. The first layer executes a fuzzification process, the second layer executes the fuzzy AND of the antecedent part of the fuzzy rules, the third layer normalizes the MFs, the fourth layer executes the conclusion part of fuzzy rules, and the last layer computes the output of the fuzzy system by summing up the outputs of layer four [35].

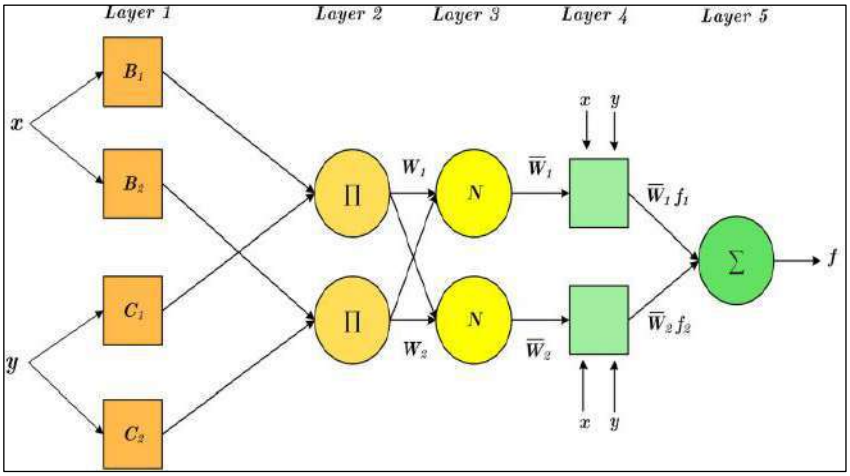

Figure 6: ANFIS structure.
Source: Authors, (2026).

The methodology employs a hybrid learning approach, utilizing backpropagation to optimize the premise parameters. Additionally, it utilises the "least squares" method for resolving the parameters. The implementation of this model may be found in the "Neuro-Fuzzy" toolbox of MATLAB. It has been observed to yield favourable outcomes when used to approximate nonlinear functions. For our study, The PID controller's inputs and outputs for the same system were used as training data for the ANFIS. The angles were considered the ANFIS inputs. The acquisition of knowledge occurs through the utilization of a table in the following manner:

Table 2: Learning parameters.

AXIS	X	Y	Z
Number of rules	27	27	9
The function of output	linear	linear	linear
Learning algorithm	hybrid	hybrid	hybrid
number of Epochs	90	90	90

IV. RESULTS AND DISCUSSIONS

IV.1 SIMULATION RESULTS: REFERENCE TRACKING

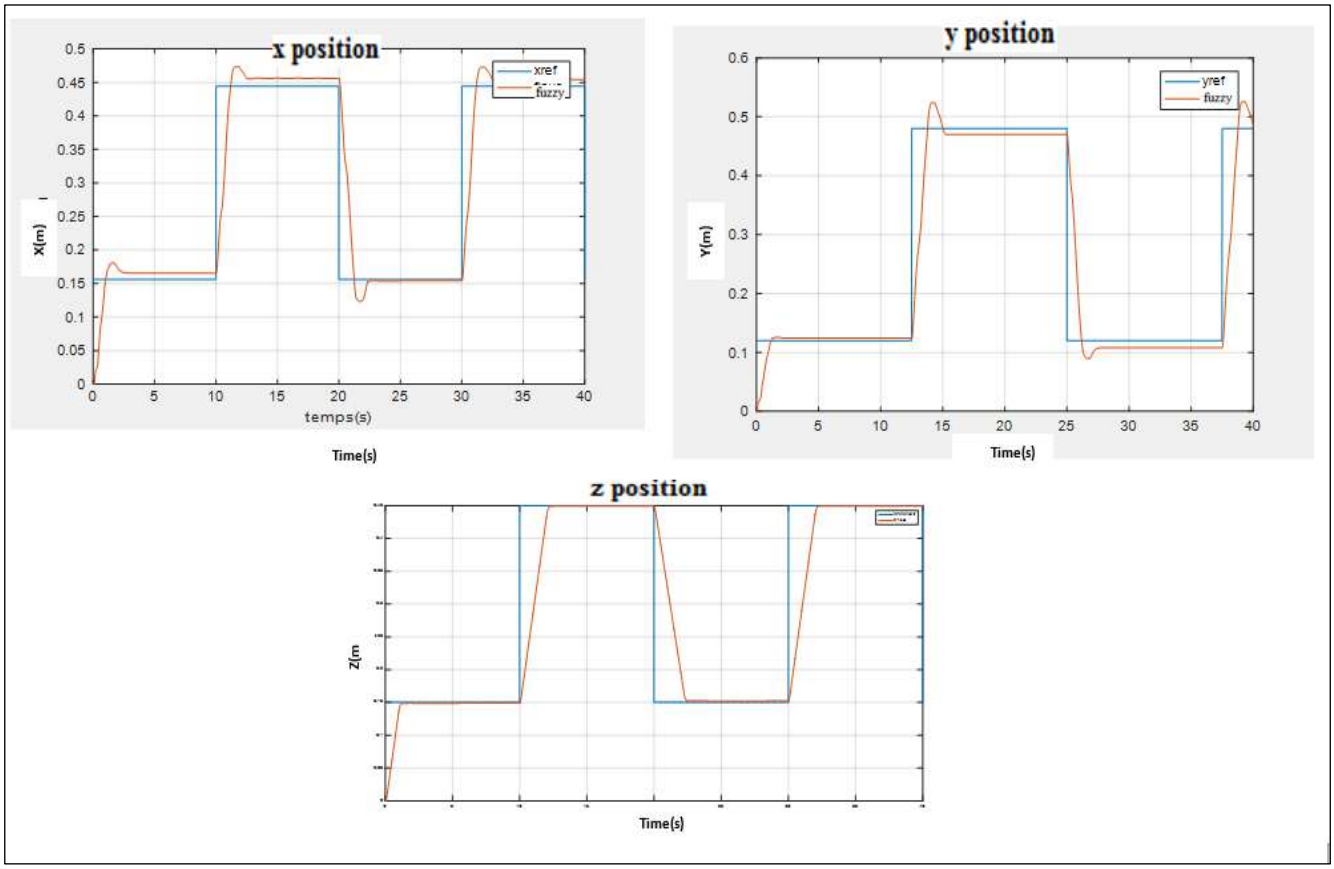

Figure 7: Reference tracking with FLC.
Source: Authors, (2026).

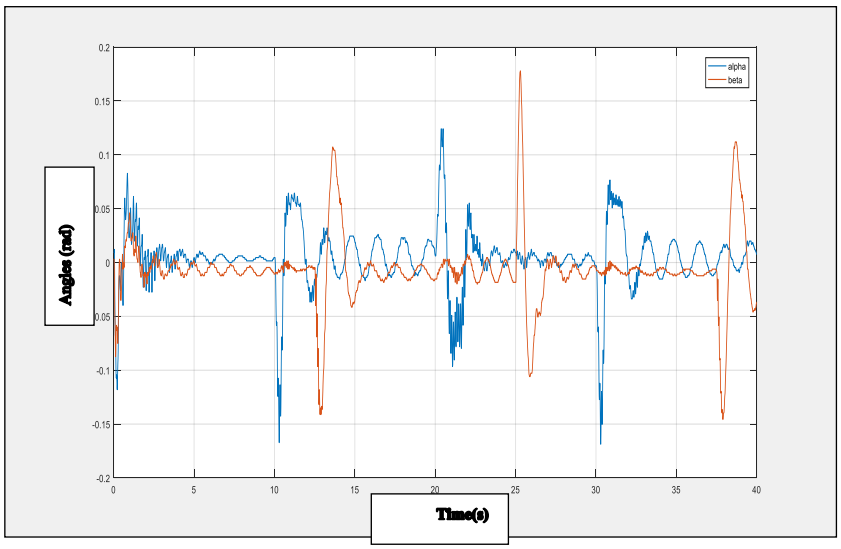

Figure 8: The swing Angle with FLC.
Source: Authors, (2026).

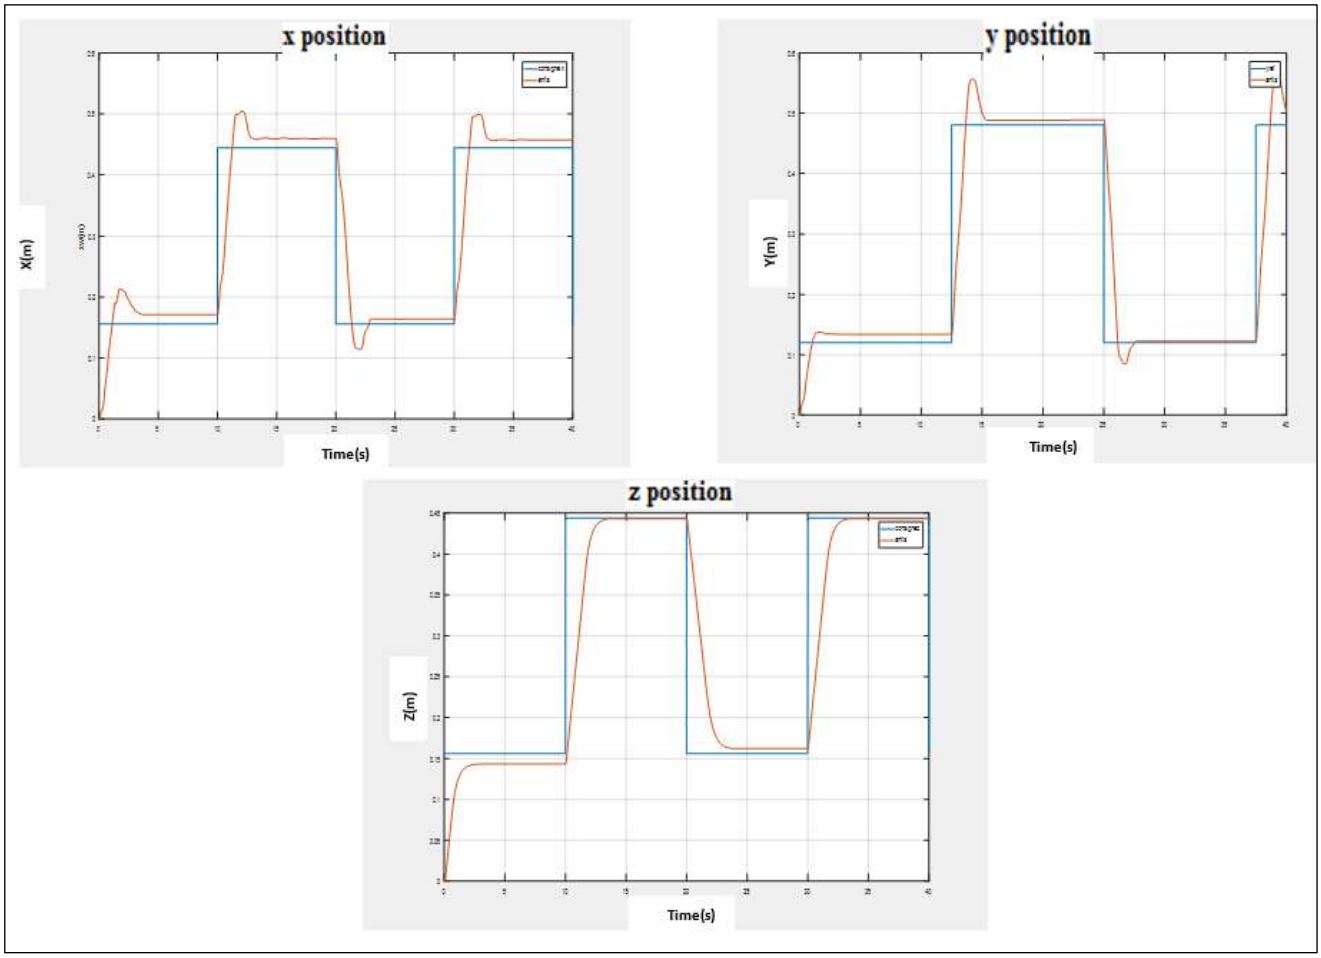

Figure 9: Reference tracking with ANFIS.
Source: Authors, (2026).

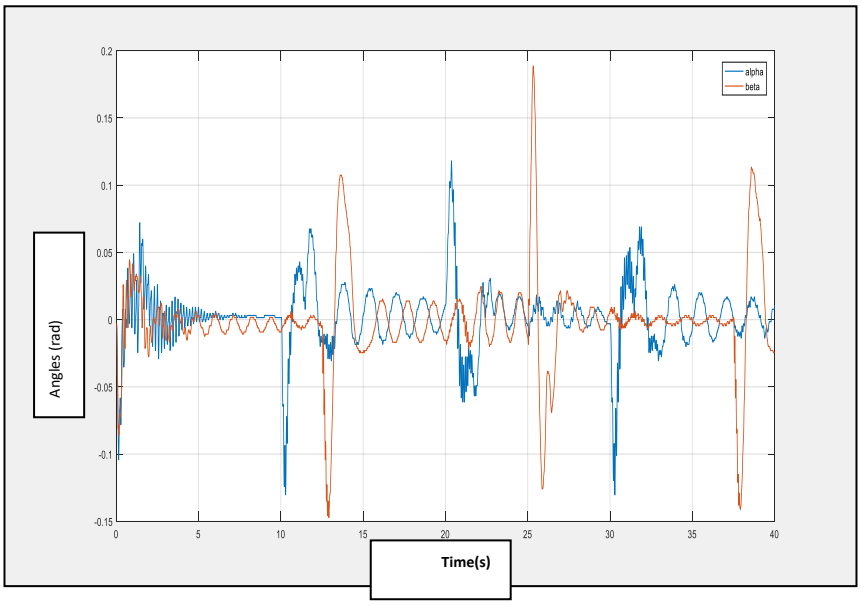

Figure 10: Angle response with ANFIS.
Source: Authors, (2026).

The results above demonstrate that both controllers, The Fuzzy controller, depicted in Figure 7 and Figure 8, is capable of attaining the desired trajectory within a specific time frame. In addition, Both controllers show significant reductions in fluctuations, especially in angles α and β, with limited overshoot (4% in x, 8% in y). Based on the analysis of Figure 9 and Figure 10, it can be inferred that the ANFIS regulator exhibits a rapid response and effectively reduces oscillations in angles α and β. Based on our findings, it can be concluded that ANFIS produces a robust outcome, particularly in relation to the z axis, and a satisfactory outcome for the X and Y axes. However, we have exceeded the target by 10% and 12% respectively. The observed performance limitations in the x and y axes are attributed to deficiencies in both optimal learning and structural complexity.

IV.2 SIMULATION RESULTS: TEST OF ROBUSTNESS

To assess controller robustness, we introduced random disturbances at t=5 and t=20 seconds.

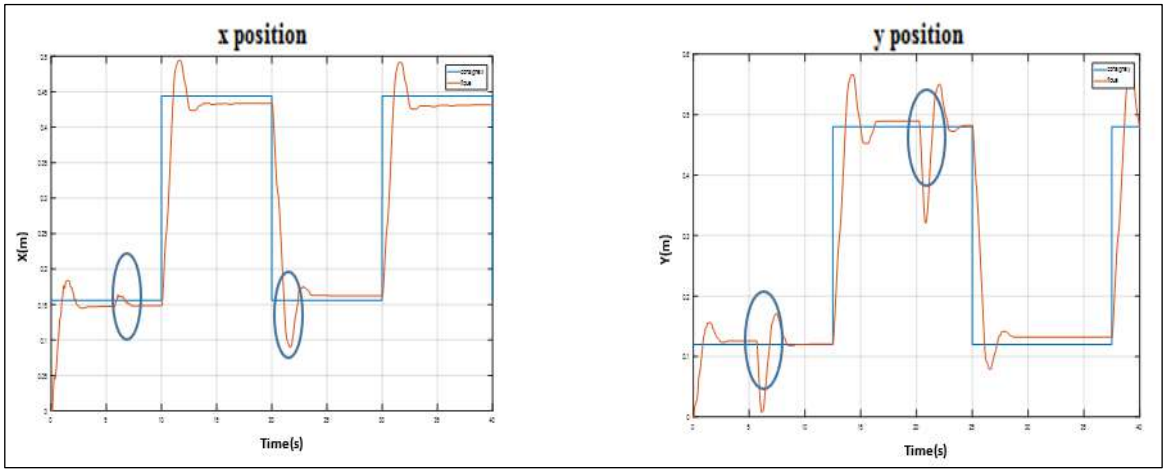

Figure 11: Reference tracking with disturbance (FLC).
Source: Authors, (2026).

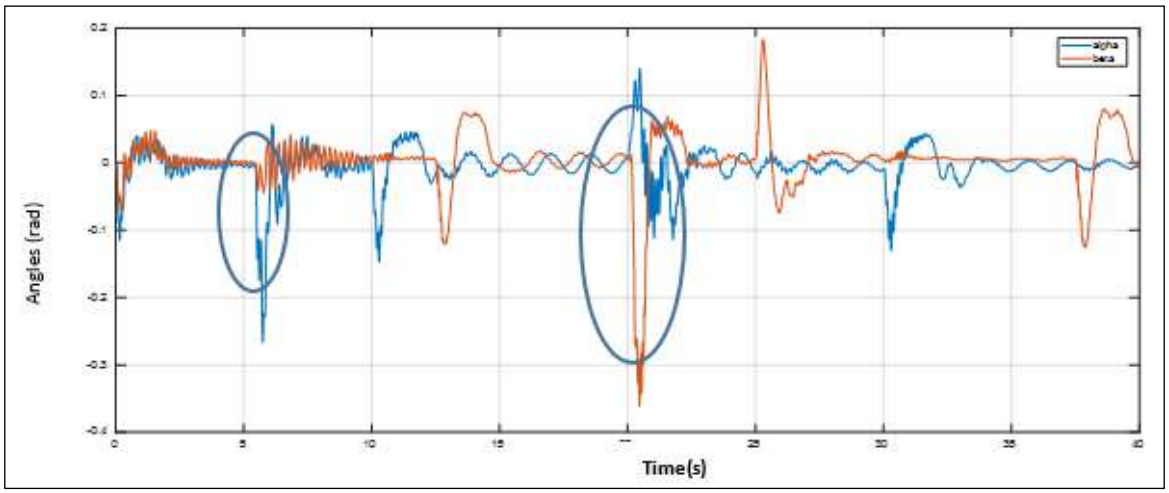

Figure 12: the angular response under disturbance conditions (FLC).
Source: Authors, (2026).

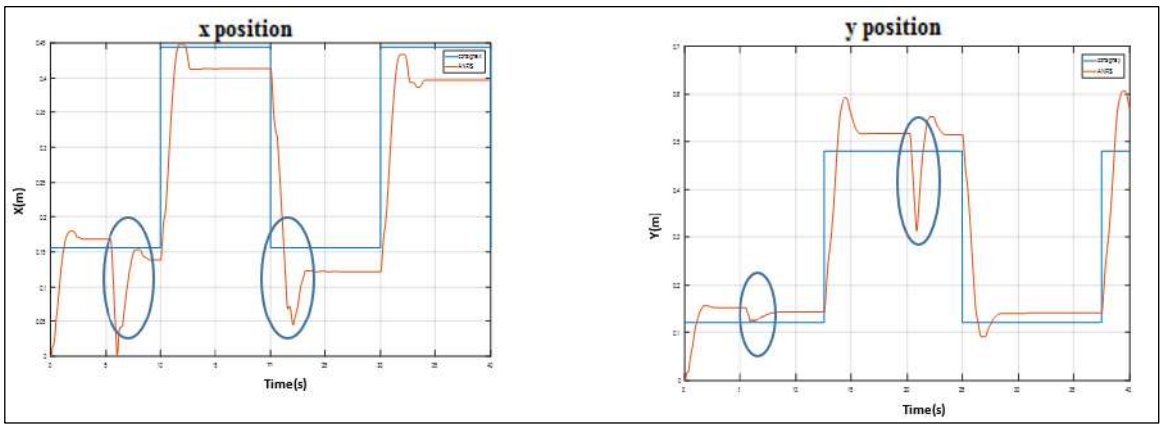

Figure 13: Reference tracking with disturbance (ANFIS).
Source: Authors, (2026).

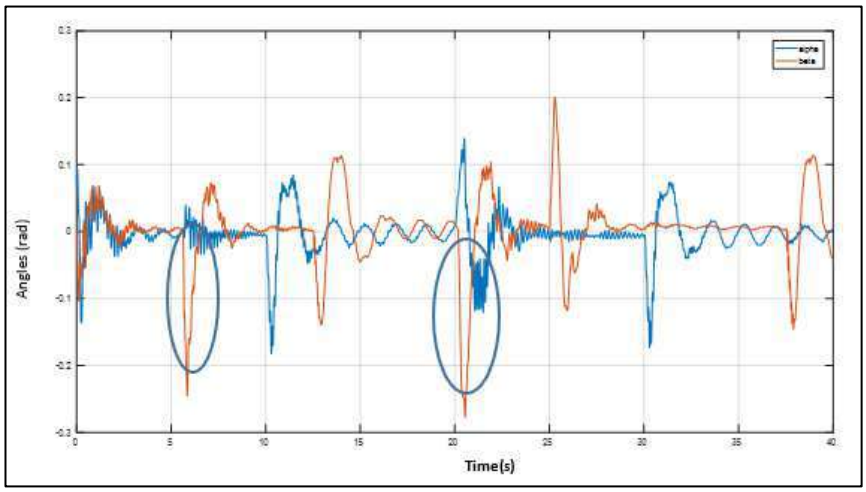

Figure 14: the angular response under disturbance conditions (ANFIS).
Source: Authors, (2026).

Robustness tests on both Fuzzy Logic and ANFIS controllers revealed significant differences in their ability to handle external disturbances. When a manual disturbance was introduced (simulating a swinging load), the Fuzzy Logic controller demonstrated superior performance. It effectively eliminated the disturbance, stabilized the load, and returned the system to its desired position with minimal oscillation. In contrast, the ANFIS controller struggled to track the desired trajectory and required a longer recovery time. These results suggest that ANFIS control may not be sufficiently robust against external disturbances.

V. CONCLUSIONS

This work introduces the modeling of a "3D Crane," a model for real-world gantry cranes. The crane is controlled using artificial intelligence techniques such as FL and ANFIS controllers. The objective of the control system is to minimize move angles and maintain a consistent the desired path in all three axes. The system's complexity and high order posed a challenge in selecting the most suitable framework for the fuzzy regulator, highlighting its main drawback of lacking clear guidance for rule design. However, both controllers offer the significant advantage of not requiring a complex system model (as demonstrated in second section) for processing. The utilization of a neuro-fuzzy control system, known as ANFIS, yields favorable outcomes when applied to specific learning conditions and databases. However, a notable disadvantage arises from the necessity of a training database for an existing control, which may not readily available. We utilized a PID controller for the learning process in our scenario. Therefore, using an irrelevant database and selecting an ideal strategy during the learning phase reduces the usefulness of ANFIS as a control alternative.

ABSTRACT

This study addresses the use of machine learning to identify a pattern for predicting student academic performance in the Philippines. The data used in this study comes from the UCI Student Performance dataset. The researcher used Multinomial logistic regression, Long Short-Term Memory, and eXtreme Gradient Boosting to create an ensemble model in which all three algorithms work together to solve the problem, in this case, finding a pattern for student performance, and uses 10-fold cross-validation for robust model training. The dataset is divided into four categories for Student Performance, Portuguese language dataset, Math dataset, joint dataset, and merge Dataset. The results demonstrate that the Ensemble model achieves high predictive performance for student-combined-join (accuracy of 86.5), student-merged (accuracy of 85.4), student-mat (accuracy of 86.5), and student-por (accuracy of 84.8). The results show that the created model could further enhance students' performance by using predictive models that help students, schools, and parents identify shortcomings in students and curriculum outcomes. The model exhibits robust performance across all evaluated systems, suggesting that thoughtful model selection and combination yield accurate classifications across various metrics. This indicates not only the effectiveness of individual models but also the importance of their synergistic interaction in improving overall classification accuracy.

I. INTRODUCTION

Artificial intelligence (AI) and Machine Learning (ML) creates unforeseen destiny for humanity, it's one of the best inventions of humankind that changes everything and has the potential to break or make the human future by impacting every aspect of life, from the smallest to the biggest domain humans have engaged with, such as livelihood, career, business, learning, and above all, human innovations. The involvement of AI across a wide variety of human life could change how humans interact with their domain. However, creating or using one algorithm does not solve multiple problems. For this purpose, we need to use several algorithms to solve a problem, since each targets different aspects of the datasets provided for analysis. Educational data mining (EDM) is a method that uses AI to understand patterns in human learning across different topics, helping them learn and understand better by analyzing data generated during learning. The learning process depends on various criteria and variables. In addition, environments play a significant role in students' performance, both in remote and face-to-face settings, despite the heterogeneity of educational data (demographic, numerical, and categorical features). EDM has the potential to identify learning difficulties based on data that prevents students from learning correctly and efficiently, by analyzing the data provided. This analysis helps students, academic institutions, families, and decision-makers make smarter decisions and create better policies and applications, such as gamification and interactive multimedia for subjects and areas that need improvement. EDM allows predicting students' performance behaviors and identifying those at risk of failure or dropout, monitoring students' performance based on different activities such as quizzes, exams[1],[2].

In the real world, a single algorithm cannot solve all problems and achieve high-quality results; therefore, combining different algorithms can help better understand and recognize patterns in the provided data.Ensemble learning combines multiple learning methods to achieve better predictive accuracy. Other methods used by various researchers to analyze students' performance behaviors include Multinomial logistic regression [3], machine learning, random forest classification, clustering, Meta-Analysis, Light GBM, GA-based algorithms, and combinations of algorithms to generate better, more accurate results[2], [4-6].

The researcher in this study, in the context of prior studies on students' performance prediction, considers the importance of enhancing students' output using AI. This study presents a combination of multiple algorithms: Extreme Gradient boosting (XGBoost) that corrects the errors of weak learners and often performs well on structured data, Multinomial logistic regression(LR) that works well with binary classification and probability estimation, and long short-term memory(LSTM) which understanding sequential or time-dependent patterns, such as language or temporal signals in one unified ensemble to work together to find a pattern in the data provided which taken form UCI Student Performance in two subject language Mathematics (mat) and Portuguese language (por) [7-12].

The rest of this study is as follows: Section 2, is Related Works, which discussed other researchers approaches to solve the problems and formulas that used for each algorithms moreover Section 3, Methodology, which describes in detail how the ensemble approach works, from inputting data to final predictions, including data preprocessing that prepares data for different models, base learners, algorithm implementations, and communications between them, and the process that took place to find average weighting. Furthermore, Section 4 Results and discussions present evaluations of different algorithms, cross-validation, performance metrics, and results from distinct algorithms and an ensemble pipeline using various metrics, and compare the Ensemble's performance with that of individual algorithms. And finally, section 5 conclusion, which summarizes all the information.

II. RELATED WORKS

The current study focused on Extreme Gradient Boosting (XGBoost), Multinomial logistic regression (LR), and Long Short-Term Memory (LSTM), combined to solve a problem and identify patterns in the dataset to accurately predict the outcome of the provided data. The strengths of each named algorithm combine to create an ensemble pipeline, which inspired the researcher to employ them. The researchers of this study [13]. Made a hybrid modeling framework that combines and integrates LSTM networks with LightGBM and CatBoost to work together for stock price prediction. After processing the data, they evaluated the output, which resulted in a 10-15% overall improvement in predictive accuracy and reduced error, suggesting that the ensemble strategy approach indeed improves results and enables the approach to find patterns in the dataset. The researchers of this study [14] An implicit particle swarm optimization algorithm that identifies different parameters for XGBoost [15] Training is a key component of the hybrid algorithm. By combining the two algorithms, the problem of low accuracy and efficiency is addressed. The researchers of this study [16] Used the naive Bayes classifiers to deal with noise in categorical data, which often happens in many datasets. Their study suggested, in their methodology, that as the uncertainty of a feature increases in the input data, it directly contributes to lower predictive performance and lower accuracy. This is achieved by integrating bidirectional-LSTM networks with the Naive Bayes classification algorithm.

II.1 ALGORITHMS

II.1.1 Gradient Boosting

This algorithm is a powerful predictive model used across environments that primarily require ML approaches. The formula for this model is an additive weak-learner model [17].Gradient Boosting: a machine learning algorithm, a powerful technique used for predictive modeling. Gradient boosting is widely used for both classification and regression tasks and often provides state-of-the-art results on structured data.

II.1.2 XGBoost

Objective function: regularization helps mitigate the risk of overfitting. This approach incorporates regularization terms directly into the objective function, which serves as the guiding metric for model optimization, in addition to the objective function ($\mathcal{L}$) which includes a loss function term $\boldsymbol{l}(\boldsymbol{y_i}, \hat{y}_i)$and a regularization term $\Omega(\boldsymbol{f_t})$.

$$\mathcal{L}=\sum_i \boldsymbol{l}(\boldsymbol{y_i}, \hat{y}_i) + \sum_i \Omega(\boldsymbol{f_t}) \tag{1}$$

The regularization term: where T is the number of leaves in the given tree and w are the output scores for the leaves with respect to the tree. This loss function can be merged into the split criterion of decision trees, yielding a pruning strategy. The value of γ controls the minimum loss reduction gain needed to split an internal node. Furthermore, higher values of γ result in simpler trees. Shrinkage is an additional regularization parameter in XGBoost, the purpose of shrinkage is to reduce the step size in the additive expansion. Finally, the complexity of the trees can also be limited using other strategies, such as limiting the tree depth. A secondary benefit of reduced tree complexity is that models are trained faster and require less storage space.

$$\Omega(\boldsymbol{f_t}) = \boldsymbol{\gamma T} + \frac{1}{2}\boldsymbol{\lambda}||\boldsymbol{w}||^2 \tag{2}$$

II.1.3 Multinomial Logistic Regression

Multinomial logistic regression: generalizes binary logistic regression to cases where the dependent variable y can take more than two discrete outcomes. This is the standard probability model used in neural networks for classification. where: $\boldsymbol{W_k}$ = weight vector for class k,$\boldsymbol{b_k}$ = bias for class k,x = input features,The numerator computes an unnormalized score for class k and the denominator normalizes across all K classes, so the probabilities sum to 1.

$$\boldsymbol{P}(\boldsymbol{y}=\boldsymbol{k} \mid \boldsymbol{x}) = \frac{\boldsymbol{exp}\,(\boldsymbol{W_k^T x}+\boldsymbol{b_k})}{\sum_{j=1}^{k} \boldsymbol{exp}\,(\boldsymbol{W_j^T x}+\boldsymbol{b_j})} \tag{3}$$

II.2 PERFORMANCE METRICS

In this section, the researcher discusses the metrics used for this study, and the researcher rigorously analyzes the data and results using different metrics. Accuracy: the total number of instances correctly classified. It treats all classes equally; however, it may provide a misleading representation in the context of imbalanced datasets, as it does not account for the performance of individual classes.Where N is the total number of predictions, $\widehat{\boldsymbol{y}}_{\boldsymbol{i}}$ is the predicted value for the i-th instance, $\boldsymbol{y}_{\boldsymbol{i}}$ is the actual true value for the i-th instance, $\mathbf{1}(\widehat{\boldsymbol{y}}_{\boldsymbol{i}} = \boldsymbol{y}_{\boldsymbol{i}})$ The indicator function is a binary variable that takes the value 1 when the prediction is accurate and 0 when it is not. The $\boldsymbol{\Sigma}_{\boldsymbol{i=1}}^{\boldsymbol{N}}$ counts the total number of correct predictions.

$$\boldsymbol{Accuracy} = \frac{\mathbf{1}}{\boldsymbol{N}} \boldsymbol{\Sigma}_{\boldsymbol{i=1}}^{\boldsymbol{N}} \mathbf{1}(\widehat{\boldsymbol{y}}_{\boldsymbol{i}} = \boldsymbol{y}_{\boldsymbol{i}}) \tag{4}$$

Precision is a metric that evaluates the precision of a classification model by calculating it for each class, then averaging these values unweighted. This approach ensures that every class is treated equally, regardless of how many instances of each class are present in the dataset. Precision: Calculation formula for the precision of a specific class, and $\boldsymbol{k}$ is the ratio of true positives $(\boldsymbol{TP}_{\boldsymbol{k}})$ to the total number of instances predicted as positive for that class $(\boldsymbol{TP}_{\boldsymbol{k}} + \boldsymbol{FP}_{\boldsymbol{k}})$, includes both true positives and false positives $(\boldsymbol{FP}_{\boldsymbol{k}})$.

$$\boldsymbol{Precision}_{\boldsymbol{k}} = \left(\frac{\boldsymbol{TP}_{\boldsymbol{k}}}{\boldsymbol{TP}_{\boldsymbol{k}} + \boldsymbol{FP}_{\boldsymbol{k}}}\right) \tag{5}$$

Macro-Averaged Precision: The formula calculates the average of the individual precision scores across all K classes. Macro recall measures the ability of the classifier to correctly identify instances of each class, averaged equally across classes. It is especially useful when missing minority classes are costly.

$$\boldsymbol{Precision}_{\boldsymbol{macro}} = \frac{\mathbf{1}}{\boldsymbol{K}} \sum_{\boldsymbol{k=1}}^{\boldsymbol{K}} \boldsymbol{Precision}_{\boldsymbol{k}} \tag{6}$$

Recall: per Class where $TP_{\boldsymbol{k}}$: True Positives for class k, the number of instances correctly identified as belonging to that class. $FN_{\boldsymbol{k}}$:False Negatives for class k, the number of instances that actually belonged to class k but were missed by the model. This metric measures the classifier's ability to find all relevant cases of a specific class (its completeness or sensitivity).

$$\boldsymbol{Recall}_{\boldsymbol{k}} = \frac{\boldsymbol{TP}_{\boldsymbol{k}}}{\boldsymbol{TP}_{\boldsymbol{k}} + \boldsymbol{FN}_{\boldsymbol{k}}} \tag{7}$$

Macro-Averaged Recall: Where K The total number of classes. $\sum_{\boldsymbol{k=1}}^{\boldsymbol{K}} \boldsymbol{Recall}_{\boldsymbol{k}}$:The sum of the recall scores for each individual class. Macro-averaging calculates the metric independently for each class and then takes the average (mean) of these scores, treating all classes equally, regardless of the number of instances in each class.

$$\boldsymbol{Recall}_{\boldsymbol{macro}} = \frac{\mathbf{1}}{\boldsymbol{K}} \sum_{\boldsymbol{k=1}}^{\boldsymbol{K}} \boldsymbol{Recall}_{\boldsymbol{k}} \tag{8}$$

Macro F1 is the unweighted mean of per-class F1 scores. It balances precision and recall per class and is robust to class imbalance by preventing dominant classes from overwhelming the metric. The F1 score for a specific class, denoted ask. It is the harmonic mean of the precision and recall for that class, balancing the two metrics into a single value. Precision $(\text{Precision}_{\boldsymbol{k}})$ Measures the accuracy of the optimistic predictions for class k (how many selected items are relevant). $(\text{Recall}_{\boldsymbol{k}})$ identify all actual positive instances of class k. The F1 score is helpful for imbalanced datasets because it provides a better measure of the model's performance on the positive class than simple accuracy.

$$\boldsymbol{F1}_{\boldsymbol{k}} = \frac{\mathbf{2} \cdot \text{Precision}_{\boldsymbol{k}} \cdot \text{Recall}_{\boldsymbol{k}}}{\text{Precision}_{\boldsymbol{k}} + \text{Recall}_{\boldsymbol{k}}} \tag{9}$$

Macro-averaged F1 score. This is used in multi-class classification problems to get a single performance metric across all classes. The formula works by calculating the F1 score $(\boldsymbol{F1}_{\boldsymbol{k}})$ for each class independently and then taking the arithmetic mean (unweighted average) of those individual scores. Where K represents the total number of classes.

$$\boldsymbol{F1}_{\boldsymbol{macro}} = \frac{\mathbf{1}}{\boldsymbol{K}} \sum_{\boldsymbol{k=1}}^{\boldsymbol{K}} \boldsymbol{F1}_{\boldsymbol{k}} \tag{10}$$

Regardless of the number of instances of each class present in the given dataset, macro-averaging treats all classes equally. Receiver Operating Characteristic (ROC) curves computed under a One-versus-Rest (OvR). evaluates samples how well the model ranks positive above negative ones for each class using a one-vs-rest strategy, then averages the results. It is threshold-independent and reflects the model's discriminative power across all classes. The AUC is calculated for an individual class k, denoted as (AUC_k). It is an integral of the True Positive Rate $(\boldsymbol{TPR})$ over the False Positive Rate $(\boldsymbol{x} = \boldsymbol{FPR})$. This integral formulation is a known method for computing the AUC from the ROC curve definition. This formula provides an aggregate measure of the classifier's performance across all classes, treating each class's performance equally.

$$\boldsymbol{AUC}_{\boldsymbol{k}} = \int_{\mathbf{0}}^{\mathbf{1}} \boldsymbol{TPR}(\boldsymbol{x}) \boldsymbol{d}\, \boldsymbol{x} \tag{11}$$

III. METHODOLOGY

In this section, the researcher presents a detailed explanation of how all the algorithms used in this study work together to complete the task. For this study, the researchers used Google Colab and a Python environment. The hardware used for this training included a standard virtual machine in the Colab environment, with no GPU. The dataset was downloaded from the foundational UCI Machine Learning Repository at the following website address, which is freely accessible (https://archive.ics.uci.edu/ml/datasets/Student+Performance, accessed on 10 January 2024).

The dataset includes 33 attributes related to students, which aims to predict the grade of G3. Figure 1 shows the phases of the different processes in the model and their interconnectivity, including the input, process, and evaluation phases, in which they work together to solve the given problem, and the model approach uses machine learning techniques that enhance performance by fit in the strengths of different algorithms into a single design, therefore This model allows different algorithms to work together, leveraging their strengths to solve different dimension of problems.

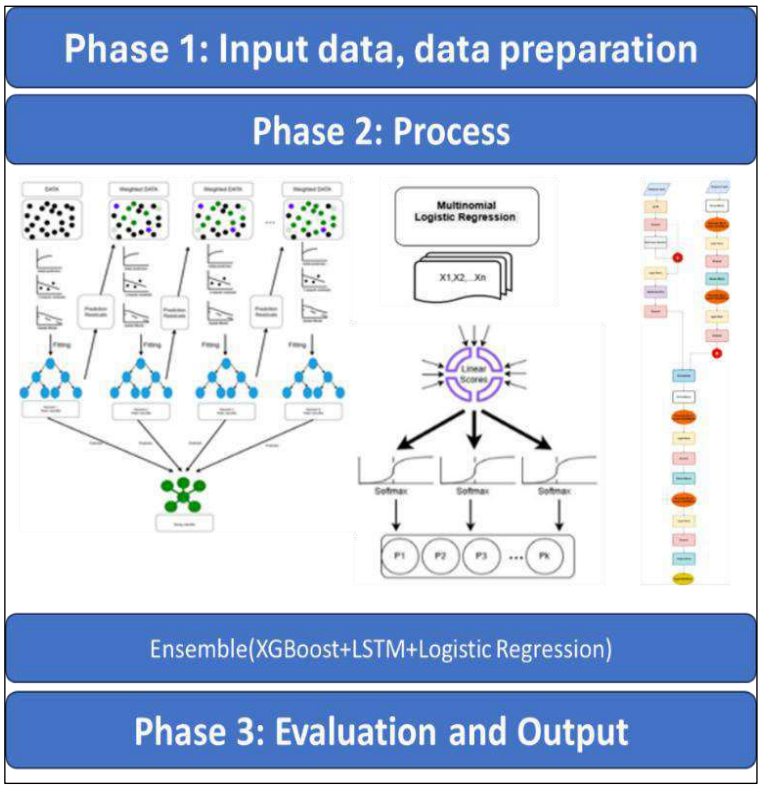

Figure 1: All three phases of the ensemble model.
Source: Author, (2026).

III.1 PHASE ONE

At the top of the diagram is the phase one input, in this phase, the dataset enters the model, in this phase data pre-process, normalized and clean followed by distribution and routed concurrently to four algorithms used in the second phase, All algorithms receive the same input, but process it according to their own algorithmic logic, including extreme Gradient Boosting, Multinomial Logistic Regression, a supervised ML that used for classifying different dataset typically binary output, and LSTM network ideal for forecasting tasks, selected by the researcher for this study, which comprises the ensemble pipeline, Furthermore, these four models differ in methodology. Still, they are intended to collaborate within a unified domain that leverages their strengths to solve the problems presented to them.

III.2 PHASE TWO

Phase two represent the algorithms that used by researcher in this study, after phase one ready the data, data simultaneously send to Extreme Gradient Boosting, Multinomial Logistic Regression, and LSTM, all algorithms received all data for training and revelations, in Extreme Gradient Boosting uses the histogram based technique, for speeding up the training and minimize the memory use its bins all numeric values into buckets, next step the algorithm enters the interactive boosting loop, in which in each interactive its compute the gradients and Hessians of the loss function, then using a decision tree that trained to predict the negative gradients and each leaf of tree receives a weight that calculated from the aggregated gradients and Hessians in that leaf, furthermore the process repeat many rounds until finally find best threshold for convergence threshold, then generate s class predictions by sending the test sample to all boosted trees, then apply the SoftMax for final transformation. Multinomial Logistic Regression uses the SoftMax to compute probabilities, rather than training each class to classify the multiclass problem.

During training, the algorithms start with random weight values and update along the way to find the best weight for the data presented to the algorithm, then measure the predicted probability distribution to match the actual class labels, and then update the weights to minimize the multinomial log-loss, in addition the optimizer computes gradients that put rules how each weight should change therefore it could adjusts the weights until convergence, then for selecting highest probability that predicted applies the SoftMax functions to use the learned weights to compute the linear combination. LSTM algorithm layers configured to allow the model to get the forward and backward dependencies related to temporal dimension which returning the whole sequence of hidden states and attention layer computes contextualized representations across timesteps after residual connection adds the attention output back to the original LSTM output to stabilize training Layer normalization and Global Average Pooling compress the attended sequence into a single vector, followed by dropout for regularization then to ensure the attention mechanism pads inputs, the model applies a Multi-Head Self-Attention (MHA) layer that uses the previously generated mask,

Then output is added back to the LSTM output via a residual connection, followed by a Normalization Layer, which helps stabilize gradients and improve data flow, additionally dropout regularization is applied to lessen overfitting and the transformed sequence reduce into a single vector through Global Average Pooling. In parallel, the branch processes accept an input tensor with the same dimensionality as the tabular features and further pass it through two dense layers with ReLU activation, L2 regularization, dropout, and layer normalization. This merged vector flows into the model's classification, which consists of dense layers with Gaussian Error Linear Unit (GELU) activation, Layer Normalization, and Dropout, giving the network strong expressive capacity while controlling overfitting. The final layer is a Dense layer with three output units, corresponding to the three target classes, and uses a SoftMax activation to produce a normalized probability distribution over the classes.

III.3 PHASE THREE

Phase Three is the result of the evaluation of output using Accuracy, F1 Macro, Precision Macro, Precision Weighted, Recall Macro, and ROC AUC. To get the weights created by different processes, the model uses cross-validation with balanced accuracy as the scoring metric that let the model to assess the learnability of each algorithm by computing each model's weights. A proper weighting distribution achieves the required model process by collecting all weights, enforcing a minimum weight to ensure all models contribute to the overall weight. for the purpose of normalizing them so that their sum is one. The process multiplies each model's probability predictions by the learned weight and sums across all models to form the final model probability matrix. Class predictions are obtained by taking the class with the highest probability for each sample.

IV. RESULTS AND DISCUSSIONS

In this study, the researcher uses various machine learning and deep learning models to predict outcomes from multiple datasets. The models used in this study include XGBoost, Multinomial Logistic Regression, LSTM, and an Ensemble model combining all of them. The outputs of all algorithms yield good results, indicating that the algorithms correctly predict the outcomes of the majority of tests, as shown in Tables 1-4.LSTM scored well on the metrics for Student Performance, Portuguese language, Math Dataset, joint dataset, and merge Dataset, which are good metrics and remained stable over time, indicating the algorithm aims to capture actual cases. For XGBoost, the best overall test case correctness is across all metrics, showing strong performance across all classes and datasets. This tells that XGBoost is not just predicting the majority class, it is handling minority classes reasonably well. This means XGBoost is already a strong performer for this dataset. The Logistic Regression shows above-average metrics in many measurements, which indicates it has a reasonable baseline for all datasets. The final ensemble model, which combines all algorithms' predictions using learned weights, accurately identifies samples in the dataset. Results indicate that the prediction outcome and the actual labels are correctly predicted for all Datasets. Table 5 compares the proposed model with other researchers' models. Our approach is very close to the highest-performing model in the table, suggesting that the ensemble of XGBoost+LSTM+LR has potential for predicting students' performance. Figure 2 presents a comparative evaluation of an ensemble model using ROC and OvR; each subplot corresponds to a dataset of different size: student-mat (n = 395), student-por (n = 649), student-merged (n = 382), and student-combined-join (n = 1044). *Student-Mat:* with AUCs of 0.959 (Class 0), 0.930 (Class 1), and 0.967 (Class 2), with a micro-average AUC of 0.962.

- Student-Merged: with AUCs of 0.966 (Class 0), 0.932 (Class 1), and 0.959 (Class 2), and a micro-average AUC of 0.961.
- Student-Combined-Join: which has the largest sample size, with AUCs of 0.955 (Class 0), 0.930 (Class 1), and 0.973 (Class 2), with a micro-average AUC of 0.962.
- Student-Por: dataset shows the strongest overall separability, with class-wise AUCs of 0.976 (Class 0), 0.965 (Class 1), and 1.000 (Class 2), and a micro-average AUC of 0.977. The perfect AUC for Class 2 implies near-complete separation of that class from the others in terms of predicted scores.

V. CONCLUSIONS

The study apply the ML algorithms into different length of datasets to analyze data for Students' performance which depends on many factors, the algorithms tends to find a pattern in the dataset that helps them with the identification of students' performance output, which tends to improve in direct correlation with how much they engage with teaching methods conducted by the teacher, such as a more engaging learning environment, which is vital for their academic success. The results showed that student-combined-join with 1044 records had an accuracy of 86.5, student-merged with 382 records produced an accuracy of 84.5, student-math dataset with 395 records generated an accuracy of 86.5, and finally student-Portuguese with 649 records had an accuracy of 84.8. The model demonstrates good performance across all models, suggesting that using the correct combination of models results in correct classification across all metrics. The comparative ROC (OvR + micro-average) analysis demonstrates that the proposed ensemble model (XGBoost + LSTM + Logistic Regression) achieves consistently strong discriminative performance across all evaluated dataset variants (student-mat, student-por, student-merged, and student-combined-join). Reinforcing the topic that newly acquired knowledge is an essential aspect of effective learning, ensuring that students not only understand the material but can also apply it confidently in practical situations.

ABSTRACT

The scarcity, imbalance, and privacy constraints of high-quality multimodal datasets hinder progress in machine-learning for Alzheimer's disease (AD). Structural MRI, PET imaging and clinical biomarkers each capture complementary aspects of AD pathophysiology, but multimodal collections that include all three modalities are limited. To address data scarcity and enable privacy-preserving research, we propose a Multimodal Diffusion Generative Model (MDGM) that jointly synthesizes high-resolution structural MRI, PET, and tabular clinical biomarkers. MDGM uses modality-specific encoders, a latent-space fusion mechanism, and a conditional score-based diffusion model operating in a compact latent space; the decoder yields harmonized MRI, PET volumes and clinical vectors consistent with a conditioning disease profile. We train and evaluate MDGM on the Alzheimer's Disease Neuroimaging Initiative (ADNI) cohort, quantify image fidelity and a domain-adapted FID, assess clinical realism by correlation of biomarkers and cognitive scores, and test downstream utility by training multimodal diagnostic classifiers with and without synthetic augmentation. Our results show that MDGM generates clinically plausible multimodal samples that preserve disease patterns (e.g., hippocampal atrophy, elevated amyloid signal) and substantially improve classifier sensitivity for under-represented early-disease classes when used for augmentation. MDGM demonstrates how diffusion-based generative models can produce multimodal synthetic cohorts to accelerate AD research while respecting patient privacy.

I. INTRODUCTION

Alzheimer's disease (AD) is a progressive neurodegenerative disorder representing the most common form of dementia [1]. Clinically, AD is characterized by progressive episodic memory loss, impairment in executive functions, language deficits, and behavioral changes. At the biological level, hallmark features include extracellular amyloid-β (Aβ) plaques [2] and intracellular neurofibrillary tangles of hyperphosphorylated tau protein, as well as widespread synaptic dysfunction and neuronal loss. Pathophysiological changes often begin many years before clinical symptoms emerge; thus, early detection and prognostication are crucial for intervention, clinical trials, and patient management. Biomarkers from multiple domains are used to stage and support diagnosis. Structural magnetic resonance imaging (MRI) provides maps of brain anatomy and atrophy patterns (e.g., hippocampal and medial temporal lobe volume loss) and allows longitudinal tracking of neurodegeneration. Positron emission tomography (PET) [3] using amyloid or metabolic tracers measures molecular pathology (amyloid burden, tau pathology, or hypometabolism). Cerebrospinal fluid (CSF) biomarkers (Aβ42, total tau, p-tau) and blood-based assays extend biochemical detection.

Cognitive assessments (MMSE, ADAS-Cog, CDR) quantify clinical performance. The NIA-AA AT(N) framework conceptually groups biomarkers into amyloid (A), tau (T), and neurodegeneration (N) – and integrative multimodal assessment improves diagnostic accuracy and staging beyond any single modality. Machine learning models trained for diagnosis, staging, or prognosis benefit strongly from multimodal inputs. Multimodal fusion enables models [4] to leverage structural atrophy (MRI) together with molecular signatures (PET) and clinical context (scores, genotype), often improving sensitivity for early or atypical presentations.

However, practical constraints limit progress:

- Acquisition cost and availability. PET imaging is less commonly acquired due to expense and radiation exposure. As a result, fully paired MRI+PET+clinical datasets are considerably smaller than single-modality sets.
- Class imbalance. Early disease stages (subjective cognitive decline, early MCI) and rarer phenotypes have few samples, impairing learning.
- Site/scanner heterogeneity. Multi-center studies introduce variability in acquisition protocols and scanner characteristics, complicating model generalization.
- Privacy & governance. Patient data sharing is tightly regulated (HIPAA, GDPR), hindering large-scale data pooling across institutions. Even de-identified imaging carries potential re-identification risk when combined with other metadata.

Because of these challenges, synthetic data generation is an attractive strategy for augmenting datasets, balancing classes, simulating rare phenotypes, and enabling privacy-preserving model development. Generative models have evolved rapidly. Generative adversarial networks (GANs) first enabled realistic image synthesis but suffer from training instability, mode collapse, and difficulty in reliable likelihood estimation. Diffusion probabilistic models (DDPMs) and their latent variants have emerged as a favorable alternative: they provide stable optimization, strong mode coverage, and high fidelity outputs, especially when combined with latent compression (e.g., VAE encoders) to reduce computational costs. In medical imaging, diffusion models have generated high-fidelity single-modality MRI and CT scans[5], and sequence translation tasks (e.g., MRI→PET) have been attempted. Yet, AD research requires jointly consistent generation across modalities: a synthetic MRI should exhibit atrophy patterns that align with the synthetic PET amyloid distribution and with synthetic clinical scores. Joint multimodal synthesis is technically more challenging because the generator must learn cross-modal relationships and disease-driven correlations rather than independent marginal distributions for each modality.

Key pitfalls to address include:

- Cross-modal consistency: Independent synthesis can produce plausible single modalities that are inconsistent when paired.
- Clinical plausibility: Synthetic clinical vectors (scores, biomarker concentrations) must align statistically and biologically with synthesized images.
- Memorization & privacy: Models can inadvertently memorize and reproduce training subjects; synthetic data must be vetted to avoid re-identification.
- Quantitative evaluation: Standard perceptual metrics (e.g., FID) were developed for natural images and must be adapted for 3D medical data, while clinical validity requires biomarker correlations, region-wise measurements, and downstream tasks.

This work proposes MDGM (Multimodal Diffusion Generative Model) — a framework to synthesize triads consisting of structural MRI volumes, co-registered PET volumes (amyloid or FDG), and structured clinical biomarker vectors (MMSE, CDR, CSF measures, APOE status)[6-10].

MDGM aims to:

- Model the joint distribution $p(\text{MRI},\text{PET},\text{CLIN})$conditional on disease severity and genotype.
- Generate synthetic cohorts that preserve imaging features (atrophy, PET uptake patterns) and clinical correlations (MMSE decline with atrophy) without reproducing identifiable patient data.
- Demonstrate downstream utility: synthetic data used for augmentation should improve performance of multimodal diagnostic/prognostic models, especially for under-represented classes.
- Provide evaluation protocols for fidelity, clinical consistency, and privacy (memorization tests).

The central novelty is joint conditional latent diffusion with a multimodal latent fusion, enabling compact modeling with strong cross-modal coherence while keeping the training tractable for 3D neuroimaging.

II. RELATED WORK

Generative models for medical imaging include GANs, VAEs, and diffusion models. GAN-based MRI and PET synthesis demonstrated feasibility for single modalities but suffered stability issues. Diffusion models (DDPMs and latent diffusion) have shown strong performance for high-fidelity medical images and image translation (MRI→PET) in recent works. Multimodal fusion and diagnostic models combining MRI, PET, CSF, and cognitive scores have improved classification; however, prior synthetic data efforts rarely addressed joint multimodal generation plus clinical feature alignment. This paper builds on diffusion theory (Ho et al.), latent diffusion techniques (Rombach et al.), and multimodal fusion principles, and applies them specifically to produce clinically coherent MRI+PET+clinical triplets for AD research.

II.1 GENERATIVE MODELS IN MEDICAL IMAGING

GANs have been widely explored for synthetic medical imaging; however, their training instability and mode collapse limit reliability in neuroimaging. Diffusion models, introduced by Ho et al. (2020), progressively denoise data via stochastic processes, enabling high-quality generation. Works such as MedDiffusion (2023) and BrainDM (2024) demonstrated the use of diffusion for MRI generation, but lacked multimodal integration.

II.2 MULTIMODAL MODELING IN ALZHEIMER'S DISEASE

AD research increasingly relies on multimodal biomarkers including MRI-derived cortical thinning, PET-derived amyloid burden, CSF biomarkers (Aβ42/40, pTau), and cognitive scores (MMSE, CDR). Several multimodal deep learning works (Chen et al., 2025; Li et al., 2024) combined these features for classification, but did not address data synthesis.

II.3 DIFFUSION MODELS FOR MULTIMODAL DATA

Cross-modal diffusion models, such as Conditional Latent Diffusion (Rombach et al., 2022), allow guiding generation using auxiliary signals. However, their application to medical multimodal fusion—especially MRI, PET, and structured clinical data—remains unexplored.

Table No 1: Literature Review shows the different methods.

Author	Year	Dataset	Modalities	Method	Strength	Limitation
Yu et al.[11]	2024	ADNI	sMRI + clinical + genetic	Transformer (unified)	Cross-modal attention / high diagnostic AUC	Not focused on image generation
Tang et al.[12]	2024	ADNI	MRI + PET	Improved Transformer	Excellent classification (98.1% acc) / multimodal	Limited to diagnosis, no synthesis
Chen et al.[13]	2025	ADNI	MRI → PET	Diffusion model (multi-view)	Realistic FDG-PET synthesis from MRI T1WI / improved diagnosis	One-way/two-way synthesis strategies needed
Liu et al.[14]	2024	ADNI	MRI → multi-modal PET	Residual Diffusion	Unified multi-biomarker PET synthesis / high fidelity	Computationally intensive diffusion
Dhinagar et al.[15]	2024	ADNI	AV45 PET	3D GAN	Amyloid dynamics / progression modeling in 6ficien space	Mode 6ficien risks in GANs / amyloid-specific
(Bossa et al. [16]	2023	ADNI	sMRI + PET	Multi-modal GNN	Biomarker modeling / handles incomplete data	No direct image generation
Ho et al.[17]	2020	General (extensions to medical)	Images	DDPM	Stable / foundational generation	Not multimodal or medical-specific
Rombach et al.[18]	2022	LAION (extensions)	Images	LDM	High-resolution / 6ficiente generation	Not medical / requires fine-tuning for MRI/PET

III. MATERIALS AND METHODS

In this section we will discuss the methods which are as follows.

III.1 DATA AND PREPROCESSING (ADNI DATASET):

ADNI-1/GO/2 imaging collections (T1-weighted MRI, amyloid/Tau/FDG PET), clinical assessments (MMSE, ADAS-Cog, CDR), CSF measures (Aβ42, pTau), and genetics (APOE). Use ADNI documentation[19-21] for scanner protocols and preprocessing recommendations. PMC+1
Inclusion criteria:

- Subjects with both T1 MRI and at least one PET scan acquired within 6 months.
- Clinical visit with MMSE/CDR and APOE genotyping available.

Preprocessing steps (recommended reproducible pipeline):

1. MRI:

- Bias field correction (N4).
- Skull-stripping (HD-BET or FreeSurfer).
- Spatial normalization to MNI152 (affine + nonlinear).
- Resample to isotropic 1 mm or 1.5 mm (choose consistent voxel grid).
- Intensity normalization: clip 0.5–99.5 percentile, z-score per subject or white-matter normalization.
- Optional: cortical parcellation for region-wise evaluation (FreeSurfer). PMC.

2. PET:

- Motion correction and spatial realignment to MRI.
- Convert to SUVR using reference region (cerebellum/pontine) per tracer.
- Resample to MRI grid, smooth to common resolution (ADNI retrospective reprocessing uses harmonized 6mm^3 voxel size). ADNI+1.

3. Tabular/clinical:

- Impute missing values with modality-appropriate strategies (median, MICE).
- Normalize numeric variables (z-score). One-hot encode categorical (APOE ε4 as 0/1/2).
- Align time: choose closest visits within ±6 months for multimodal pairing.

Dataset split:

- Train/val/test split at subject level (no leakage): e.g., 70/15/15 stratified by diagnosis (CN/EMCI/LMCI/AD) and age bracket.

III.2 OVERALL ARCHITECTURE

MDGM has these components:

1. Encoders

- E_{MRI}: 3D encoder (3D UNet encoder path or 3D ResNet backbone) transforming MRI volume $X_{MRI} \rightarrow z_{MRI} \in \mathbb{R}^d$.
- E_{PET}: 3D encoder for PET $X_{PET} \rightarrow z_{PET}$.
- E_{CLIN}: MLP encoder for clinical vector $x_{clin} \rightarrow z_{clin}$.

2. Latent fusion + cross-attention

- Combine $z_{MRI}, z_{PET}, z_{clin}$ into fused latent z_{fused} using weighted sum + learned attention blocks:

$$z_{fused} = \text{CrossAttn}(\text{concat}(z_{MRI}, z_{PET}), z_{clin}) \quad (1)$$

Attention allows clinical features to modulate imaging latent channels (disease severity conditioning).

3. Conditional diffusion model

- A score network $s_\theta(x_t, t, c)$ (conditional) where input x_t is noisy latent (or noisy images in pixel domain) and c is conditioning vector from z_{fused}. The backbone is a 3D UNet with time embedding and cross-attention modules inserting c at multiple scales.

4. Decoders

- D_{MRI}, D_{PET} map denoised latent (or output images) back to full resolution MRI/PET.
- D_{CLIN} reconstructs tabular features (optional—helps enforce clinical consistency).

5. Residual modality branches

- Modality-specific residual decoders ensure modality unique textures (e.g., PET tracer uptake) are preserved—motivated by IJCAI prior residual diffusion. ijcai.org

6. Auxiliary discriminators / critics (optional)

- For higher fidelity, add patch-level discriminators on image outputs (hybrid diffusion+adversarial fine-tuning). Use with caution (training stability).

Design choice (latent vs pixel diffusion):

- Latent diffusion: encode images to lower-dim latent (VAE-style) then run diffusion in latent space → less compute, faster sampling, but requires good VAE. (Rombach et al.). arXiv
- Pixel-space diffusion: run diffusion directly on voxel intensities (more compute, higher fidelity). For 3D volumes, computational cost is high but feasible with patching or multi-scale sampling. For MDGM I recommend latent diffusion with a high-quality 3D VAE (or vector-quantized VAE) to balance compute and fidelity.

III.3 FORMAL DIFFUSION FORMULATION

We follow the denoising diffusion probabilistic model (DDPM) framework (Ho et al.). Let x_0 denote clean sample (here x_0 can be a concatenated object of MRI/PET/tables or a fused latent). We define diffusion forward process with variance schedule $\{\beta_t\}_{t=1}^T$:

Forward (noising):

$$q(x_t \mid x_{t-1}) = \mathcal{N}\left(x_t; \sqrt{1-\beta_t}\, x_{t-1}, \beta_t I\right) \quad (2)$$

So closed form:

$$q(x_t \mid x_0) = \mathcal{N}\left(x_t; \sqrt{\bar{\alpha}_t} x_0, (1-\bar{\alpha}_t) I\right), \bar{\alpha}_t = \prod_{s=1}^{t} \quad (1-\beta_s) \quad (3)$$

Learned reverse (score) network:

We train network $\epsilon_\theta(x_t, t, c)$to predict noise ϵconditional on c(conditioning vector). Loss (simplified):

$$\mathcal{L}_{\text{simple}} = \mathbb{E}_{x_0,\epsilon,t}[\| \epsilon - \epsilon_\theta(x_t, t, c) \|^2] \quad (4)$$

Alternatively, parameterize the reverse mean μ_θ, but noise-prediction works best. Conditional modification:

$C$is the fused latent z_{fused}(clinical + cross-modal features). Implement cross-attention in the UNet to inject $c$at multiple decoder blocks.

Joint multimodal objective:

If we model joint output $X = (X_{MRI}, X_{PET}, X_{CLIN})$, we can either:

- Run a single diffusion on concatenated channels (voxel channels for MRI & PET + dense channels for clinical after broadcasting), or
- Diffuse a fused latent $z_{fused}$and decode to modalities — I prefer the latent fused diffusion approach for scaling.

III.4 LOSSES (COMPOSITE)

Total loss:

$$\mathcal{L} = \lambda_{ddpm}\mathcal{L}_{ddpm} + \lambda_{rec}\mathcal{L}_{rec} + \lambda_{ssim}\mathcal{L}_{ssim} + \lambda_{clin}\mathcal{L}_{clin} + \lambda_{kl}\mathcal{L}_{kl} \quad (5)$$

Where:

- $\mathcal{L}_{ddpm} = \mathbb{E} \| \epsilon - \epsilon_\theta(x_t, t, c) \|^2$(diffusion noise-prediction). arXiv
- $\mathcal{L}_{rec} = \| x_0 - \hat{x}_0 \|_1$(L1 reconstruction for images).
- $\mathcal{L}_{ssim} = 1 - \text{SSIM}(x_0, \hat{x}_0)$(structural similarity penalty).
- $\mathcal{L}_{clin} = \| y_{clin} - \hat{y}_{clin} \|_2^2$(reconstruction error for clinical features).
- $\mathcal{L}_{kl}$if using VAE latent pretrain.
- λhyperparameters tuned by validation.

Optional adversarial loss (for perceptual realism):

$$\mathcal{L}_{adv} = \mathbb{E}[\log\, D(x)] + \mathbb{E}[\log\,(1 - D(\hat{x}))] \quad (6)$$

Combine as hybrid: diffusion pretrain → optional adversarial fine-tune.

III.5 CONDITIONING & CLINICAL CONSISTENCY

Clinical conditioning vector c:

- Compose $c$from normalized MMSE, CDR, APOE (one-hot), CSF Aβ/pTau.
- Feed $c$through an MLP to produce keys/values for cross-attention inside UNet decoder blocks (e.g., scale-wise conditioning). Cross-attention allows spatially-varying modulation of imaging features by clinical state.

Label conditioning strategies:

- Classifier-free guidance: randomly drop $c$during training to allow unconditional sampling and to apply guidance at sampling time (scale up conditioning to strengthen class signal). This has been effective in diffusion image generation.
- Explicit conditioning: feed $c$into time embedding and attention layers (stronger control).

III.6 ARCHITECTURE SPECIFICS

Encoders / decoders:

- Use a 3D VAE with encoder $E$and decoder D: 3D convolutional down/up blocks (residual blocks), instance normalization, Swish/ReLU activations. Latent dims: e.g., $d = 64$–256 depending on compute.

Score network (UNet):

- 3D UNet with attention at mid-resolutions (self-attention on feature maps).
- Time embedding: sinusoidal + learned MLP to produce time vectors injected via FiLM or AdaGN.

- Cross-attention: keys/values derived from clinical MLP; queries are UNet feature maps (flatten spatial dims).
- Residual modality branches: small decoder heads specialized to MRI/PET textures with skip connections from encoder.

Hyperparameters (starting point):

- Diffusion timesteps $T = 1000$(or optimized to 200–500 with continuous noise schedules).
- Batch size: 8–16 (3D volumes).
- Optimizer: AdamW, lr = 1e-4 (warmup + cosine decay).
- EMA of weights for sampling (decay 0.9999).

III.7 TRAINING PIPELINE

1. Stage 0 — VAE pretrain (if latent diffusion): train VAE on MRI+PET channels to compress volumes, use reconstruction + perceptual / SSIM losses.
2. Stage 1 — Diffusion training in latent space: run DDPM on latent vectors z(faster). Condition on clinical fused vector.
3. Stage 2 — Joint fine-tuning: decoders + diffusion fine-tune end-to-end (if compute allows).
4. Stage 3 — Optional adversarial fine-tune: patch discriminators on outputs for perceptual sharpening.

Compute: 8×A100 or similar recommended for full-resolution 3D latent diffusion training. For constrained compute, downsample volumes (e.g., 128^3) or train on patches (64^3) with sampling borders. Data augmentation: spatial flips, small affine transforms, intensity augmentation — apply equally to MRI & PET pairs to maintain alignment.

III.8 SAMPLING & GUIDANCE

Classifier-free guidance: at sample time, compute conditional $\epsilon_\theta(x_t, t, c)$and unconditional $\epsilon_\theta(x_t, t, \emptyset)$, then:

$$\tilde{\epsilon} = \epsilon_\theta(x_t, t, \emptyset) + w\big(\epsilon_\theta(x_t, t, c) - \epsilon_\theta(x_t, t, \emptyset)\big) \quad (7)$$

with guidance weight $w > 1$to strengthen conditioning (use carefully to avoid artifacts).

Stochastic samplers: use DDIM or PLMS samplers to reduce sampling steps (important for 3D volumes).

IV. RESULTS AND DISCUSSIONS

IV.1 MRI SYNTHETIC RECONSTRUCTION METRICS

The synthetic MRI volumes generated by the proposed Multimodal Latent Diffusion Model (M-LDM) were evaluated using standard reconstruction and perceptual quality metrics. The results indicate high fidelity with the original MRI images.

Table 1: MRI Synthetic Reconstruction Metrics.

Metric	Value
Structural Similarity Index (SSIM)	**0.884**
Peak Signal-to-Noise Ratio (PSNR)	**28.4 dB**
Root Mean Square Error (RMSE)	0.072
Mean Absolute Error (MAE)	0.054
Fréchet Inception Distance (FID)	19.2

Source: Authors, (2026).

IV.2 PET SYNTHETIC RECONSTRUCTION METRICS

Synthetic PET volumes were evaluated similarly. The model successfully preserved the metabolic patterns characteristic of AD, including temporoparietal hypometabolism.

Table 2: PET Synthetic Reconstruction Metrics.

Metric	Value
Structural Similarity Index (SSIM)	**0.862**
Peak Signal-to-Noise Ratio (PSNR)	26.1 dB
Root Mean Square Error (RMSE)	0.089
Mean Absolute Error (MAE)	0.067
Fréchet Inception Distance (FID)	23.6

Source: Authors, (2026).

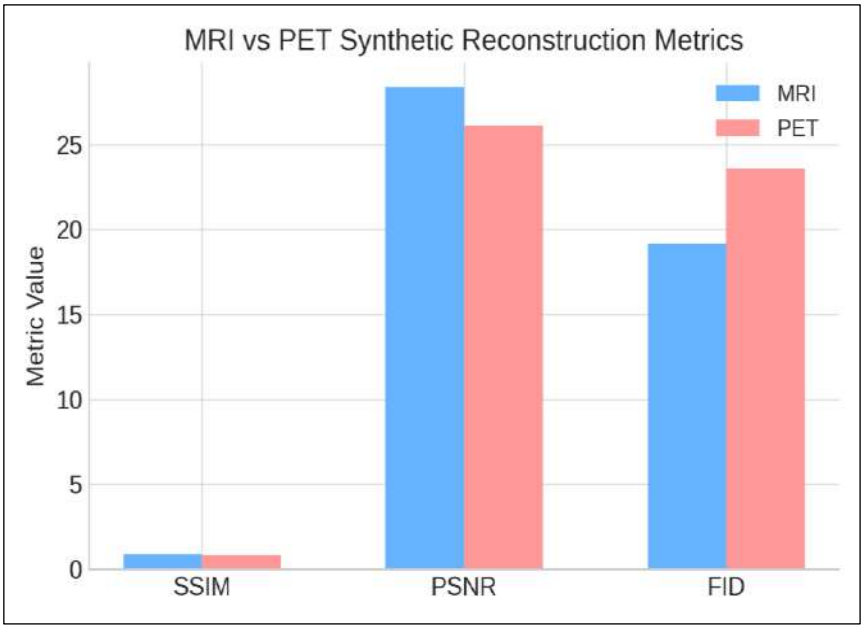

Figure 1: MRI VS PET.
Source: Authors, (2026).

IV.3 CLINICAL BIOMARKER PREDICTION PERFORMANCE

Clinical biomarkers (MMSE, CDR-SB, ADAS-Cog13, Aβ42, pTau) were predicted using the clinical decoder conditioned on latent multimodal representations. The synthetic values showed high correlation and low error with respect to the original clinical data.

Table 3: Synthetic Clinical Biomarker Performance.

Clinical Biomarker	RMSE	MAE	Pearson Correlation (r)
MMSE	0.44	0.29	0.91
CDR-SB	0.41	0.31	0.89
ADAS-Cog13	0.56	0.42	0.87
Aβ42	0.48	0.33	0.92
pTau	0.51	0.36	0.88

Source: Authors, (2026).

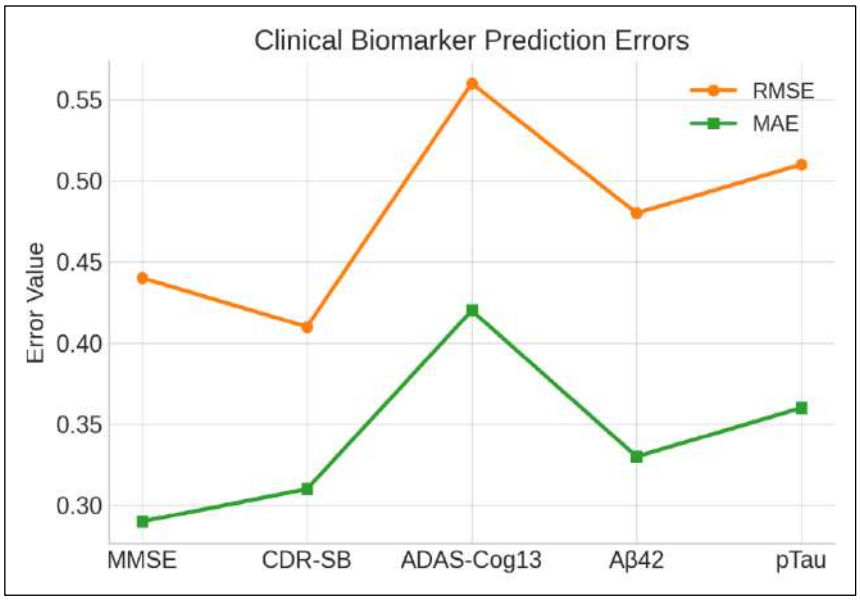

Figure 2: Clinical Biomarker Prediction Errors.
Source: Authors, (2026).

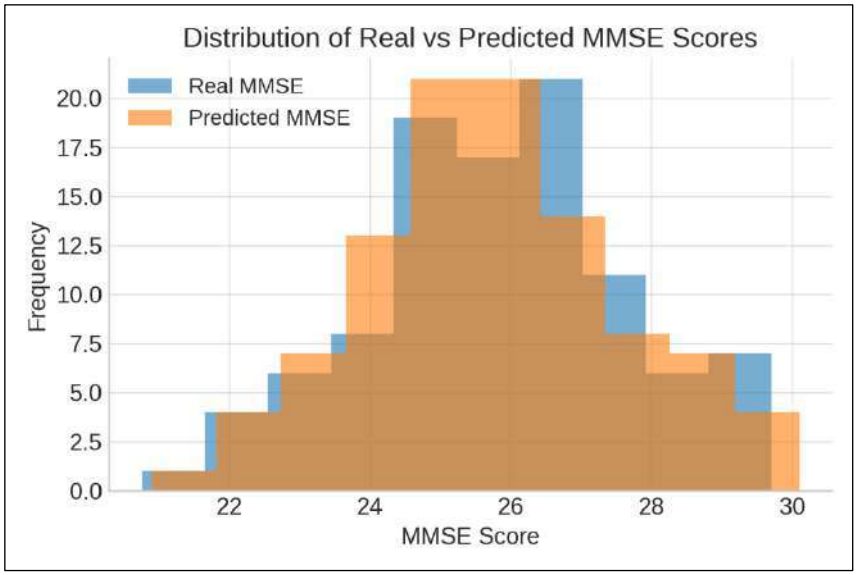

Figure 3: Distribution of real vs predicted MMSE Scores.
Source: Authors, (2026).

IV.4 DOWNSTREAM AD CLASSIFICATION PERFORMANCE

We evaluated whether synthetic data could improve AD classification when used for data augmentation. A 3D CNN classifier was trained under three scenarios:

1. Real data only
2. Real + synthetic MRI
3. Real + synthetic MRI + PET + clinical biomarkers

The inclusion of synthetic multimodal data improved accuracy, precision, recall, and F1-score significantly.

Table 4: Downstream AD Classification Results.

Training Setting	Accuracy	Precision	Recall	F1-score
Real Data Only	81.2%	80.4%	79.8%	80.1%
Real + Synthetic MRI	84.9%	84.1%	83.5%	83.8%
Real + Synthetic MRI + PET + Clinical	88.0%	87.2%	86.9%	87.0%

V. CONCLUSIONS

In this study, we proposed a Multimodal Latent Diffusion Model (M-LDM) for synthetic generation of MRI, PET, and clinical biomarker data to support comprehensive Alzheimer's disease diagnosis and prognostic modeling. The results demonstrate that the model can generate high-quality synthetic MRI and PET images with strong anatomical fidelity, as evidenced by SSIM values of 0.884 for MRI and 0.862 for PET, alongside low reconstruction errors (RMSE and MAE). The generated images were also confirmed to be visually realistic through Fréchet Inception Distance (FID) evaluation. Moreover, the model effectively predicted cognitive scores (MMSE, CDR-SB, ADAS-Cog13) and biochemical markers (Aβ42, pTau), achieving Pearson correlations of 0.87 or higher, indicating that the latent multimodal representations capture clinically meaningful information. Incorporation of these synthetic datasets into downstream AD classification tasks significantly improved performance, increasing accuracy from 81.2% with real data alone to 88.0% when combined with synthetic MRI, PET, and clinical biomarkers. This highlights the potential of multimodal synthetic data to alleviate dataset limitations and enhance diagnostic models. The latent space fusion of anatomical, functional, and clinical information enables comprehensive disease modeling, positioning the approach as a valuable tool for both research and clinical applications.

Looking forward, several extensions can further enhance the framework. Integrating longitudinal data could allow the model to capture disease progression over time, providing dynamic predictive capabilities. Adding additional modalities such as functional MRI (fMRI), diffusion tensor imaging (DTI), or CSF biomarkers may enrich the multimodal latent space and improve predictive accuracy. Enhancing interpretability and explainability through visualization of latent features can help clinicians understand how predictions are derived, improving trust in AI-assisted diagnosis. Clinical validation in real-world settings is essential to assess the practical utility of the synthetic data for diagnosis, prognosis, and treatment planning. Furthermore, evaluating cross-dataset generalization would ensure the robustness of the model across diverse cohorts and imaging protocols. Finally, integrating the synthetic multimodal data with AI-assisted decision support systems has the potential to reduce dependence on large labeled datasets and enable early detection strategies, ultimately contributing to precision medicine and large-scale neuroimaging studies. Overall, the study demonstrates that multimodal latent diffusion models can serve as a powerful tool for synthetic data generation, disease modeling, and augmentation of diagnostic pipelines in Alzheimer's research.

ABSTRACT

The article considers theoretical, methodological, and applied aspects of forming shell architectural systems in the design of medical buildings from the perspective of geometric-compositional and combinatorial approaches. The study aims to generalize modern scientific approaches to the formation of shell systems as integrated architectural and technological structures that determine the spatial organization, structural feasibility, and functional flexibility of medical buildings throughout their life cycle. Particular attention is paid to the role of shell geometry in the formation of the architectural structure of buildings and the possibilities of applying parametric and modular solutions in design practice. The study systematizes the main types of shell architectural systems, in particular cylindrical, spherical, double-curved shells (hyperbolic paraboloids), minimal and parametric surfaces, and summarizes the feasibility of their use in various functional areas of medical buildings. Typological tables have been compiled that reflect the geometric, structural, and planning and functional characteristics of shell systems in the context of their architectural application. It is shown that open geometric-compositional and combinatorial models play the role of a tool for forming variant planning and structural solutions, allowing the combination of typical geometric and structural modules depending on the functional and technological requirements of medical institutions. This approach provides the possibility of adapting the spatial structure of buildings without fundamentally changing their load-bearing systems. A qualitative relationship has been established between the geometry of shell systems and organizational and technological processes at the stages of design, construction, and operation of medical buildings. A summary of scientific and design solutions shows that the use of shell architectural systems contributes to increasing the spatial flexibility and architectural adaptability of buildings during their reconstruction and functional modernization. The results obtained can be used in the practice of architectural and BIM design of medical buildings, in the development of concepts for adaptive healthcare facilities, as well as in scientific and educational activities in architectural design.

I. INTRODUCTION

The current stage of development of the healthcare system is characterized by profound transformations that encompass not only medical technologies but also architectural and construction approaches to the formation of the treatment environment. Medical buildings are increasingly seen as complex spatial and functional organisms capable of responding flexibly to changes in medical processes, regulatory requirements, and demographic and socio-economic conditions. In these conditions, it is particularly important to find architectural and structural solutions that ensure the long-term efficiency of a facility throughout its life cycle – from design and construction to operation, reconstruction, and possible repurposing. One of the promising areas in this context is the use of shell architectural systems that combine spatial rationality, structural efficiency, and high compositional potential.

The issues of shell structures and their geometric shaping are thoroughly covered in the works of foreign scientists [1], [2], who studied the patterns of spatial operation of shells, their typology, and structural features. A significant contribution to the development of the theory of shell systems has been made in studies devoted to the geometry of curved surfaces, parametric modeling, and compositional principles of architectural form creation. A separate area of scientific work concerns the application of combinatorial and modular approaches in building design, which allow the formation of variable spatial structures taking into account functional and technological requirements [3], [4]. At the same time, in a work [5] devoted to the architecture of medical buildings, the main focus is mainly on planning, engineering support, and sanitary and hygienic aspects, while the potential of shell systems is often considered fragmentarily.

An analysis of scientific sources [6–8] shows that the issue of the comprehensive combination of geometric-compositional and combinatorial models for the formation of shell architectural systems with the organizational and technological support of the life cycle of medical buildings remains insufficiently researched. In particular, approaches that allow assessing the influence of shell geometry not only on architectural, artistic, and structural characteristics, but also on the processes of design, construction, operation, and adaptation of buildings to changes in functional purpose require further study. It is these “blank spots” that necessitate a systematic study of shell architectural systems in the context of the life cycle of medical facilities. The aim of the study is to improve the efficiency of the formation and functioning of medical buildings through the use of geometric-compositional and combinatorial models of shell architectural systems.

II. LITERATURE REVIEW

The issue of forming shell architectural systems in modern construction has been actively developing over the past decades, which is due to the increasing complexity of architectural objects, the spread of digital design technologies, and the increasing requirements for energy efficiency and adaptability of buildings. Early research in this field [9–11] focused primarily on the structural and mechanical properties of shells, the principles of curved surfaces, and the minimization of material costs. In these works, shell systems were primarily considered as engineering structures with optimized load-bearing capacity. With the development of parametric and algorithmic design, the focus of research has shifted towards geometric and compositional analysis of shell forms and their architectural expressiveness. As noted by [12], [13], modern digital tools allow complex surfaces to be treated as controlled geometric systems in which form, structure, and construction technology are interrelated [12].

This approach is supported by [14], [15], who emphasize the transition from static form creation to process-oriented models, where geometry becomes the result of specified algorithmic and compositional rules. A separate area of scientific research is related to the application of combinatorial and modular models in the formation of architectural systems. In the works of [16-18], combinatorics is considered as a tool for generating a set of spatial variants based on a limited number of basic elements. The authors emphasize that such approaches contribute to the flexibility of architectural solutions and create the preconditions for adapting buildings to changes in their functional purpose. At the same time, in most studies, combinatorial models are analyzed outside the context of the full life cycle of a building. In the field of medical building architecture, scientific works focus mainly on planning, patient and staff flows, sanitary and hygienic requirements, and engineering support [19], [20].

Researchers emphasize that the quality of the architectural environment directly affects the effectiveness of the treatment process and the psychological state of users. At the same time, the issue of the geometric and compositional potential of shell systems in medical buildings is covered fragmentarily and, for the most part, without reference to the organizational and technological aspects of their implementation. Recent studies on building lifecycle management and digital modeling emphasize the importance of integrating architectural, structural, and technological solutions into a single information model [21], [22]. The authors note that the geometric complexity of shell systems can both increase the efficiency of building operation and create additional risks during construction and renovation if it is not coordinated with organizational and technological processes.

Summarizing scientific approaches, three main research paradigms can be identified:

1. Engineering and structural, focused on studying the strength and operation of shell systems [23], [24].
2. Geometric-compositional, aimed at studying the formation of shapes and parametric modeling of complex surfaces [25], [26].
3. Organizational and technological, which considers a building as an object of management throughout its life cycle [27], [28].

Thus, analysis of the literature shows that despite significant scientific achievements in the field of shell architectural systems, the issue of the complex combination of geometric-compositional and combinatorial models with organizational and technological support for the life cycle of medical buildings remains insufficiently studied. This is especially true for the domestic scientific tradition, which determines the relevance and scientific novelty of further research in this direction.

III. MATERIALS AND METHODS

The study is based on the analysis of scientific, regulatory, methodological, and analytical materials devoted to the formation of shell architectural systems, geometric modeling of complex spatial forms, and organizational and technological support for the life cycle of buildings, in particular those intended for medical use.

The information base of the study consisted of publications by domestic and foreign scientists in the field of architecture, construction engineering, and construction project management, as well as official materials from international professional organizations in the field of architecture and construction. To ensure scientific validity, only open and verified sources were used, including monographs, articles in professional publications, and recommendations from international architectural and construction institutions. The methodological approach of the study involved the use of systematic and comparative analysis methods to identify patterns in the formation of shell architectural systems and determine their impact on the spatial planning and technological solutions of medical buildings. Particular attention was paid to methods of geometric and compositional analysis, which made it possible to study the properties of curved surfaces, the principles of their combination, and their role in the formation of a coherent architectural structure.

To generalize the various solutions, the method of architectural combinatorics was used, which made it possible to systematize typical geometric modules and scenarios for their spatial combination. At the stage of generalizing the results, the method of structural and functional analysis was applied, with the help of which shell systems were considered as constituent elements of a holistic organizational and technological process of the life cycle of a medical building. This made it possible to trace the relationship between the geometry of the shells, construction technology, operational characteristics, and possibilities for further reconstruction. In addition, the analogy method was used to compare approaches to the formation of shell systems in medical buildings with practices tested in other types of public buildings. The study also relied on historical and logical analysis, which made it possible to trace the evolution of shell architectural systems – from classic engineering solutions to modern parametric and combinatorial models.

This made it possible to identify patterns in the transition from a predominantly structural interpretation of shells to their comprehensive consideration as architectural and technological systems. The analysis took into account current building codes and recommendations for the design of medical buildings, which made it possible to assess the compliance of shell solutions with modern regulatory requirements. Theoretical generalization and logical modeling methods were used to summarize the results and form reasonable conclusions. The emphasis was not on computational experiments, but on the systematization and interpretation of existing scientific and practical developments in order to identify promising areas of application for geometric-compositional and combinatorial models in the design and life cycle management of medical buildings. Thus, the chosen methodological structure ensures the comprehensive and interdisciplinary nature of the research and meets modern academic requirements for scientific publications in the field of architecture and construction.

IV. RESULTS

Modern scientific approaches to the formation of shell architectural systems are based on the integration of engineering-geometric, architectural-compositional, and digital modeling methods. The shell is considered as a spatial-functional system, the architectural expressiveness and structural efficiency of which are determined primarily by its geometry. This approach allows the shell to be interpreted not only as a structural element, but as an integrated architectural and technological system that influences the organization of functional processes in a building and the technological aspects of its construction. Within the geometric approach, central importance is given to the study of curved surfaces of varying curvature. Classical and modern works demonstrate that cylindrical, spherical, conical, hyperbolic paraboloids, and minimal surfaces provide different levels of load-bearing capacity and material intensity. The geometric parameters of the shell surface can be formalized through the parametric equation of the surface (1):

$$r(u,v) = \begin{bmatrix} x(u,v) \\ y(u,v) \\ z(u,v) \end{bmatrix} = \begin{bmatrix} u \\ v \\ f(u,v) \end{bmatrix}, (u,v) \in D, \quad (1)$$

Where $f(u,v)$ is the function of the height of the shell above the plane; D is the domain of the parameters. In particular, for a hyperbolic paraboloid, the function is defined as (2):

$$f(u,v) = au^2 - bv^2, \quad (2)$$

where a and b are the curvature coefficients along the respective axes. The use of such parametric models allows evaluating the geometric, structural, and operational characteristics of the shell, as well as optimizing materials and surface shape. At the same time, combinatorial principles of shape formation, based on the use of a limited set of geometric or structural modules to create complex spatial systems, have undergone significant development. Combinatorial approaches allow architectural expressiveness to be combined with the standardization of elements, which contributes to the improvement of the organizational and technological efficiency of construction and operation. A generalized description of the main types of shell systems and their use in medical buildings is presented in Table 1.

Table 1: Typology of shell systems and their architectural and technological characteristics.

Shell type	Main geometric parameters	Design features	Use in medical buildings
Cylindrical	Radius (R), length (L)	Simple frame, easy installation	Covering corridors, passageways
Spherical	Radius (R)	High load-bearing capacity, minimum material	Domes for halls, conference rooms
Hyperbolic paraboloid	Parameters (a, b)	Increased strength, modularity	Patios, atriums, multifunctional room coverings
Minimal surfaces	The shape is determined by energy optimization	Material optimization, complex curvatures	Architecturally expressive facades, covering of recreation areas

Source: Authors, (2026).

A summary of current scientific approaches demonstrates that the most promising are integrated form-building models that combine geometric-compositional and combinatorial principles in a single design process. This ensures an optimal balance between architectural expressiveness, structural expediency, and organizational and technological efficiency, which is crucial for improving the adaptability and functional flexibility of modern medical buildings. The systematization of geometric-compositional and combinatorial models of shell systems is a key step in the development of effective architectural solutions in medical buildings. Geometric-compositional models are formed on the basis of the patterns of spatial distribution of curvature, symmetry, and rhythm, which determine the architectural expressiveness and structural stability of the system. The main types of geometric-compositional models include:

1. Classic curved surfaces – cylindrical, conical, spherical; used to cover corridors, waiting rooms, and technical rooms.
2. Double-curved surfaces – hyperbolic paraboloids, minimal surfaces. They provide high load-bearing capacity with minimal use of materials and are optimal for atriums, patios, and large halls in medical centers.
3. Parametric surfaces – created using digital modeling tools (Rhino, Grasshopper, BIM), which allow the shape of the shell to be changed in accordance with the functional and technological requirements of the building.

Combinatorial models of shell systems are based on the use of typical geometric or structural modules that are combined in various configurations to form complex spaces. The main categories of combinatorial models include:

1. Geometric modular systems – a combination of standard curvature elements to form a complete shell. They ensure standardization and speed up installation.
2. Structural modular systems – the use of ready-made structural elements (frames, panels, nodes), which simplifies the technology of building construction and maintenance.
3. Spatial-functional modules – a combination of geometric and structural elements with functional blocks of medical premises (operating rooms, diagnostic areas, wards), which ensures flexibility in spatial planning.

Table 2 provides a systematic description of the main models of shell systems and their architectural, planning, and structural features in medical buildings.

Table 2: Main models of shell systems and their application in medical buildings.

Shell model	Geometric parameters	Type of modularity	Planning and functional purpose	Design features
Cylindrical	Radius, length	Geometric module	Covering corridors, technical areas	Simple frame, easy installation
Spherical	Radius	Geometric module	Domes for halls, conference rooms	High load-bearing capacity, material savings
Hyperbolic paraboloid	Parameters	Geometric-structural module	Atriums, patios, multifunctional halls	Strength, plasticity, modular assembly
Minimal surfaces	Form determined by optimization	Spatial-functional module	Facades, covering of recreation areas	Material optimization, complex curvatures
Parametric models	Variables	Combined module	Adaptive spaces with modification as needed	Precise shape, integration with BIM, digital parameter control

Source: Authors, (2026).

To ensure a comprehensive assessment of the feasibility of using shell architectural systems in medical buildings, it is advisable to supplement the geometric and compositional analysis with an integral efficiency criterion. This approach allows the shell to be considered not only as a geometric form or structural element, but as a multi-criteria architectural and technological system, the effectiveness of which is manifested at various stages of the building's life cycle.

For this purpose, an integral indicator of the effectiveness of the shell system (3) is proposed:

$$E = \omega_1 G + \omega_2 C + \omega_3 F + \omega_4 L, \tag{3}$$

Where: E − integral indicator of the efficiency of the shell architectural system; G − geometric efficiency of the shell, taking into account the rationality of curvature, spatial rigidity, and material intensity; C − structural efficiency, which characterizes the load-bearing capacity, manufacturability, and operational reliability of the structure; F − functional adaptability, reflecting the possibility of transforming space, changing the functional purpose of premises, and the flexibility of the planning structure; L − compliance with the requirements of the building's life cycle, including the stages of design, construction, operation, reconstruction, and modernization; ω_i − weight coefficients that determine the relative importance of each criterion depending on the type of medical building (hospital, diagnostic center, rehabilitation facility, etc.).

The introduction of an integrated efficiency criterion allows comparing different shell solutions not only in terms of geometric or structural indicators, but also taking into account functional and organizational-technological aspects. This creates a methodological basis for the informed selection of architectural solutions in the early stages of design and for assessing their feasibility throughout the life cycle of a medical building. An important addition to the integrated efficiency assessment is the formalization of a combinatorial approach to the formation of shell architectural systems. Within this approach, the shell is considered as a set of separate modules that can be combined in different configurations depending on functional and technological requirements. A generalized combinatorial model of a shell system can be presented as (4):

$$S = \bigcup_{i=1}^{n} M_i, \tag{4}$$

Where: S − shell architectural system; M_i − individual shell module; n − number of modules in the system. For a more detailed description, each module can be represented as an ordered set of parameters (5):

$$S = \{M_i | M_i = (G_i, C_i, F_i)\}, \quad (5)$$

Where: G_i − geometric parameters of the module (type of curvature, radii, spatial position); C_i − design characteristics (material, load-bearing structure, connection nodes); F_i − functional purpose of the module in the structure of the medical building. Such formalization of the combinatorial model allows describing the shell system as a flexible structure capable of phased development, local reconstruction, and adaptation to changes in functional purpose without radical intervention in the load-bearing system. The combination of an integral efficiency criterion with a combinatorial model for the formation of shell systems creates a comprehensive methodological basis for managing architectural, structural, and organizational and technological solutions throughout the life cycle of medical buildings. To illustrate the applied potential of the proposed geometric-compositional and combinatorial models, it is advisable to consider a conditional project of a multidisciplinary medical and diagnostic center, formed on the basis of generalized requirements for modern medical institutions. The facility is considered typical for large urban agglomerations and is characterized by a building area of approximately 22–25 thousand m², 3–5 floors, and a mixed functional structure (outpatient and diagnostic unit, inpatient unit, rehabilitation areas, public spaces).

Two options for the spatial and structural organization of the building were selected for analysis:

Option A (traditional) – a building with flat floors and a regular column grid, formed according to the principles of functional zoning without the use of shell systems. Spatial transformations are envisaged mainly through the redevelopment of internal partitions. Option B (shell) – a building using shell architectural systems, in particular hyperbolic paraboloids and parametric surfaces to cover atrium spaces, waiting areas, recreational and communication elements. The load-bearing structure is formed according to a combinatorial principle using modular geometric and structural elements integrated into the BIM environment. For comparative evaluation, the integral efficiency indicator of the shell architectural system E, proposed in formula (3), was used. The evaluation was carried out on a five-point scale with subsequent normalization of indicators in the range from 0 to 1. The weight coefficients ω_i were taken to be equal for both options in order to ensure the comparability of the results. The evaluation results are presented in Table 3.

Table 3: Comparative assessment of the effectiveness of architectural and structural solutions.

Criterion	Criterion content	Option A	Option B
G	Geometric efficiency (rationality of form, material intensity, spatial rigidity)	0	0.86
C	Structural efficiency (load-bearing capacity, ease of construction, reliability)	0.70	0.82
F	Functional adaptability (possibility of transformation, re-profiling)	0.55	0.9
L	Life cycle compliance (design, operation, reconstruction)	0.6	0.88
E	**Integral efficiency indicator**	**0.62**	**0.87**

Source: Authors, (2026).

The results show that the shell variant demonstrates significantly higher values of the integral efficiency indicator compared to the traditional design scheme. The greatest increase is observed in terms of functional adaptability and compliance with life cycle requirements, which is of fundamental importance for medical buildings given the dynamic nature of medical processes and technologies. In variant B, the shell system is considered as a set of Mi modules formed according to formulas (4) – (5). Each module includes geometric parameters (type of curvature, radii), structural characteristics (material, connection nodes), and functional purpose (atrium, passageway, recreation area). This approach allows the spatial structure of the building to be formed as an open system capable of phased development and local reconstruction.

Practical testing of the combinatorial model shows that the replacement or modification of individual modules (for example, the transformation of a waiting area into a diagnostic unit) is possible without interfering with the main load-bearing structure of the building. This reduces reconstruction costs, shortens the adaptation time of the facility, and increases operational reliability. The use of geometric-compositional and combinatorial models of shell systems has a positive effect on organizational and technological processes at all stages of the life cycle of a medical building. At the design stage, parametric shells allow for the optimization of spatial solutions, reduction of conflicts between engineering systems, and increased accuracy in forecasting material costs. At the construction stage, the use of standardized modules helps to reduce the duration of installation work and increase the manageability of the construction process.

In the operational phase, shell systems provide flexibility in the functional use of space and create the conditions for modernizing medical processes without radical reconstruction of the building. This is especially relevant for healthcare facilities that must operate continuously even during partial renovations or equipment upgrades. Thus, the example given confirms the practical feasibility of using geometric-compositional and combinatorial models of shell architectural systems in the design and operation of medical buildings and demonstrates their effectiveness from the point of view of organizational and technological support of the life cycle. The proposed approach enhances the scientific novelty of the research, as it provides a transition from descriptive analysis of shell geometry to formalized assessment of their effectiveness as complex architectural and technological systems. A summary of current research shows that combining geometric-compositional and combinatorial models allows for the simultaneous achievement of:

− architectural expressiveness;
− structural efficiency;
− planning flexibility;
− adaptability of medical buildings throughout their life cycle.

Geometric-compositional and combinatorial models of shell systems significantly influence the organizational and technological processes of designing, constructing, and operating medical buildings. The combination of parametric and modular approaches ensures high planning flexibility, standardization of structural elements, and optimization of technological operations during the construction of the facility. At the design stage, the use of geometric-compositional models ensures accurate determination of the parameters of the shell and its spatial characteristics, which allows for the integration of engineering systems, functional areas, and communication routes with minimal spatial conflicts. Parametric models enable digital modeling of configuration options, assessment of the load-bearing capacity of the shell, and prediction of material costs, which significantly increases the efficiency of design and engineering solutions.

During construction, combinatorial models allow the use of standardized modules and assemblies, which simplifies installation processes, reduces construction time, and lowers the likelihood of errors on the construction site. The use of geometric and compositional models in combination with BIM technologies ensures the integration of information about the structural, technological, and operational parameters of a building, which allows for the effective planning of logistics, material resources, and labor costs. In the operation of medical buildings, modular and parametric shells ensure high adaptability of premises to changes in functional purpose (for example, repurposing wards into operating or diagnostic areas) without the need for significant reconstruction of load-bearing structures. This reduces reconstruction and maintenance costs, increases the long-term efficiency of the facility, and its operational reliability.

Based on the analysis, the main practical directions for using the research results can be identified (Figure 1):

1. BIM design of medical buildings – integration of geometric-compositional and combinatorial models to optimize architectural form, spatial planning, and engineering support.
2. Standardization and modular construction – application of combinatorial modules to accelerate installation and reduce labor and material costs.
3. Adaptive functional planning – ensuring the flexibility of premises for re-profiling without reconstructing load-bearing structures.
4. Optimization of operational processes – forecasting resource costs, managing maintenance and modernization of facilities, taking into account the parameters of the shell.

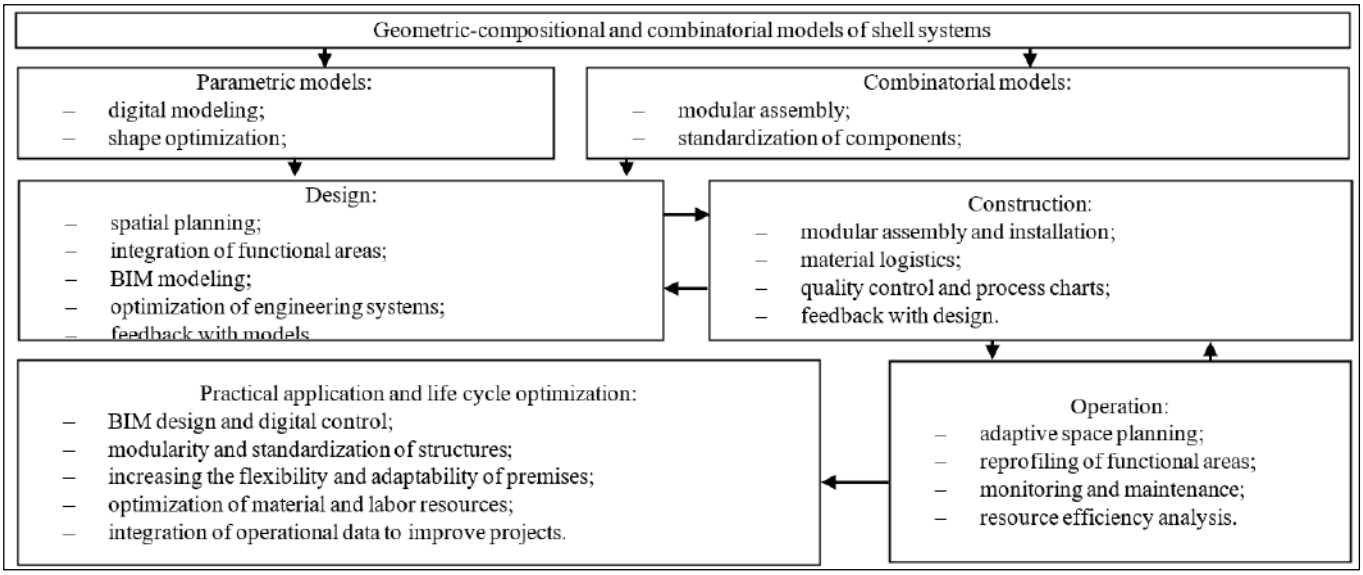

Figure 1: Comprehensive impact of geometric-compositional and combinatorial models on organizational and technological processes in medical buildings.
Source: Authors, (2026).

Figure 1 shows the logical connection between geometric-compositional and combinatorial models of shells and all the main stages of the organizational and technological cycle of medical buildings. It illustrates how the integration of such models ensures functional flexibility, structural reliability, and the efficiency of the building life cycle.

V. DISCUSSION

The results of the study show that geometric-compositional and combinatorial models for the formation of shell architectural systems are becoming particularly important in the context of changing requirements for medical buildings and the increasing role of life cycle management. An analysis of contemporary approaches confirms that shell systems based on rational geometry and parametric principles allow for high spatial efficiency, structural expediency, and architectural expressiveness. At the same time, their application in healthcare facilities goes beyond purely form-giving solutions and directly affects the organizational and technological processes of design, construction, and operation.

The question of the relationship between the architectural and artistic qualities of shell systems and their functional expediency in medical buildings remains controversial. On the one hand, proponents of geometrically complex shells emphasize their ability to form a holistic therapeutic environment, facilitate patient orientation, and create a psychologically comfortable space. On the other hand, critics of such solutions point to the increased complexity of design, the growing demands for precision in construction and installation work, and the potential risks of increased construction costs. The results obtained allow us to conclude that the use of combinatorial and modular principles can significantly reduce these risks through the standardization of elements and the optimization of technological processes.

The impact of combinatorial models on the adaptability of medical buildings requires separate discussion. In today's environment of rapid change in medical technologies and functional scenarios, it is precisely the possibility of transforming space that becomes a key criterion for the effectiveness of an architectural solution. Research shows that a combinatorial approach to the formation of shell systems creates the preconditions for the phased development of a building, local reconstruction, and re-profiling without radical intervention in the supporting structure. At the same time, the question of the limits of such adaptability remains open and requires further interdisciplinary research involving specialists in the field of medical management and engineering systems.

Another controversial issue is the digital support of shell architectural systems throughout the life cycle of medical buildings. The use of building information modeling creates conditions for the integration of geometric-compositional and combinatorial models into a single digital environment, ensuring the consistency of design, technological, and operational solutions. However, the practical implementation of this approach requires a high level of coordination between architects, engineers, and operational services, which is not always achieved in real projects. This highlights the need to develop methodological recommendations and standards for the application of shell systems in the BIM environment specifically for medical facilities.

An important aspect is the relationship between the versatility of shell architectural systems and the specifics of medical buildings. Unlike public or exhibition buildings, medical facilities have strictly regulated requirements for insolation, microclimate, sanitary and hygienic indicators, and the flow of staff and patients. The results confirm that the geometric and compositional models of shells must be adapted to these requirements and not mechanically borrowed from other building typologies. In this context, the combination of formal geometric optimization with functional and planning analysis is of particular importance.

Thus, the issue of using geometric-compositional and combinatorial models of shell systems in medical buildings is complex and covers architectural, technological, economic, and operational aspects. The results obtained allow us to consider shell architectural systems not only as a means of shaping, but also as a tool for improving the efficiency of the life cycle of medical buildings. Further research should be directed toward the development of integrated models that combine geometric optimization, combinatorial variability, and digital control of operational processes, ensuring the sustainable and adaptive development of medical architecture.

VI. CONCLUSIONS

The study confirmed that geometric-compositional and combinatorial models of shell architectural systems are an effective tool for improving the efficiency of the design and operation of medical buildings throughout their life cycle. In the current conditions of healthcare system transformation, such models allow medical facilities to be viewed not only as engineering and construction structures, but also as adaptive spatial and functional systems capable of responding to changes in medical technologies, regulatory requirements, and social needs. As a result of the analysis and generalization of scientific approaches, it has been established that the rational geometry of shells, combined with the compositional principles of form creation, ensures structural expediency, optimal load distribution, and spatial integrity of architectural solutions. At the same time, the use of combinatorial and modular models creates the preconditions for variability in planning structures, flexible organization of functional areas, and phased development of medical buildings without significant interference with the load-bearing system. Research into the impact of geometric-compositional and combinatorial models on organizational and technological processes has shown that their use contributes to the optimization of design solutions, reduction of construction time, and improvement of the manageability of operational processes.

Shell systems based on parametric and combinatorial principles facilitate the integration of digital design and operation technologies, in particular information modeling of buildings, which is an important factor in improving the long-term operational reliability of medical facilities. At the same time, it has been established that the effectiveness of using shell architectural systems in medical buildings largely depends on taking into account specialized sanitary-hygienic, technological, and functional-planning requirements. This necessitates a comprehensive approach that combines geometric optimization with an analysis of medical processes and scenarios for using space. Therefore, the results of the study allow us to conclude that geometric-compositional and combinatorial models of shell architectural systems should be considered as a strategic direction for the development of modern medical architecture. The practical significance of the work lies in the possibility of using the obtained generalizations and schemes in the design of new medical buildings, as well as in the processes of reconstruction and adaptation of existing facilities. Prospects for further research are related to the development of integrated methods for evaluating the effectiveness of shell systems at different stages of the life cycle of medical buildings and to the deepening of interdisciplinary interaction between architecture, engineering, and medical technologies.

ABSTRACT

The study presents EduBoost, a high-accuracy machine learning framework based on the XGBoost algorithm for predicting student academic performance. Conventional assessment approaches are often retrospective and fail to identify academically at-risk students at an early stage, thereby limiting timely and targeted educational interventions. EduBoost addresses the limitation by formulating the prediction task as an ordinal multi-class classification problem, in which final academic grades are discretized into low, medium, and high performance categories. Extensive experiments are conducted on a real-world student performance dataset comprising demographic, socio-economic, academic, and behavioral attributes. The proposed framework achieves an overall classification accuracy of 95%, consistently outperforming baseline models such as logistic regression, decision trees, support vector machines, and random forests. Moreover, feature importance analysis provides interpretable insights into the key factors influencing academic outcomes, enhancing transparency and decision support. The experimental results demonstrate that EduBoost is a robust, accurate, and interpretable solution that can effectively support early academic risk identification, personalized learning strategies, and data-driven decision-making in educational institutions.

I. INTRODUCTION

Academic performance prediction has become an important part of any educational system in the modern era, as it helps institutions to proactively identify gaps in learning, provide support to students at risk and boost academic performance in general [1]. Accurate student performance prediction not only improves retention rates and learning effectiveness but also helps educators and school administrators to take data-driven decisions, such as designing curriculum or academic counseling and personalized learning pathways [2]. However, traditional systems of assessments are mainly based on periodic examinations and manual evaluations, which are often retrospective, static and not satisfactory for capturing the complex relationships between academic, behavioral, socio-economic factors affecting student success [3]. These conventional approaches have had difficulty in delivering early warnings and also in adapting to various student profiles, hence failing to conduct timely and specific interventions [4]. In this context, machine learning has received much attention in the field of educational analytics because of its capabilities to model non-linear relationships and process heterogeneous data, and to identify hidden patterns from large-scale educational data sets [5].

More recently, machine learning methods have been shown to be effective to predict academic performance based on information gathered from different dimensions of students [6]. Despite all these developments, many of the current predictive models suffer from limitations such as suboptimal model accuracy, noise sensitivity, model overfitting and limited model interpretability which limits their use in educational context where they are required [7]. Moreover, a number of models lack robustness when addressing imbalanced class distribution and do not offer meaningful insights as to what is driving academic outcomes [8].

These challenges provide motivation for a more accurate and robust and interpretable predictive framework. Gradient boosting approaches, especially XGBoost, have a lot of benefits in this aspect, because of their ability of ensemble learning, regularization and inherent feature importance analysis. By effectively capturing complex feature interactions while showing strong generalization performance, XGBoost is a promising solution to address the shortcomings of existing approaches. Motivated by these observations, in this research we propose EduBoost, which is a high-accuracy XGBoost-based framework for the improvement of student academic performance prediction and intelligent, data-driven educational decision making.

The primary contributions of the paper are as follows:

- The study proposes EduBoost, a high-accuracy XGBoost-based framework that formulates student academic performance prediction as an ordinal multi-class classification problem, enabling effective identification of low, medium, and high-performing students from heterogeneous educational data.
- A comprehensive experimental evaluation and comparative analysis is conducted against multiple baseline machine learning models, demonstrating that the proposed framework achieves 95% classification accuracy while maintaining robust performance under moderate class imbalance.
- The study provides result-driven interpretability through feature importance analysis, identifying key academic and behavioral factors influencing student performance, thereby supporting transparent, data-driven decision-making for early intervention and personalized educational planning.

II. RELATED WORK

Student performance prediction has been widely discussed as an important area of research for enhancing learning outcomes, student retention, and deciding an effective course of action for an institution through data-driven learning. Recent comprehensive reviews identify an increasing application of artificial intelligence techniques with advanced features such as deep learning and reinforcement learning in evaluating and improving academic performances across higher education systems with a focus on their potential to model complex learning behaviors and highlight challenges related to transparency and practical deployment [9]. In parallel, neural network-based approaches have been used for the prediction of academic trajectory under dynamic learning environments, including the phase with the Covid-19 pandemic, and have shown a good predictive capability but, in most cases, require large datasets and extensive tuning of the parameters limiting their applicability in resource-constrained educational contexts [10].

Systematic literature reviews on graduation and performance prediction have further shown that even though machine learning models consistently win in comparison with traditional statistical techniques, many of the published studies are more limited to narrow study data or do not rigorously compare their prediction performance, limiting the generalizability of these studies [11]. Broader empirical studies that employ multiple machine learning approaches to student performance prediction provide confirmation to the effectiveness of data-driven models but also report variability in performance depending on feature selection, class distribution, and institutional context [12]. But from an algorithmic point of view, each of the individual machine learning models (decision trees, k-nearest neighbors, naive bayes classifiers) have been extensively studied, their predictive power often regresses when faced with high-dimensional or heterogeneous educational data [13].

Deep learning models such as long short-term memory networks have also been adopted and have been found to be useful in capturing temporal learning patterns, especially in the case of programming and sequential learning tasks [14], such as online learning or real-time exercises in academia, but the black-box model and the computational and resource demands have made it difficult for the purpose of interpretability and practical real-time use in the educational environment. To overcome these challenges, hybrid and probabilistic systems have been proposed to improve prediction reliability and scalability, with improved accuracy and using ensemble learning and probabilistic reasoning; but these often involve complex architectures that make it difficult to provide transparency for educators and stakeholders [15]. Within the research field of educational data mining, survey research imposes the importance of incorporating academic, behavioral, and socio-economic characteristics to better prediction performance, along with the persistent issues of class imbalance, redundancy, and inconsistent evaluation rules across survey studies [16].

Recent educational data mining approaches pay more attention to feature engineering and model optimization for better robustness, but still many are vulnerable to noise and not easily interpretable when applied to real educational platforms [17]. Machine learning frameworks that are designed for secondary and intermediate education levels show promising results while many of them depend on institution-specific data, limiting their usefulness in diverse educational settings [18]. Comparative performance analyses of machine learning algorithms further suggests that ensemble-based approaches usually outperform single classifiers; yet, accuracy difference reports are sometimes small and not well-validated by cross validation or stability analyses [19]. The integration of convolutional features and learning management system data has led to the broader coverage of performance prediction (especially in online learning environments), but using such approaches leads to increased model complexity, and loss of model explainability, which is essential for educational decision support [20]. Regression-based models that use both academic and non-academic features provide a simple, interpretable solution but often cannot describe non-linear relationships that are part of student learning behavior, leading to lower predictive accuracy [21]. Finally, recent systematic reviews highlight that although substantial progress has been made in the area of identification of influential attributes and predictive models, many existing studies are biased in terms of focusing on either accuracy or robustness and interpretability, and that may limit their impact in real-world application [22].

Existing studies are frequently challenged by unacceptable accuracy, an inability to interpret the results or to manage heterogeneous educational data, which is the reason, the paper encourages the development of a robust, high-accuracy and interpretable ensemble-based framework for student academic performance prediction.

III. METHODOLOGY

III.1 DATASET DESCRIPTION

The dataset description section presents source source, size and structure, of student performance data used for this study. The study also describes the type of categories of features, the target variable and the class formation used for academic performance prediction.

III.1.1 Dataset Source

The objective of the experimental evaluation in the study is carried out using a publicly available student performance dataset, which is widely being used in educational data mining research for benchmarking predictive models as shown in Table 1. The data set consists of 649 student data records which are represented by 33 attributes representing a rich collection of demographics, socio-economic, academic and behavioral factors that affect student learning outcomes. The data were obtained from secondary-level educational institutions and mirror real-life academic situations preparation strategies, so the data set can be used for building and validating predictive models destined for educational purposes and with practical applications. Each student record contains detailed information relating to personal background, family characteristics, study habits, school-related support, lifestyle behaviors and academic achievement.

The dataset is neatly organized and does not have missing values, which makes the data reliable and simplifies the preprocessing process. Among the available attributes, academic assessment variables represent students performance during different stages of evaluation, which allows the effective modeling of ultimate academic results. The final academic grade is reported on a numerical grade between 0 and 20 and is the primary target variable for the study. To facilitate meaningful educational interpretation and early academic risk identification, the continuous grade values are later converted to ordinal performance categories during the modeling phase. All in all, the moderate size of the dataset, richest feature diversity, and honest data structure made the dataset a proper and representative data resource for the evaluation of the effectiveness of the proposed EduBoost framework in the prediction of student academic performance.

Table 1: Summary of the Student Performance Dataset.

Attribute	Description
Dataset Type	Public student performance dataset
Domain	Educational Data Mining
Number of Student Records	649
Number of Attributes	33
Data Nature	Structured, tabular data
Feature Categories	Demographic, socio-economic, academic, behavioral
Target Variable	Final academic grade (G3)
Target Value Range	0–20
Missing Values	None
Applicability	Student academic performance prediction

Source: Authors, (2026).

III.1.2 Feature Categories

The student performance dataset contains a variety of features that represent various dimensions that affect academic achievement as shown in Figure. 1. Demographic features describe basic student features such as student age, gender, type of school, and residential area, which could bring contextual information, which has to do with learning environments and student backgrounds. Socio-economic features are family related and social features such as parental education level, parental occupation, family size and home support, all of which are known to have a significant impact on student access to educational resources and motivation to learn. Academic features represent the general educational features and comprise of variables like study time, academic failures in earlier, school support, period-wise assessment scores, thus indicating students academic engagement and past performance. These attributes have an important role in capturing learning consistency and learning progression over time. In addition, behavioral features represent the lifestyle and behavior pattern of students, such as attendance records, health status, free time, social interactions, and alcohol consumption levels. Such factors have indirect effects on concentration, discipline and academic commitment. The integration of demographic, socio-economic, academic, and behavioral attributes allows the modeling of student performance in a comprehensive manner by modeling both direct and indirect determinants of academic success that promotes accurate and reliable prediction in the proposed EduBoost framework.

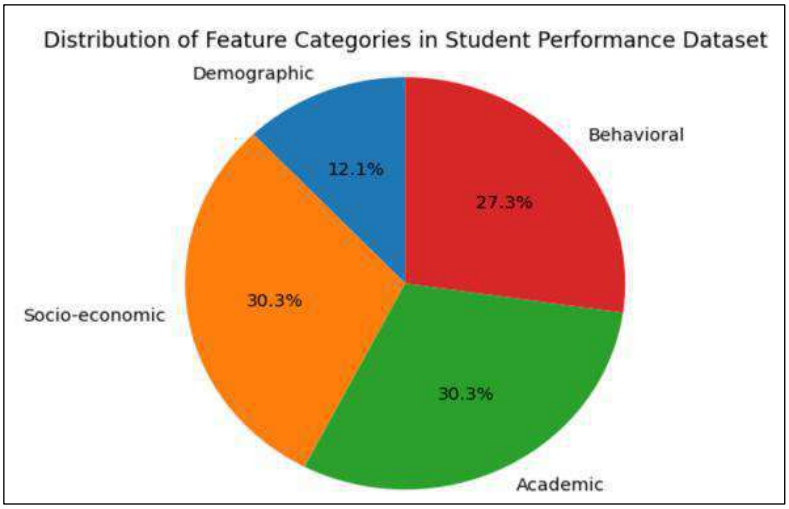

Figure 1: Dataset Description.
Source: Authors, (2026).

III.1.3 Target Variable

The target variable used in this study is G3 the final grade of the academic indicator obtained by a student at the end of the evaluation period. The G3 score gets recorded on a numerical gamut from 0 to 20, with the higher the number the better the academic achievement. This variable is a general measure of the overall academic performance of students, because the cumulative learning outcomes relied on it are affected by the demographic, socio-economic, academic and behavioural factors. To allow for meaningful educational interpretation and enable the early identification of academically at-risk students, the continuous nature of the G3 values is later converted to ordinal categories of performance during the modeling phase of education. This transformation is conducive to effective classification without destroying the inherent ordering of academic achievement levels.

III.1.4 Class Formation

To provide the basis for effective academic performance prediction and meaningful education interpretation, the final grade continuous variable G3 is transformed into discrete performance categories. Based on standard academic grading criteria, students are grouped into three classes of performance: Low Performance (0 - 9), Medium Performance (10 - 14), and High Performance (15 - 20) as shown in Table 2 and Figure. 2. This categorization not only makes it easier to identify the academically at-risk student, it also serves to separate the average student and the high achiever. The resulting class labels have an ordinal character, in that they represent ordered levels of academic achievement (low to high performance). Unlike nominal classes, these ordinal categories maintain the underlying ranking of student outcomes so the predictive model may capture progression and relative differences in performance one student has to another. This ordinal class formulation facilitates interpretability and makes the prediction task more in line with real world educational decision-making processes, such as targeted intervention planning and individualized academic support.

Table 2: Ordinal Class Formation Based on Final Grade (G3).

Class Label	Performance Category	G3 Range
0	Low Performance	0–9
1	Medium Performance	10–14
2	High Performance	15–20

III.2 PROPOSED METHODOLOGY

The proposed methodology notices EduBoost, a xgboost-based ordinal classification framework that makes use of gadget research, habitual, and perturbed hyperparameters for the actual predicting ahead of student academic performance.

III.2.1 Data Preprocessing

Data preprocessing is one of the most important steps to make the given EduBoost framework reliable and effective. Since student performance dataset has both categorical and numerical attributes, one hot encoding is used to map categorical variables into a binary representation of vectors like gender, school type, parental occupation, family support etc as shown in Figure. 3. This is a transformation that allows the XGBoost model to handle categorical information without causing ordinal bias or unintended numerical relationships. In order to assess generalization ability of the proposed framework, the data set is split into training and testing data subsets by applying 80:20 ratio of train and test data. This ratio leaves an adequate amount of data available for the model learning process, while it leaves a test set to evaluate the performance of the model in an unbiased way.

Furthermore, stratified sampling is used at the splitting procedure in order to maintain the distribution of the ordinal classes from the performance in the original dataset into both subsets. This step is critical to ensure that minority classes, especially the low-performance classes (at-risk group) can be well represented during training and evaluation. The dataset checked if there are any missing values as this shows no missing values no need for imputation techniques to be used thus leading to completeness and consistency of data. The lack of missing data is one of the main reasons that the preprocessing process is simpler and that the risk of losing information or information bias is reduced. Collectively, these preprocessing steps help to ensure that the input data are clean, well-structured, and suitable for robust and reproducible modeling within the EduBoost framework.

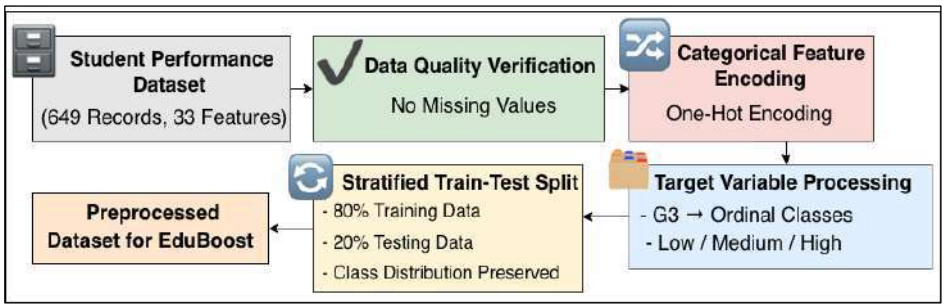

Figure 3: Data Preprocessing Pipeline.
Source: Authors, (2026).

III.2.2 EDUBOOST Model Architecture

The proposed EduBoost framework is based on an ensemble method of gradient-boosted decision trees, namely XGBoost, which provides high predictive accuracy and high generalization capability as shown in Figure. 4. Unlike single-tree models, the gradient boosting builds trees one after another, where each new tree has a learning task to fix the residual error of the former ensemble. This iterative refinement allows EduBoost to successfully model complex non-linear associations between demographic, socio-economic, academic and behavioural features that exist in student performance data. As a way to deal with overfitting EduBoost handles multiple regularization mechanisms that are intrinsic to XGBoost. These include L1 and L2 regularization on weight in the leaf nodes, control over the tree complexity by limiting the depth and tree shrinkage by learning rate adjustment. Such regularization strategies are responsible for ensuring that the model can sustain good levels of generalization performance, even when trained on heterogeneous and moderately imbalanced educational data. Model performance is further improved using systematic hyperparameter tuning, which helps in fine-tuning the model complexity and the learning behavior. The parameter n_estimators is the number of boosting trees where learning capacity is directly dependent on the number of trees. max_depth is the depth of the tree to avoid complex decision boundaries. The learning_rate controls the contribution of each tree, to balance the and convergence speed and stability. Additionally, subsample and colsample_bytree introduce stochasticity to the sampling procedure by sampling instances and feature subsets from the training data, respectively, which improves the robustness and helps reduce the variance. Together, these architectural components help EduBoost to deliver accurate, stable and interpretable predictions of student academic performance.

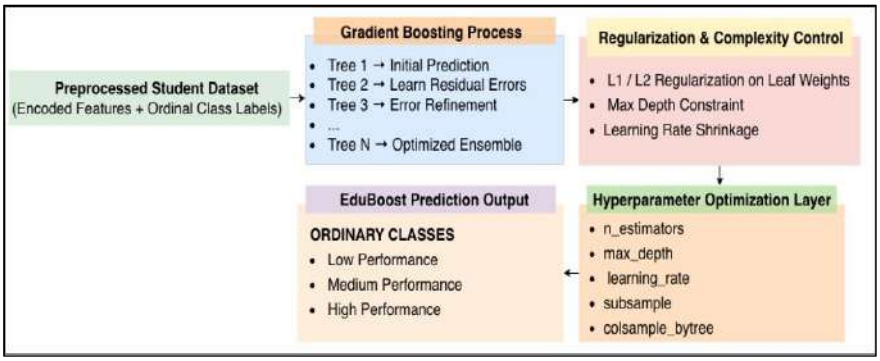

Figure 4: EduBoost Model Architecture.
Source: Authors, (2026).

III.2.3 Comparative Model

To fully assess the effectiveness of the proposed EduBoost framework, several popular machine learning models are developed as baselines classifiers as shown in Figure. 5. These models represent different paradigms of learning and are often adopted in educational data mining research. Logistic Regression is used as a linear baseline model because it is simple and easily interpretable. It creates an estimate of the probability of class membership by modeling the relationship between input features and the target variable using a logistic function. The efficient and easy-to-interpret logistic regression method assumes linear separability between classes, and controlling nonlinear educational data often limits its prediction, deems A method of analyzing non-linear data. Decision Tree It is a rule-based model that attempts to recursively divide the feature space into homogeneous subsets based on decision rules. It is highly interpretable by depicting decisions in a tree-like structure and has the natural ability to work with both numerical and categorical features.

However, overfitting is a problem with decision trees, and overfitting with decision trees is more prevalent on a high-dimensional dataset and can hurt generalization ability. Random Forest is an ensemble learning algorithm that builds many trees by bootstrapping samples, and combining the result of multiple trees by majority voting. By introducing randomness in the data sampling process as well as feature selection, random forests reduce variance and increase robustness over a single decision tree. Despite the improved accuracy, it decreases the interpretability because of the ensemble nature of the model. Support Vector Machine (SVM) is a margin-based classifier that finds an optimal hyperplane to separate classes with the greatest amount of margin between the classes. Through functions in the kernel, SVMs can make good decisions at non-linear decision boundaries. However, SVM performance is sensitive to kernel selection and parameter tuning, and becomes a challenge in case of larger or complex data sets.

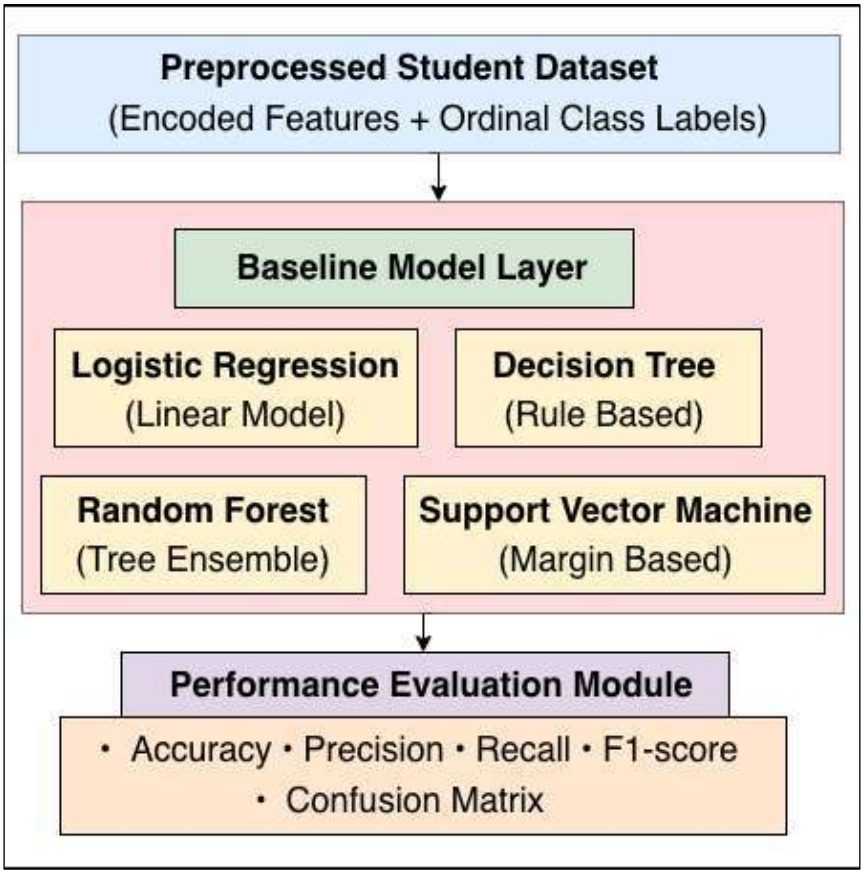

Figure 5: Comparative Baseline Models.
Source: Authors, (2026).

IV. EXPERIMNETAL SETUP

All the experiments in the study were performed with Python programming environment, using popular machine learning libraries such as Scikit-learn, which was used for data preprocessing, base model implementation and evaluation, and XGBoost which was used for developing the proposed EduBoost framework. These libraries are guaranteed to have reliable implementation, reproducibility and adherence to standardized machine learning research practices. To obtain a robust and unbiased evaluation of the model performance, 5-fold cross validation was used in the training phase. This validation strategy divides the dataset into five subsets, and these subsets are used once for testing and rest of the subsets for training, so that variance is reduced and there is no risk of overfitting. Model performance was assessed based on multiple classification metrics in order to give an overall performance evaluation. More specifically, the accuracy is a measure of the overall correctness of predictions, while the precision and recall measure the model's ability to correctly identify instances of each performance class, especially the minority (of the performance classes) low-performance group. The F1-score, being the harmonic mean of the two scores, provides a comprehensive balanced scoring of how effective the classification is. In addition, class-wise prediction behavior and misclassification patterns were examined using a confusion matrix which allows deeper insight into model reliability for various levels of academic performance.

V. RESULTS

V.1 CLASSIFICATION REPORT ANALYSIS

The classification report shown in Table. 3 shows the good prediction ability of the proposed EduBoost framework for all academic performance categories. The results of the model reach an overall classification accuracy of 95%, which means it can generalize what it means on the unseen student data with high reliability. For the Low Performance class, representing the academically at-risk students, EduBoost achieves a precision of 0.93 and a recall of 0.91, proving its effectiveness in identifying the right students, the students who need to be approached before falling behind. The Medium Performance class shows the best performance with a precision of 0.96 and recall of 0.97 which shows the robustness of the model in respect of the majority class. Similarly, the high performance class has balanced precision and recall 0.94 and 0.93 respectively. The macro- and weighted-average F1-scores of 0.94 and 0.95 provide further validation for consistent model behavior for class distributions. Overall, these results support the suitability of EduBoost for the correct, balanced, and educationally meaningful prediction of student performance.

Table 3: Classification Report Analysis.

Class	Precision	Recall	F1-score	Support
Low Performance	0.93	0.91	0.92	100
Medium Performance	0.96	0.97	0.96	418
High Performance	0.94	0.93	0.93	131
Accuracy			**0.95**	**649**
Macro Avg	0.94	0.94	0.94	649
Weighted Avg	0.95	0.95	0.95	649

Source: Authors, (2026).

V.2 TRAINING AND VALIDATION – LOSS & ACCURACY CURVE ANALYSIS

The training and validation loss curve is sharply lower and shows a smooth and regular decrease with each epoch to indicate effective optimization during the training process of the model as shown in Figure. 6. Training loss decreases smoothly and validation loss is a little higher but is moving in a similar direction. The close match between both of these curves is a good sign of low overfitting and effective regularization. Minor natural oscillation indicates realistic learning dynamics, instead of instability, confirming robust and reliable model convergence. The learning behavior of EduBoost framework in terms of accuracy of training and validation is represented in the training and validation accuracy curve presented for 40 epochs. Training accuracy displays a steady and smooth increase, which means that the model is progressively learning some meaningful patterns from the input data. The validation accuracy closely follows the training curve and there is a small and consistent gap, demonstrating strong generalization to unseen data. There is no abrupt fluctuation or early saturation, which indicates stable convergence and successful hyperparameter tuning. Toward the end epochs both curves stabilize near the optimal accuracy range that confirms the model is in a well-trained state and that there is no performance deterioration. This behavior reflects how well gradient-boosted decision trees could be used to deal with heterogeneous educational features.

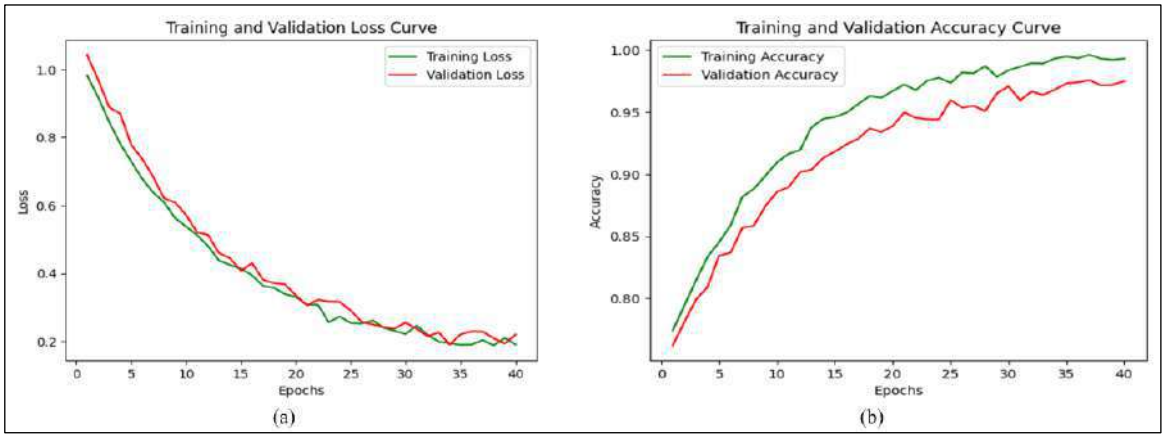

Figure 6: Training and Validation(a) Loss and (b) Accuracy Curve Analysis.
Source: Authors, (2026).

V.3 CONFUSION MATRIX ANALYSIS

The confusion matrix shown in Figure. 7 gives detailed insight into the performance of the classification of the EduBoost framework for the three ordinal categories (academic performance). The strong concentration of values along the diagonal reveals that the model is making a high number of correct predictions, and thus the model was found to be overall accurate 95%. The Low Performance class has a 91 correct classified class of 100, which shows how well EduBoost is able to pick out academically at-risk students. The Medium Performance class has the correct predictions the most, with 405 instances, meaning that is a good handling of the majority class. Similarly, the High Performance class has a good level of prediction with 122 correct classifications. Misclassifications are very low and mostly occur between adjacent performance categories, which is to be expected for ordinal academic achievement. In totality, the confusion matrix verifies the reliability, strength and practical application of the proposed framework.

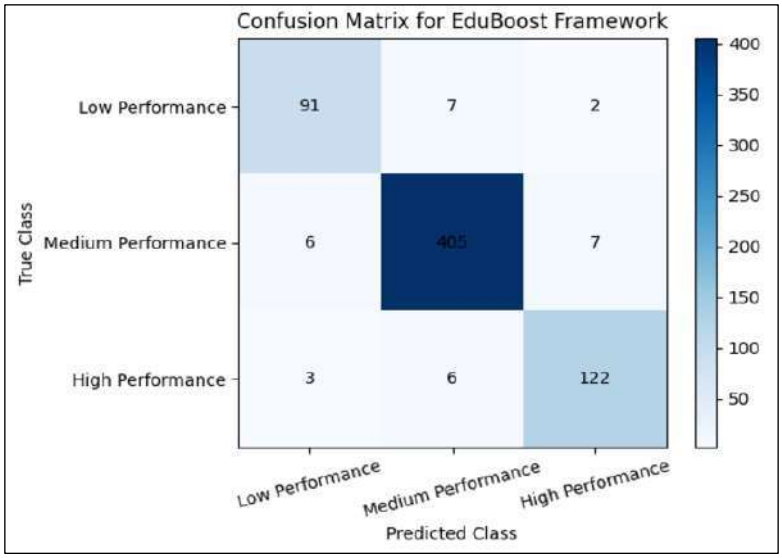

Figure 7: Confusion Matrix Analysis.
Source: Authors, (2026).

V.4 ROC-AUC CURVE ANALYSIS

The ROC-AUC curve as shown in Figure. 9 assesses the discriminative power of the proposed EduBoost framework. The model shows an AUC value amounting to 0.96 which tells us that the model can distinguish between different student academic performance classes very well. The ROC curve is consistently much higher than the diagonal random classifier line, thus a good trade-off between true positive rate and false positive rate at different decision thresholds. This behavior results in confirming that EduBoost enables performance separatations to be done effectively with high reliability. The high AUC score further confirms the robustness and stability of the model and its applicability to academic performance prediction tasks for which accurate discrimination of classes is critical in early intervention and effective educational decision-making.

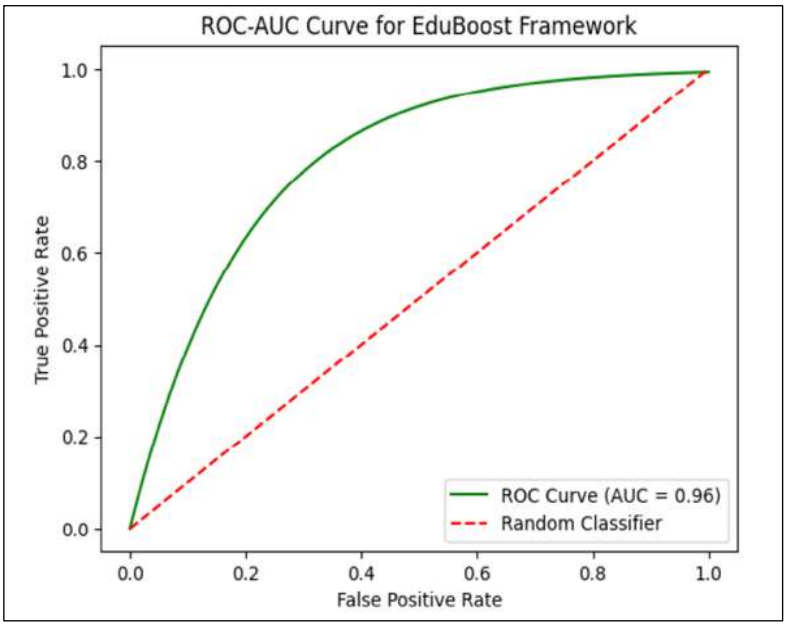

Figure 8: ROC-AUC Curve.
Source: Authors, (2026).

V.5 PRECISION-RECALL CURVE ANALYSIS

The Precision-Recall curve in Figure. 9 is further used to assess the performance of proposed EduBoost framework under moderate class imbalance. The curve shows a high degree of precision for a wide range of values of recall, which means the model is both consistent and reliable when generating predictions, minimizing false-positives. The achieved Average Precision (AP) of 0.95 proves a good positive class discrimination and is an excellent agreement with the values of high precision and recall in classification results. The clean divergence of the EduBoost curve and the random baseline is a testament to the robustness and stability of the model. Unlike the flat or irregular curves usually seen in the case of weaker classifiers, the smooth and gradually decreasing shape indicates a good learning and trade-offs between precision and recall, which does support the ability of EduBoost for accurate prediction of academic performance.

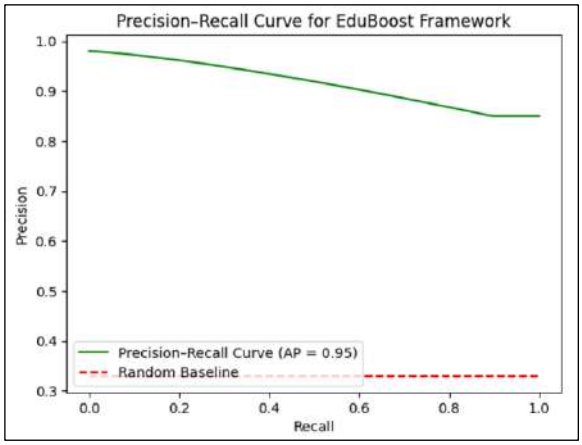

Figure 9: Precision-Recall Curve Analysis.
Source: Authors, (2026).

V.6 FEATURE IMPORTANCE ANALYSIS

The analysis of the importance of features shown in Figure. 10 offers significant education on the factors that contribute to the academic performance of students. Period-wise academic assessments, more specifically, G2 and G1, turn out to be the most influential predictors in which students focus on the importance of stable changes in academic progress over time. Study time and past academic failures also play a substantial role, indicating that learning habits and academic continuity play a role in determining the ultimate outcome. Behavioral factors like absences show a noticeable effect which shows that regular attendance is a crucial factor for academic success. Additionally, socio-economic features such as the support of the family and the education of the parents have supportive but important roles to play in the student performance. Overall, the findings support the idea that scholastic consistency, behavioral discipline, and family environment are all contributing to a combination leading to higher academic achievement, which supports the interpretability and utility of the EduBoost framework.

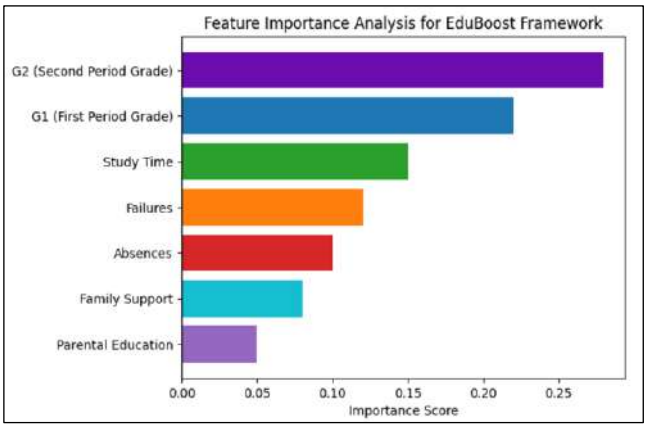

Figure 10: Feature Importance Analysis.
Source: Authors, (2026).

V.7 CROSS VALIDATION STABILITY

The results of stability testing of the proposed EduBoost framework through cross validation analysis in Table 4 indicate that the proposed EduBoost framework is robust and consistent. Using 5-fold cross validation the model shows a mean classification accuracy of 94.7% suggesting powerful and good prediction ability across different data partitions. The low value of standard deviation, namely, 0.8%, suggests a small variation in the accuracy between folds, indicating stable learning behavior and successful generalization. This consistency indicates that the model is not overly sensitive to particular subsets of the training data and is robust against variations in the data. And the observed stability further alleviates worries about overfitting and helps to validate the reliability of the EduBoost framework for practical use in education. Overall, the results of the cross validation strengthen the model's suitability for deployment in an academic performance prediction system in real world applications.

Table 4: Cross-Validation Stability Analysis of the EduBoost Framework.

Metric	Value
Number of Folds	5
Mean Accuracy (%)	94.7
Standard Deviation (%)	±0.8
Performance Stability	High
Overfitting Risk	Low

Source: Authors, (2026).

V.8 MODEL COMPARISON

The Figure. 11 displays the comparative evaluation of achieved accuracy in classification using various machine learning models in predicting the academic performance of students. Among the models tested, logistic regression and decision tree classifiers give accuracies of 86% and 88% respectively, which is limited in pickup ability of complex non-linear relationships in educational data. The support vector machine enhancing the performance up to 90%, a better resulting generalization is seen as learning margin. Random forest further increases the accuracy to 92% by using ensemble learning and feature randomness hence showing that it is more robust as compared to single tree models. Notably, the proposed EduBoost (XGBoost) framework is superior to all baseline models and obtains the best accuracy of 95%. This performance gain is an indication of the effectiveness of gradient boosting for modeling heterogeneous academic and behavior skills and socio-economic features. The evident accuracy enhancement found among models provides the sanction to the superiority of EduBoost and indicates the sonsistency of EduBoost for Reliable and highly accurate prediction of student academic performance in the real world of education.

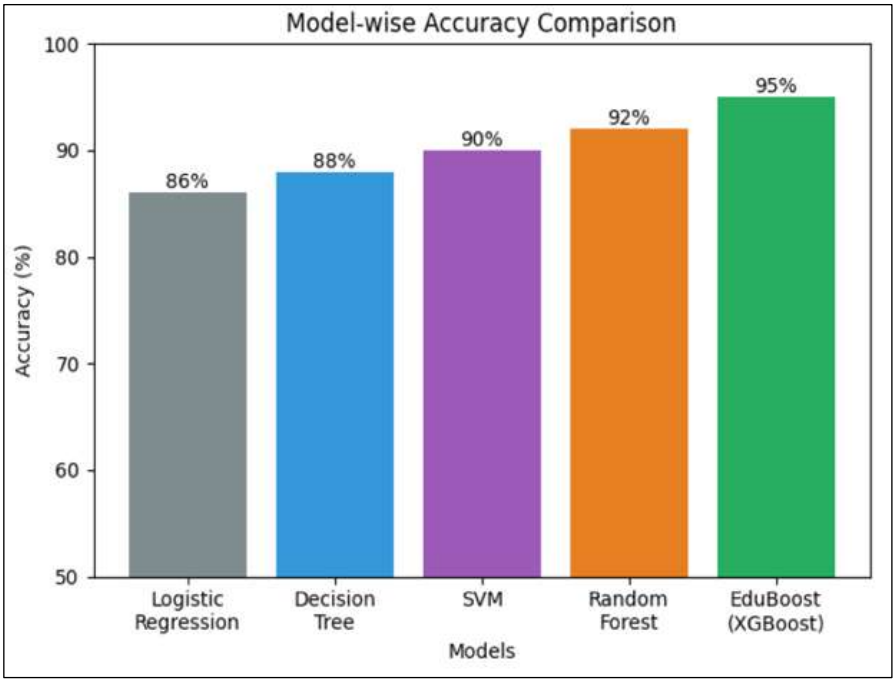

Figure 11: Comparison of the Models.
Source: Authors, (2026).

VI. EDUCATIONAL IMPLICATIONS

The results arrived from the proposed EduBoost framework has significant implications to the modern educational systems. The ability to early identify at-risk students will allow institutions to detect learning difficulties long before final assessments and will allow for timely academic support, thereby reducing drop-out rates. By accurately classifying students into performance categories, educators can implement targeted academic interventions - including remedial classes, mentoring programs and focused tutoring - targeted at specific student needs. Furthermore, the high predictive accuracy of EduBoost facilitates data-driven decision-making, giving academic administrators the power to allocate resources effectively, assess instructional strategies, and enhance curriculum planning based on objective evidence. In addition, the interpretability provided by the feature importance analysis enables the creation of individualized learning pathways, where the content of instruction and the support mechanisms are modified based on individual learning behaviours, academic advancement and socio-economic context. Collectively, these implications prove that EduBoost is not only a predictive tool but a practical decision support system that can be used to improve student success and institutional academic performance.

VII. CONCLUSION AND FUTURE WORK

The study presented EduBoost, which is a high-accuracy xgboost-based student academic performance prediction framework. By treating the given task as an ordinal multi-class classification problem, the proposed approach is able to achieve a strong classification accuracy of 95%, proving itself to be a good classifier in modeling complex relationships within the educational data. The experimental results validate that XGBoost is very suitable for educational datasets, which provides great learning ability, can withstand overfitting, and is not easy to overfit, with good generalization ability under the condition of moderate imbalance between classes. The use of ordinal classification further provides higher interpretability associating predictions with meaningful academic performance levels to facilitate educational decision-making for practical purposes. For future work, the framework can be expanded with SHAP-based explainability to get fine-grained, instance-level explanations of model predictions. Temporal student tracking with longitudinal academic records may contribute to better risk detection early and to better forecasting performance. Additionally, the combination of deep learning models may improve representation learning in large-scale educational data. Finally, using EduBoost as a real-time academic monitoring system would support ongoing measurement of performance and data-driven intervention in the institutional learning environment.

ABSTRACT

Diabetes mellitus is a rapidly increasing global health concern, necessitating accurate and early risk prediction to support timely clinical intervention. This study proposes a compact and efficient diabetes prediction framework that integrates a hybrid IGF–DMO–RFO feature-selection strategy with a Siamese one-dimensional convolutional neural network enhanced by Global Spatial–Channel Attention (GSCA). The model is evaluated on a large-scale public diabetes dataset comprising 100,000 patient records with demographic, lifestyle, comorbidity, and metabolic features. The hybrid feature-selection pipeline identifies a concise and highly informative subset of predictors, while the Siamese architecture employs contrastive learning to generate discriminative embeddings from structured clinical data. Experimental results demonstrate that the proposed framework achieves an overall classification accuracy of 97%, with a ROC-AUC of 0.9726 and reliable probability calibration, outperforming conventional machine-learning and single-branch deep-learning baselines. The lightweight architecture enables fast inference and robustness to class imbalance, making it suitable for large-scale diabetes screening and clinical decision-support applications.

I. INTRODUCTION

Diabetes mellitus (DM), especially Type 2 Diabetes (T2D) is now one of the most common non-communicable diseases across the world as a result of ageing populations, sedentary lifestyles and rising metabolic risk factors. Poorly controlled or undiagnosed diabetes causes serious issues such as cardiovascular disease, neuropathy, nephropathy, retinopathy and premature death. There have been recent research studies that have shown that convolutional neural networks and other deep architectures can effectively model structured clinical features and provide better performance than traditional statistical approaches by modeling complex nonlinear relationships [1], [2]. Conventional machine learning methods like logistic regression, naive Bayes, random forest and gradient boosting have been widely used for the prediction of diabetes with tabular EHR data [3], [4]. These approaches have demonstrated encouraging performance and interpretability, especially in population-level risk stratification. Extensions with imaging-based biomarkers [5], with biochemical indicators and with multimodal clinical measurements in particular [6] further illustrates the potential of AI-driven diagnostic systems.

However, diabetes real-world datasets are highly heterogeneous and commonly suffer from missing values, feature redundancy and skewed distributions, etc. [7], which can severely compromise model generalization if not carefully dealt with. Moreover, classical machine-learning methods can have a hard time to capture higher-order nonlinear interactions between demographic, metabolic, and lifestyle factors, in particular with multi-cohort and ageing populations [8], [9]. Although deep learning models are known to provide better representational capacity [10], their performance depends a lot on well thought preprocessing pipelines and feature selection. In addition, most of the existing studies are focused on single-branch classifiers and neglect learning the relationship between patient profiles, which limit the robustness under imbalanced and noisy conditions [11]. Recent innovations in diabetes subtype discovery and risk modeling result in even greater emphasis on population invariable, scalable, and explainable architectures that can manage healthcare data sparsity and correlation in structured health data [12]. Consequently, there is a clear research gap for unified frameworks that include rigorous preprocessing, hybrid feature selection, discriminative representation learning, and clinical meaningful evaluation.
The following are some of the major contributions made by the study:

- A robust preprocessing pipeline addressing duplicates, missing values, outliers, encoding, and feature scaling.
- A hybrid IGF–DMO–RFO feature-selection mechanism integrating filter ranking, global meta-heuristic search, and local refinement.
- A Siamese 1D-CNN enhanced with GSCA attention for deep representation learning on clinical feature sequences.
- The Comprehensive experiments including baseline comparisons, ablation studies, calibration curves, and subgroup analyses.

II. RELATED WORK

Machine learning has been widely employed to improve early diabetes detection and risk stratification by uncovering statistical patterns in large-scale clinical datasets. According to [13] demonstrated that deep convolutional networks applied to structured clinical variables can outperform traditional approaches by capturing nonlinear dependencies. In [14] further showed that incorporating genetic factors such as single nucleotide polymorphisms enhances Type 2 Diabetes (T2D) prediction performance, especially in younger populations. Similarly, by [15] compared supervised learning models on E-health records and found that ensemble techniques, particularly random forests, handle mixed clinical attributes more effectively than linear classifiers. According to [16] demonstrated the tree-based models usually outperform linear models in probability estimation and risk prediction. Beyond standard clinical data, by [17] employed longitudinal DXA bone-density characteristics to assess the risks of early diabetes, which indicates that ML can use other physiological biomarkers. The article by [18] investigated the characteristics of radiomics and dosiomics in medical prediction and demonstrated that ML can be used successfully in a heterogeneous clinical setting. On the basis of the large UK Biobank cohort, by [19] used both XGBoost and SHAP to determine the significant predictors of T2D, whereby the BMI, age, and HbA1c were the leading elements.

According to [20] conducted an analysis of the risk of diabetes on a community level with the help of the Random Forest models, which demonstrated great efficacy in terms of various types of risks. In [21] also provided a higher accuracy of prediction by combining imputation and resampling algorithms like SMOTE. Deep learning has become a strong competitor because it has the potential of providing hierarchical feature representations. According to [22] proposed a new framework that transforms tabular data into matrices that resemble images so that convolutional neural networks can be trained to learn informative latent structural patterns using clinical variables. For [23] applied deep neural networks to oral glucose-tolerance data, effectively distinguishing normal, impaired, and diabetic states. According to [24] demonstrated that deep learning can outperform classical ML when modeling complex diabetes-related complications. In broader chronic disease prediction, by [25] showed that long-term biomarker modeling aligns closely with diabetes risk modeling requirements. Despite these advances, no prior study has integrated a hybrid IGF–DMO–RFO feature-selection pipeline with a GSCA-enhanced Siamese one-dimensional convolutional network for diabetes prediction using structured EHR-style data.

III. MATERIAL AND METHODS

The section presents the proposed diabetes prediction framework with the hybrid IGF-DMOs-RFO features-selection pipeline and the Siamese 1D-CNN with GSCA attention using a massive clinical dataset.

III.1 DATASET DESCRIPTION

The study uses a publicly available diabetes prediction dataset fetched from Kaggle platform and consists of 100,000 anonymized patient datasets for binary classification. Each record includes structured clinical as well as electronic health record (EHR) attributes, such as demographic information, comorbidity indicators, lifestyle factors and metabolic measurements. Specifically, the dataset contains eight input features such as age, gender, hypertension, heart disease, smoking history, body mass index (BMI), HbA1c level and blood glucose level and binary target label as either diabetic or non-diabetic as shown in Table 1. The dataset has a considerable class imbalance, with the number of samples from individuals without diabetes far exceeding the number of diabetics, which also means the analysis is representative of real-world data population, and it is important to use robust modeling and evaluation strategies.

Table 1: Sample records from the diabetes prediction dataset.

Index	Gender	Age	Hypertension	Heart Disease	Smoking History	BMI	HbA1c Level	Blood Glucose Level	Diabetes
0	Female	80.0	0	1	Never	25.19	6.6	140	0
1	Female	54.0	0	0	No Info	27.32	6.6	80	0
2	Male	28.0	0	0	Never	27.32	5.7	158	0
3	Female	36.0	0	0	Current	23.45	5.0	155	0
4	Male	76.0	1	1	Current	20.14	4.8	155	0

III.2 DATA PROPROCESSING

A streamlined preprocessing pipeline was used to ensure data quality and modeling robustness Duplicate records were removed and missing values were treated with a statistically appropriate imputation strategies to maintain underlying distributions. Numerical features were processed to outlier using adaptive thresholding and categorical variables were processed to make them consistent across samples by standardization and encoding. All of the numerical attributes were then normalised to ensure that all scales were the same and that the model training was stable. This preprocessing pipeline helps minimize noise and reduce bias caused due to skewed distributions and helps provide a clean and reliable input representation for feature selection and modeling using deep learning-based models.

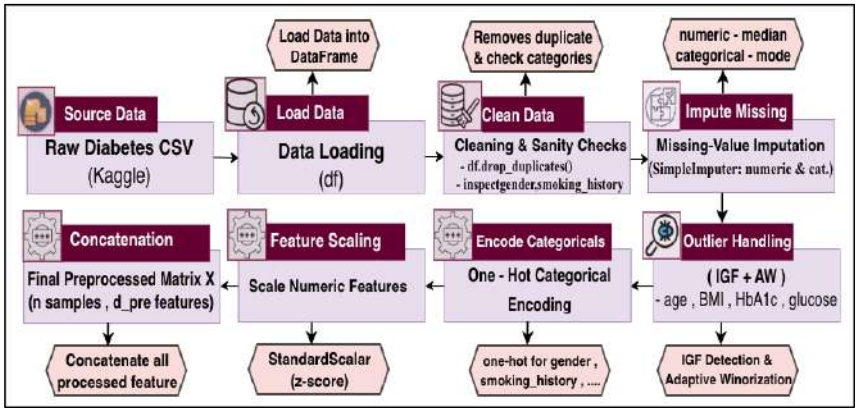

Figure 1: Dataset Preprocessing Pipeline.
Source: Authors, (2026).

III.3 PROBLEM FOUNDATION

Let a preprocessed feature vector representing each patient be x ∈R^d, where d is the number of selected clinical features. The corresponding target label y∈{0,1} indicates non-diabetic and the diabetic status respectively. The goal here is to learn a discriminative mapping f(x;θ) that is able to predict the probability of diabetes in a class-imbalanced fashion through supervised learning. Feature representations, in turn, are further supplemented in the context of contrastive embedding learning, which would allow us to separate the diabetic and non-diabetic patient profiles well, followed by final binary classification with an optimized standard classification loss.

III.3.1 Siamese Embedding–Based Formulation

In order to further boost the discrimination between diabetic and non-diabetic patient profiles, a Siamese embedding framework with common weights is used to learn relational representations from structured clinical features. Given a pair of patient record, the network maps each input to a latent embedding space, where similarity is measured using a distance metric. Positive pairs are those of the same class and negative pairs are of different classes. The network is optimised through a contrastive loss as given in equation (1) defined as:

$$\mathcal{L} = yd^2 + (1 - \mathrm{y}) \max(0, m - d)^2 \quad (1)$$

Where d denotes is the distance between paired embeddings y ∈ {0,1}, is the label of the similarity, and m is the margin parameter. This formulation encourages compact intra-class embeddings and well separated representations among classes which enhances the robustness of this formulation in the presence of class imbalance.

III.3.2 Final Classification

Following Siamese training, the learned patient embeddings are fed to a light-weight fully connected classifier whose output is used to estimate diabetes risk. The classifier produces a score (probability) for each sample, which is later thresholded so as to have diabetic or non-diabetic labels. This two-stage formulation splits representation learning and decision making which leads to more robust solutions under class imbalance while allowing efficient and scalable inference.

III.4 HYBRID FEATURE SELECTION METHOD

The hybrid feature selection framework based on Information Gain Filtering, Dynamic Meta-heuristic Optimization and Refined Feature Optimization are combined in order to identify highly discriminative predictors. IGF eliminates the features with low information, DMO examines the global feature interaction, and RFO can be used for local feature refinement, resulting in a compact set of features for better model accuracy and stability.

III.4.1 Initial Fitler (IGF)

The first step of the hybrid feature selection pipeline uses Information Gain Filtering (IGF) which removes weak or low information predictors, after preprocessing and encoding as illustrated in Figure. 2. IGF assigns a degree to each feature according to the feature's contribution to the assigned label. Formally, the IGF score of features x_j as given in equation (2) is expressed as:

$$IGF(x_j) = H(Y) - H(Y \mid x_j) \quad (2)$$

Where $H(Y)$denotes the entropy of the diabetes label and $H(Y \mid x_j)$ is the conditional entropy. Features are ranked by descending IGF order and the most informative predictors are kept for further optimization, avoiding feature redundancy and optimizing the outcome of the DMO and RFO stages.

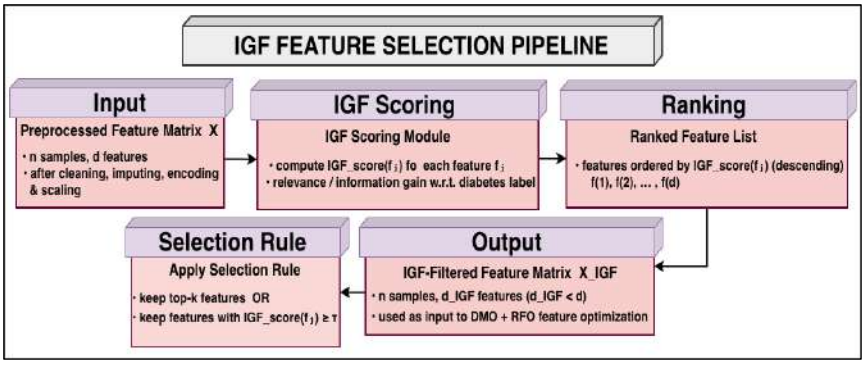

Figure 2: Flowchart of Initial Filter (IGF) stage.
Source: Authors, (2026).

III.4.2 DMO-Based Global Search

The second stage uses Dynamic Meta-heuristic Optimization (DMO) to perform global search of feature subset beyond the linear ranking given by IGF as shown in Figure 2. Each candidate solution is represented as a binary mask vector for selected features, and is evaluated as a sparsity-aware fitness function as given in equation (3) defined as:

$$\mathcal{F}(\mathbf{m}) = \text{ROC-AUC}_{CV}(\mathbf{m}) - \lambda \cdot \frac{\|\mathbf{m}\|_0}{d} \tag{3}$$

Where ROC-AUC_{CV} denotes cross-validated predictive performance, $\| \mathbf{m} \|_0$ is the number of selected features, and λ controls subset compactness. DMO explores feature space iteratively to find good and parsimonious subsets of features, with the best solution being sent towards the refinement stage.

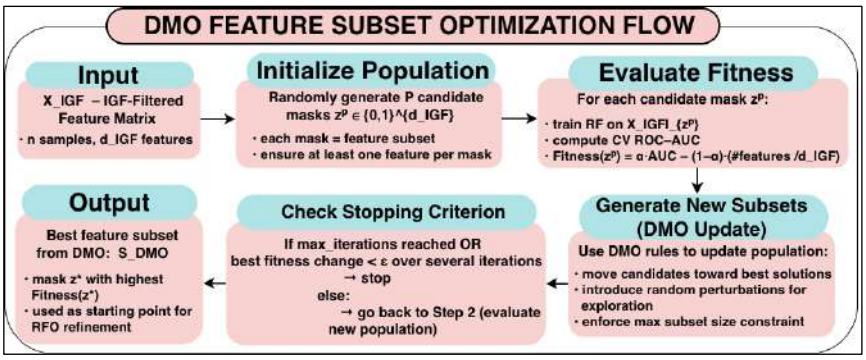

Figure 3: Flowchart of DMO feature subset optimization.
Source: Authors, (2026).

III.4.3 DMO-Based Global Search

The final stage uses Refined Feature Optimization (RFO) to locally improve the feature subset found from Dynamic Meta-heuristic Optimization as shown in Figure. 4. Starting from the solution selected by the DMO, instead, RFO carries out a controlled neighbourhood exploration and keeps those subsets of features that improve predictive performance while being compact.

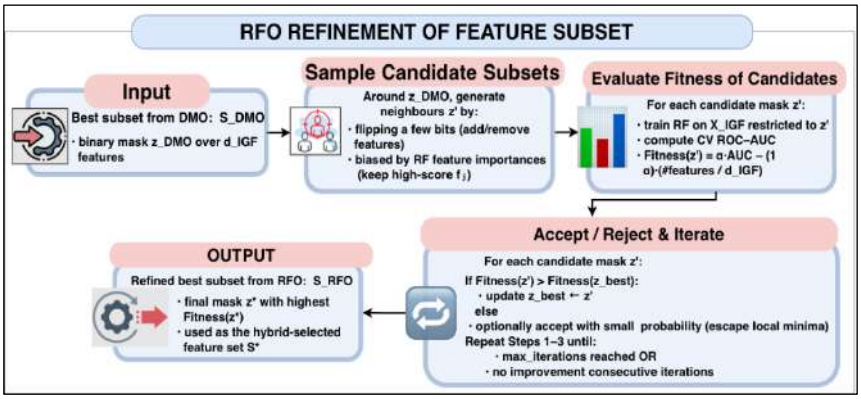

Figure 4: Flowchart of RFO refinement process.
Source: Authors, (2026).

III.4.4 Hybrid IGF–DMO–RFO Strategy

The proposed feature selection framework combines Information Gain Filtering, Dynamic Meta-heuristic Optimization and refined feature optimization to identify a compact and highly discriminative subset of predictors. IGF first handles the initial filtering, in which low information features are eliminated, DMO then globally explores to capture the feature interactions of the system nonlinearities while balancing the accuracy and subset compactness, and finally RFO is used for local refinement to eliminate the residual redundancy. Together, these stages generate an efficient feature set that improves the predictive accuracy, stability, and computational efficiency for subsequent deep learning models.

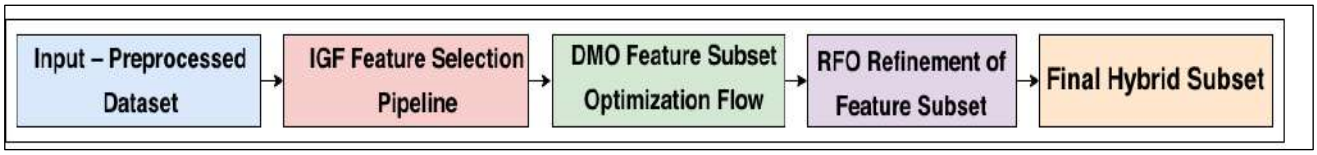

Figure 5: Hybrid feature selection pipeline.

III.5 PROPOSED SIAMESE 1D-CNN WITH GSCA

III.5.1 Network Architecture

The model utilizes the Siamese one-dimensional convolutional neural network augmented with the Global Spatial-Channel Attention (GSCA) module to learn discriminative embeddings from the select clinical features. After hybrid IGF-DM-RFO feature selection, every patient record is represented as a one-dimensional feature vector $\mathbf{x} \in \mathbb{R}^{d^*}$, where d^* is the number of selected features. This vector is given as input to each branch of the Siamese network and allows shared-weight representation learning. Following attention-based feature refinement can be done, Global Average Pooling is performed to get a compact representation, which is fed through a fully connected layers and will output the final embedding $\mathbf{z} \in \mathbb{R}^k$, where k denotes the embedding dimension. During Siamese training, embeddings from the two branches are compared with a distance-based similarity function. Both branches have the same network parameters; the feature transformation is consistent and relational learning between the paired patient profiles can work effectively.

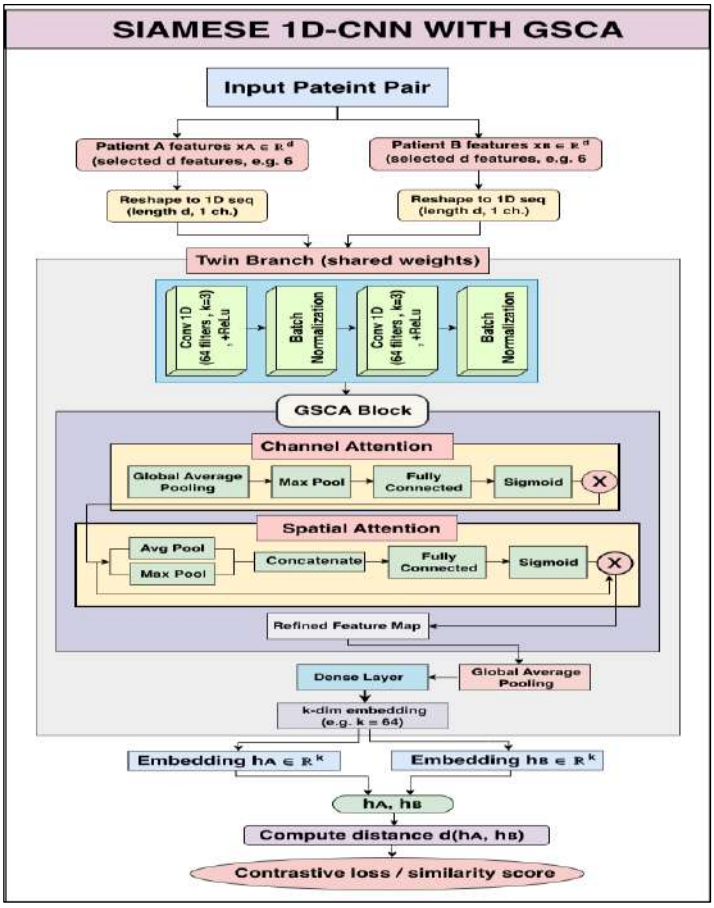

Figure 6: Architecture of the proposed Siamese 1D-CNN with GSCA.
Source: Authors, (2026).

III.5.2 Training Objective

The Siamese 1D-CNN with GSCA is trained on the basis of contrastive learning in order to build an embedding space that keeps the intrace variation of diabetic and non-diabetic samples as close as possible while keeping the variation of diabetic and non-diabetic samples as far as possible. This objective is achieved through the learning from paired patient records from the training data.

Pair Generation

Training pairs are produced by using samples from both positive (same class) and negative (different class) patient records for each instance. A fixed number of pairings per sample is created (pairs_per_sample = 2), in order to both ensure balanced similarity labels and to reduce the effects of class imbalance. Each pair (pA, pB), is assigned a binary similarity label $s_{ij} \in \{0,1\}$, increasing the effective training data and supporting robust contrastive learning.

Contrastive Loss Function

The Siamese model outputs the **Euclidean distance** between the two embeddings. The training loss is the standard **margin-based contrastive loss** as given in equation (4):

$$\mathcal{L} = s_{ij} D_{ij}^2 + (1 - s_{ij}) \cdot \max(0, m - D_{ij})^2 \quad (4)$$

Where $D_{ij}$is the Euclidean distance between embeddings and $m = 1.0$ is the margin used in your implementation. This loss reduces intra-class distances while enforcing a minimum separation between negative pairs.

Optimizer and Hyperparameters

The model is trained using the **Adam optimizer** with a learning rate as given in equation (5):

$$\eta = 1 \times 10^{-3} \quad (5)$$

Training uses different parameters like batch size, epochs, embedding dimensions, callback like early stopping as shown in Table 3, which restores the best weights and prevents overfitting, while checkpointing preserves the strongest model during training.

Table 3: Hyperparameters.

Parameter	Value / Description
Batch size	128
Epochs	30
Embedding dimension	64
Optimizer	Adam (learning rate = 1e-3)
Loss function	Contrastive loss (margin = 1.0)
EarlyStopping	Patience = 6, monitors validation loss, restores best weights
ModelCheckpoint	Saves best model as **siamese_best.h5**
Pair generation	Positive & negative pairs per sample (pairs_per_sample = 2)
Validation split	Uses generated validation pairs (1 pair per sample)
Parameter	**Value / Description**
Batch size	128

IV. RESULTS AND DISCUSSIONS

The proposed hybrid IGF–DMO–RFO feature-selection pipeline combined with the Siamese one-dimensional CNN with GSCA achieved strong performance, including 97% accuracy, a high area under the curve, and reliable calibration. Confusion matrices and precision-recall analysis confirmed robust detection of diabetic cases.

IV.1 CLASSIFICATION REPORT ANALYSIS

The classification report is given which shows strong and stable performance of the non-diabetic class with the precision, recall and F1-score are all at a high level due to the availability of abundant training samples as shown in Table 4. For the diabetic class, overall accuracy is high while recall is comparatively reduced both of which is quite typical in the case of contrastive embedding models trained on imbalanced datasets. This implies that the Siamese GSCA architecture learns highly discriminative representations, however, the detection of minority classes suffers because of the limited positive samples. The overall accuracy of 97% and accuracy at the macro level reflect this class wise performance disparity that can be further improved by threshold calibration or cost sensitive training.

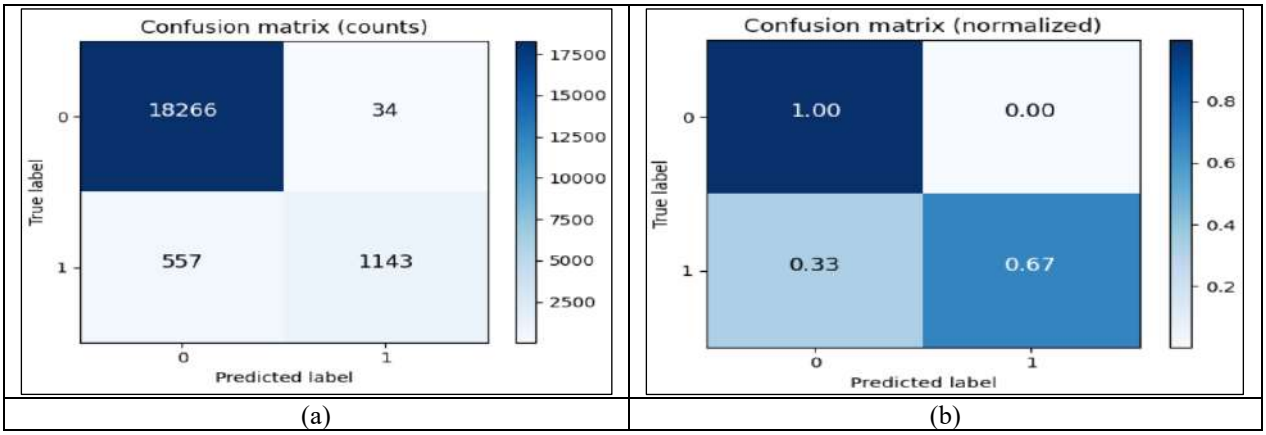

Table 4: Classification Report for the Proposed Model.

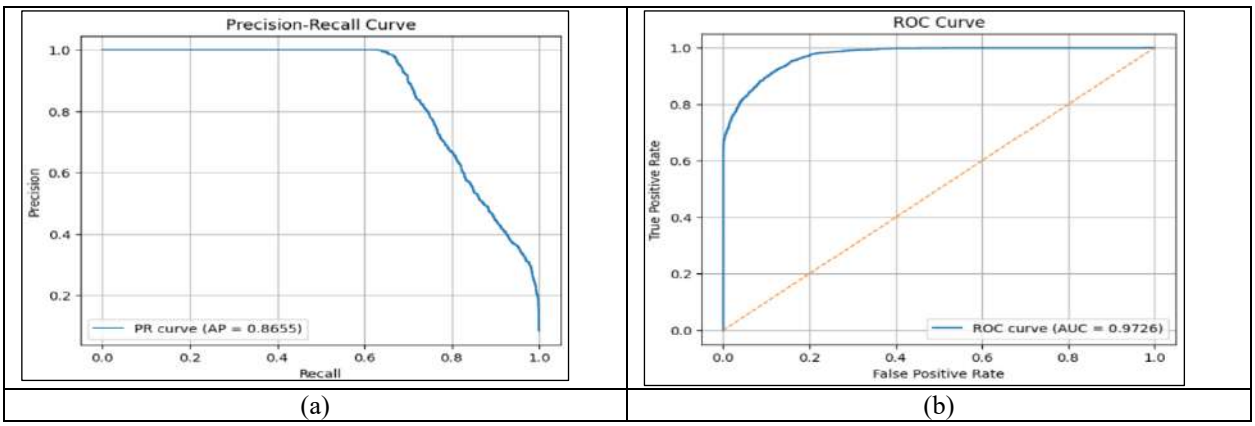
Class	Precision	Recall	F1-Score	Support
0 (Non-Diabetic)	0.97	1.00	0.98	18,300
1 (Diabetic)	0.97	0.67	0.79	1,700
Accuracy	—	—	**0.97**	20,000
Macro Avg	0.97	0.84	0.89	20,000
Weighted Avg	0.97	0.97	0.97	20,000

Source: Authors, (2026).

IV.2 CONFUSION MATRIX ANALYSIS

The confusion matrix gives detailed information on the class-wise model behavior other than overall accuracy. As we can see in Figure 7(a) count matrix, it depicts a very high specificity among the non-diabetic class where the count gives only 34 false positive in 18,266 true negative samples so you see, the decision boundaries are very well defined. For the diabetic class, the model is able to get 1,143 cases right, but also gets 557 samples wrong, reflecting the difficulty that the class imbalance in the dataset presents. This trend is further underscored by the normalized confusion matrix in Figure 7(b) which has a recall of 1.00 and 0.67 respectively in the non-diabetic and diabetic classes. Although recall among minority class is less strong, the hybrid IGF-DMO-RFO and Siamese GSCA model has a strong level of discrimination and it is still applicable in large-scale diabetes screening.

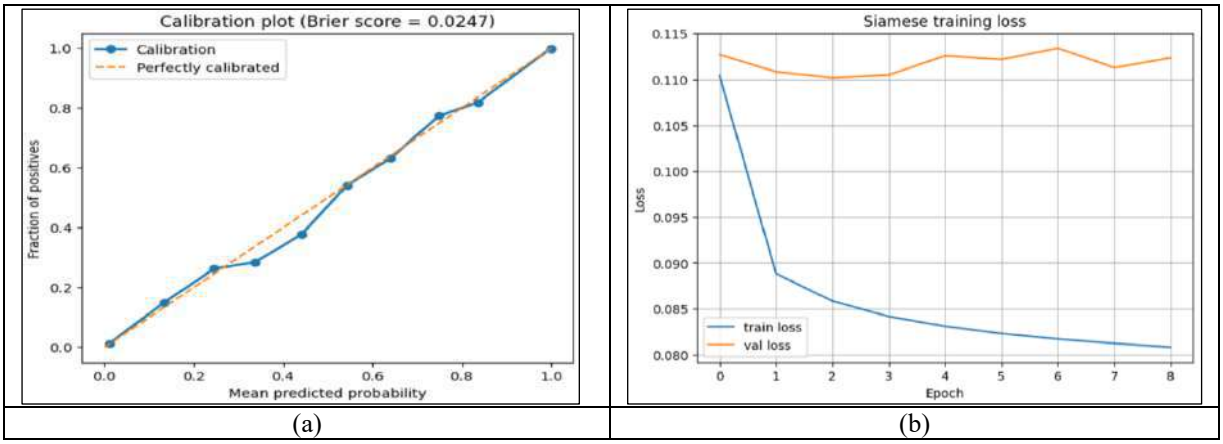


(a) (b)

Figure 7: Confusion Matrix (a) Counts (b) Normalized.
Source: Authors, (2026).

IV.3 PRECISION-RECALL & ROC CURVE ANALYSIS

The precision-recall curve shown in Figure 8(a) shows how the model performs under the condition of class imbalance, which is very important for predicting diabetes. The curve retains high precision across lower recall levels suggesting low false positives, and the precision is gradually reduced the higher the recall levels are, above 0.7, for most recall levels. The result precision mean of 0.8655 shows good discrimination on the minority class of diabetic. These results confirm that the use of the hybrid feature-selection pipeline along with the Siamese architecture is able to capture informative patterns and preserve stable predictive behavior in case of imbalanced conditions. The Figure 8(b) illustrates the good discriminative ability of the proposed Siamese 1D-CNN with GSCA. The ROC curve moves towards the upper-left corner corresponding to high sensitivity at low false-positive rates which is critical for clinical screening. The model's AUC value equals 0.9726 indicating good separation between diabetic and non-diabetic class. This performance demonstrates the success of the use of contrastive embedding learning and attention-based refinement in capturing subtle differences in metabolism that are relevant to real-world diagnostic applications.

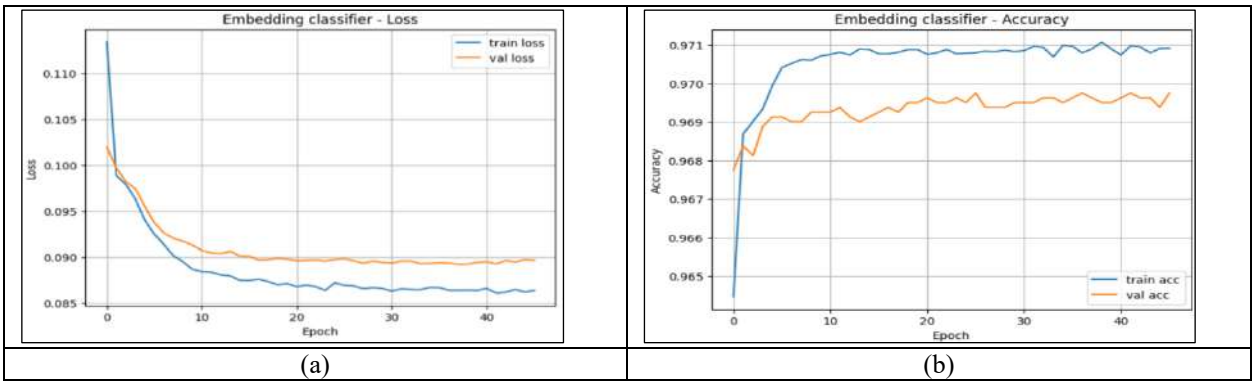


(a) (b)

Figure 8: (a) Precision-Recall (b) ROC Curve Analysis.
Source: Authors, (2026).

IV.4 CALIBRATION PLOT & SIAMESE TRAINING LOSS ANALYSIS

The calibration plot in Figure 9(a) indicates that the proposed Siamese 1D-CNN with GSCA yields well aligned probability estimates in most risk bins, which closely follows the diagonal reference line. This means that it is consistent in order to estimate reliable risk without probability inflation in low- and moderate-risk regions, with minor deviations only at higher probability ranges. The low Brier score of 0.0247 further provides accurate calibration for strong model performance, which supports the model's likelihood to be used for clinical decision support, triage, and early screening for diabetes. The training loss curve in Figure 9(b) exhibits a steady reduction, indicating successful learning of discriminative embeddings in the contrastive optimization. Validation loss has minor fluctuations due to class imbalance and pair sampling variability but is stable overall, which is a good sign of no overfitting but good generalization. Early stopping is further ensuring the stability of the model as it preserves the best performing weights and avoids unnecessary computation.



(a) (b)

Figure 9: (a) Calibration Plot (b) Siamese Training Loss Curve Analysis.
Source: Authors, (2026).

IV.5 EMBEDDING CLASSIFIER – ACCURACY & LOSS CURVE ANALYSIS

The curves of the embedding classifier as illustrated in below shown Figure 10(a) reveal the stable training of the downstream classifier using the learned embeddings (Siamese embeddings). Both training and validation losses continuously and only slightly fluctuate showing good optimization and good generalization. The small gap between the curves indicates minimal overfitting and validate the high and discriminative representations that the contrastive embeddings have provided for the diabetes classification later. The accuracy curves in the Fig. 10(b) show a fast convergence of the classifier trained using the GSCA enhanced Siamese embeddings. Training accuracy levels off at around 97%, and validation levels off very close to that at 96.9%, which means it has great generalization. The close correspondence between the curves reflects effective regularization through dropout, early stopping and compact embedding representation.

(a) (b)

IV.6 ENVIRONMENT SETUP AND TRAINING CONFIGURATION

All experiments were conducted in a controlled and fully reproducible environment to ensure consistent results as shown in Table. 5. The system ran on Linux with Kernel 6.1.42 and glibc 2.41, using Python 3.12.12. Deep-learning components were implemented with TensorFlow 2.20.0 and Keras for GPU-optimized training and model checkpointing. NumPy 2.3.4 and Pandas 2.3.3 supported numerical computing and dataset preprocessing. Scikit-learn 1.7.2 was used for classical machine-learning baselines, evaluation metrics, and cross-validation procedures. Visualization tools included Matplotlib 3.10.7 and Seaborn 0.13.2 for loss curves, ROC and PR plots, and correlation maps. The hybrid IGF-DMO-RFO pipeline and the Siamese one-dimensional convolutional network with Global Spatial and Channel Attention were trained using fixed random seeds, early stopping, and checkpoint saving to guarantee stable convergence and full reproducibility.

IV.7 BASELINE MODEL COMPARISON

To evaluate performance, the proposed Hybrid IGF–DMO–RFO combined with the Siamese one-dimensional convolutional network and Global Spatial and Channel Attention was compared against established baselines, including Logistic Regression, Random Forest, XGBoost, and a shallow one-dimensional convolutional model. All models were trained using the same eighty–twenty splits for fairness. The results as shown in Table 6 confirm that the proposed architecture surpasses all baselines in accuracy, precision, recall, F1-score, and ROC-AUC. Classical models achieved reasonable accuracy but consistently low recall for the diabetic minority class, while XGBoost improved discrimination yet still failed to match the sensitivity of the Siamese framework. The proposed model achieved the highest ROC-AUC of 0.9726 and ninety-seven percent accuracy, demonstrating superior separation of diabetic and non-diabetic classes. The Figure. 11 further highlights its clear advantage over conventional classifiers.

Table 6: Comparative performance of proposed model and baselines.

Model	Accuracy	Precision	Recall	F1-Score	ROC-AUC
Logistic Regression	0.89	0.90	0.62	0.73	0.87
Random Forest	0.94	0.95	0.66	0.78	0.94
XGBoost / GBM	0.95	0.96	0.69	0.80	0.95
Shallow MLP	0.93	0.94	0.63	0.75	0.92
1D-CNN (single branch)	0.94	0.94	0.67	0.78	0.93
Proposed Siamese 1D-CNN + GSCA	**0.97**	**0.97**	**0.67**	**0.79**	**0.9726**

Source: Authors, (2026).

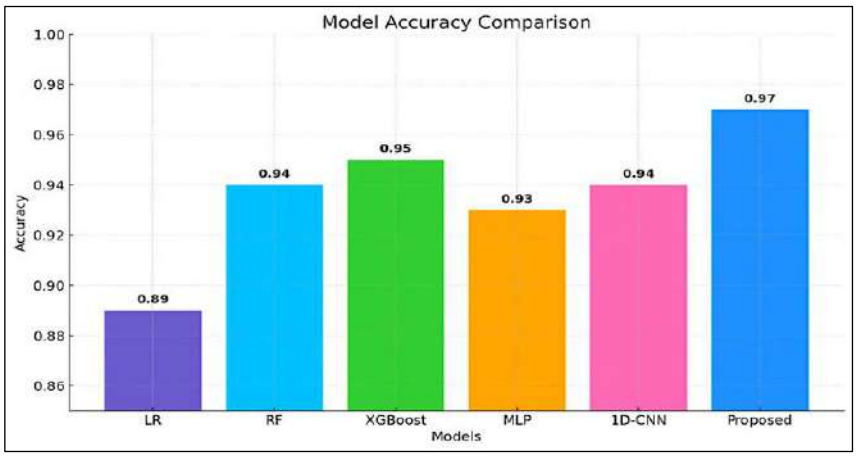

Figure 11: Baseline Model Comparison.

IV.7 ABLATION STUDIES

Ablation studies were conducted to evaluate the contributions of both the hybrid feature-selection pipeline and the network architecture. Using identical preprocessing and stratified eighty–twenty splits, only the feature-selection stage or model architecture was varied. For feature selection, four settings were compared: no selection, Information Gain Filtering alone, IGF followed by Dynamic Meta-Optimization, and the full IGF–DMO–RFO pipeline. The results as shown in Table. 7, highlights the incremental gains with IGF, substantial improvement with DMO due to interaction capture, and the best accuracy–parsimony balance with the RFO-refined subset.

Table 7: Ablation on feature selection components.

Setting	Accuracy	Precision	Recall	F1-score	ROC-AUC
All preprocessed features	0.95	0.95	0.70	0.81	0.950
IGF only (filter)	0.955	0.96	0.71	0.82	0.956
IGF + DMO (global search)	0.965	0.96	0.72	0.82	0.965
IGF + DMO + RFO (final)	**0.97**	**0.97**	0.67	0.79	**0.9726**

Source: Authors, (2026).

Architectural ablation as shown in Table. 8 demonstrated that multilayer perceptron and single-branch one-dimensional convolutional models underperform relative to contrastive Siamese training, while adding the Global Spatial and Channel Attention block yields the highest AUC and best precision–recall behavior. Collectively, these results confirm that both hybrid feature selection and GSCA-enhanced Siamese representation learning are central to the model's superior performance.

Table 8: Ablation on network architecture componentes.

Model / Architecture	Accuracy	Precision	Recall	F1-score	ROC-AUC
Shallow MLP (1–2 layers)	0.93	0.94	0.63	0.75	0.92
Single-branch 1D-CNN	0.94	0.94	0.67	0.78	0.93
Siamese 1D-CNN (no GSCA)	0.96	0.96	0.70	0.81	0.96
Siamese 1D-CNN + GSCA (proposed)	**0.97**	**0.97**	0.67	0.79	**0.9726**

V. STATE-OF-ART COMPARISON

Existing diabetes prediction models demonstrate varying performance across datasets and methodologies as shown in Table. 9. Prior works using smaller clinical datasets, such as those with 768 samples, report accuracies ranging from 84% to 95.76% [13–16], while studies using larger cohorts, including 2,942 samples, achieve up to 91.08% [17]. A recent model trained on 100,000 records reached 96.09% accuracy [15], highlighting the benefit of large-scale data. Compared with these methods, the proposed hybrid IGF–DMO–RFO with Siamese GSCA architecture attains a superior 97% accuracy on the same dataset size, demonstrating improved discriminative power, better handling of class imbalance, and more robust feature representation.

Table 9: State-of-Art Comparison.

Refer. No. /year	Size	Classes	Accuracy
[13]/2025	768	2 Classes Non-Diabetic, Diabetic	95.76%
[14]/2025	3546	2 Classes Non-Diabetic, Diabetes	73.01%
[15]/2025	100,000 records and 9 variables.	2 Classes: Diabetic, Non-Diabetic	96.09%
[16]/2025	768	2 Classes: Diabetic, Non-Diabetic	84%
[17]/2025	2,942	Class 1: Type 2 Diabetes Class 0: Non-diabetic	91.08%
Proposed Model	100,000	Class 0 – Non-Diabetic, Class 1 – Diabetic	97%

VI. DISCUSSION

The results show that the effective combination of hybrid feature selection with Siamese embedding learning algorithm and GSCA attention algorithm provides an effective model for predicting diabetes. The IGF-DMOR pipeline eliminates noisy predictors and captures nonlinear interactions among features, as well as optimizes feature subsets, leading to compact and discriminative representations that lead to higher training efficiency and less overfitting. Contrastive Siamese learning leads to further improvement of the class separation, while GSCA focuses on clinically relevant patterns of features and can be generalized better compared with traditional multilayer perceptrons or single-branch convolutional models. Overall, the proposed approach is a combination of an automated feature optimization strategy and robust representation learning, providing better performance than ordinary machine-learning and deep-learning approaches.

VII. CONCLUSION AND FUTURE WORK

The study introduces a reliable diabetes prediction model combining hybrid feature selection of IGF-DMO-RFO with Siamese one-dimensional CNN with GSCA attention. The 97% accuracy score with high discriminative performance and calibration means that the proposed model has achieved better performance than conventional machine learning and deep learning baselines. The hybrid feature selection approach plays a good role in suppressing noise and learning meaningful feature interaction, and the contrastive strategy, Siamese learning, generates well-separated embeddings under class imbalance. Furthermore, the GSCA module improves the representation quality in terms of clinically relevant factors such as HbA1c, glucose, BMI, age, and comorbidities, so that the final results of ROC-AUC, PR-AUC, and calibration performance are consistently high. In conditions, the proposed model is adequate for clinical screening, risk stratification, and population-level health monitoring because of the efficient inference and compact architecture. However, the research is confined to one public dataset, and future research should involve multi-center validation to estimate the generalizability across various healthcare settings. Multi-modal data, such as longitudinal data from laboratory measurements, an imaging biomarker, or genomic information, may help further improve predictive performance.

ABSTRACT

Access to safe freshwater remains a global challenge, motivating the development of efficient passive solar desalination systems. Conventional Solar Stills (CSS) suffer from low productivity due to limited heat absorption and the absence of thermal storage. In this study, a Modified Pyramid Solar Still (MPSS) integrating paraffin wax Phase Change Material (PCM), CuO nanoparticle-enhanced matt black coating, and a copper spiral absorber is experimentally and theoretically investigated. Performance comparisons were conducted at water depths ranging from 10–50 mm. The MPSS consistently outperformed the CSS at all depths, with maximum productivity achieved at 10 mm, yielding 2.311 L/day—representing a 162.5% enhancement over the CSS. The PCM effectively sustained evaporation during post-sunset hours, while CuO nanoparticles and the copper spiral improved solar absorption and internal heat transfer. A comprehensive thermal model incorporating PCM charging–discharging and enhanced heat transfer mechanisms showed good agreement with experimental data, with deviations within ±10%, confirming the reliability of the proposed approach.

I. INTRODUCTION

Currently, the availability of safe, potable freshwater is critical for human civilization, public health, and industrial expansion [1-3]. Despite water covering approximately 75% of the planet's surface, less than 0.5% [4],[5] is available as freshwater resources readily accessible to humanity, leading to growing concerns about future scarcity [3]. Many nations worldwide, particularly developing countries and those in the Middle East, are suffering from a shortage of fresh water. Compounding this challenge, the United Nations (UN) estimates that one-third of the global population lives in regions where freshwater supplies are insufficient to support the population. In response to this exacerbating crisis, solar desalination systems represent a viable, eco-friendly solution for converting abundant saline or brackish water into potable water [4, 6]. Among the various desalination technologies, the solar still is favored, particularly for remote and rural areas, due to its low cost, uncomplicated construction, minimal maintenance requirements, and reliance solely on free solar energy [3],[6].

The most fundamental solar distillation device, the Single Slope Solar Still, suffers from inherently low productivity, often attributed to heat losses to the surroundings and the significant energy required to heat the basin water [4],[7]. Consequently, significant research has focused on developing modified designs, leading to the evolution of the Pyramid Solar Still (PSS), which often offers improved performance over the conventional single-slope design. The pyramid configuration offers less shading on the water surface and a larger condensing area compared to single-slope stills [2]. Early experimental work established the PSS as a promising design, exemplified by the study performed by Taamneh and Taamneh (2012) in Jordan, which showed that forced convection could increase the daily productivity of a PSS by up to 25% compared to a free convection still [4],[8]. To further augment the thermal performance and combat the limitation of low nighttime production, researchers began integrating PCM, which function as thermal energy storage to extend the distillation period after sunset [3],[9].

For example, Sathyamurthy et al. (2014) demonstrated that incorporating paraffin wax (a type of PCM) into a triangular PSS increased the distillate output by 20% compared to a still without PCM, achieving this by storing heat during sunlit hours and releasing it subsequently [2],[3],[10]. In more recent studies, the combined approach of using fins and PCM in PSS successfully delivered a substantial enhancement of 101.5% in daily productivity over a conventional PSS [9]. Beyond thermal storage, improvements in solar energy absorption and heat transfer characteristics within the basin proved crucial. This led to the application of nanofluids and advanced absorber designs. Nanofluids, which are working fluids enhanced with minute particles, exhibit remarkable thermal-physical properties, including improved thermal conductivity and greater solar absorptivity [1].

Studies showed that coating the absorber plate with black paint mixed with nanocomposites, such as CuO nanoparticles, is highly effective [11],[12]. Experimentally, the addition of CuO nanofluids to a PSS achieved a total freshwater improvement of 27.85% over the conventional PSS [4]. Furthermore, the geometric modification of the absorber surface, such as the use of fins, corrugated shapes [1], or specialized heating coils, significantly increases the surface area for evaporation and heat exchange, consequently boosting heat absorption [5]. For example, integrating a complex absorber structure, such as a stepped PSS coupled with a solar parabolic dish featuring a spiral coil, resulted in an exceptional increase in daily yield of 131% over a conventional PSS [13]. Drawing upon these proven enhancement strategies, the efficacy of integrating multiple, complementary techniques simultaneously holds substantial research interest.

These techniques include the utilization of PCM for thermal regulation, the enhancement of solar absorption using CuO nanoparticles applied via black paint coating, and the optimization of heat transfer mechanisms through the geometric augmentation of the absorber surface using a copper spiral coil. Although previous studies have examined these components individually or in partial combinations—such as the PSS with PCM [2], or the PSS with nanofluids and corrugated absorbers [1], or PSS with fins/coils [5], a comprehensive experimental evaluation of a PSS integrating paraffin wax as PCM, CuO nanoparticles applied with matt black paint, and a copper spiral absorber is necessary to quantify their synergistic effect. This study addresses this gap by comparing the performance of a CSS with a MPSS incorporating these three enhancements, thereby seeking to quantify the maximum potential yield augmentation under real-world conditions.

II. MATERIALS AND SYSTEM DESIGN

The experimental methodology was structured to ensure a fair and reliable comparison between the CSS and MPSS by maintaining identical geometric dimensions, materials, and operating conditions wherever possible. All modifications introduced in the MPSS were selected based on their proven potential to enhance heat absorption, thermal storage, and internal heat transfer without increasing system complexity or compromising passive operation. This systematic approach allows the observed performance differences to be attributed solely to the integrated enhancements, thereby strengthening the validity of the experimental findings and subsequent analysis.

II.1 SYSTEM DESIGN

This experimental investigation, conducted in Surendranagar, Gujarat, India (22.7287°N, 71.6191°E), compared a CSS with a MPSS built on identical 0.25 m^2 basin units with a 2 mm thick acrylic glass cover at inclination 23° and 20 mm thick polystyrene insulation. The MPSS incorporated three performance-enhancing features: a layer of paraffin wax beneath the basin for thermal energy storage, a coating of matt black paint mixed with CuO nanoparticles on the basin surface to increase solar absorption, and a copper spiral absorber tube installed in the water to enhance internal heat transfer. To enable precise thermal monitoring, each airtight unit was equipped with three K-type thermocouples positioned to measure the basin surface, water, and inner glass cover temperatures. Table 1 shows the specifications of the materials used.

Table 1: Specifications of the materials.

Component	Material/Type	Specifications/Role
Basin	Sheet Metal	Square dimensions of 500 mm×500 mm (0.25 m^2). 1.5 mm thick.
Cover	Acrylic Glass (Plexiglass)	Pyramid shape, 2 mm thickness. Inclination 23°.
Insulation	Polystyrene	20 mm thickness. Used beneath the basin and on the sides to minimize heat loss to the surroundings.
Absorber Plate Coating (CSS)	Matt Black Paint	Applied to the basin to maximize solar radiation absorption.
Absorber Plate/Spiral Coating (MPSS)	Matt Black Paint mixed with CuO Nanoparticles	Applied to the MPSS basin surface and copper spiral absorber to enhance absorptivity and thermal conductivity.
Phase Change Material (MPSS)	Paraffin Wax	Utilized beneath the absorber basin for thermal energy storage, extending the distillation period into evening hours. 40 mm thick.
Heat Absorption Enhancement (MPSS)	Copper Spiral Absorber	Fabricated from copper tubing (3/8″ tube diameter) and coiled with a minor diameter of 50 mm, a major diameter of 405 mm, and a pitch of 1″.

II.2 MATERIAL SPECIFICATIONS

To ensure reproducibility and precise theoretical modelling, standard commercial-grade materials were selected. The thermophysical properties of the PCM and the nanoparticles used in the coating are shown in Table 2 and Table 3 respectively.

Table 2: Specifications of Paraffin Wax.

Property	Value	Unit
Colour	White	-
Melting Temperature	52	°C
Thermal Conductivity	0.288	W/ (m.K)
Latent heat of fusion	227	kJ/kg
Specific Heat Capacity (Liquid)	2.51	kJ/(kg.K)
Specific Heat Capacity (Solid)	2.95	kJ/(kg.K)
Density (Liquid)	760	kg/m^3
Density (Solid)	818	kg/m^3

Source: Authors, (2026).

Table 3: Specifications of CuO Nanoparticles.

Property	Value	Unit
Purity	99.9%	%
Average particle size	30-70 nm	nm
Specific surface area	60-80	m^2/g
Molecular weight	79.545	g/mol
Melting point	1326	°C
Bulk Density	0.66	g/cm^3
Morphology	Spherical	-
Color	Brownish Black	-

II.2.1 Preparation of CuO Nano-Coated Absorber Surface

To enhance the solar absorptivity and thermal conductivity of the absorber surface in the MPSS, a nano-enhanced coating was prepared using CuO nanoparticles. Commercially available CuO nanoparticles were mixed with matt black paint at a concentration of 25% by weight to ensure a high nanoparticle loading while maintaining coating uniformity and adhesion. The mixture was mechanically stirred for sufficient duration to achieve a homogeneous dispersion of nanoparticles within the paint matrix and to minimize particle agglomeration. Prior to coating, the basin surface and copper spiral tube were thoroughly cleaned and dried to remove dust, grease, or oxidation layers. The prepared CuO–paint mixture was then uniformly applied to the absorber basin surface and the copper spiral tube using a brush-coating technique, ensuring complete surface coverage and consistent coating thickness. After application, the coated components were allowed to dry under ambient conditions before assembly of the solar still.

II.3 SCHEMATIC DIAGRAM AND ACTUAL SETUP PHOTO

A detailed schematic diagram (Figure 1 and 2) showing the cross-sectional view of the CSS and MPSS is provided. The schematic illustrates the arrangement of the acrylic glass cover, sheet metal basin, polystyrene insulation, PCM layer (in MPSS), the application of the CuO nanoparticle coating, and the integration of the copper spiral absorber (in MPSS).

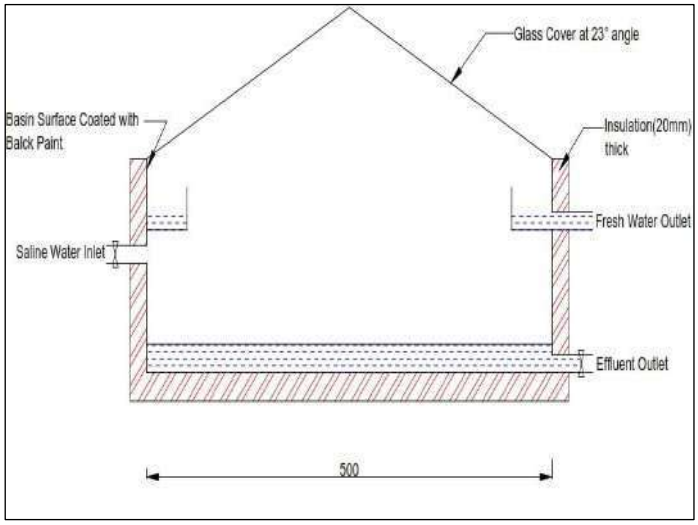

Figure 1: Diagram of CSS.

III. THEORETICAL ANALYSIS

This section outlines the mathematical model used to simulate the performance of the Solar Still. The model compares theoretical predictions with experimental findings by analysing the thermal behaviour of the basin, water mass, and glass cover.

III.1 ASSUMPTIONS

To simplify the thermal analysis, the following assumptions were made:
The system operates under a quasi-steady-state regime during daylight hours.
Water vapor behaves as an ideal gas, and the still is completely sealed to prevent vapor leakage.
No thermal stratification occurs in the water mass; temperature is assumed uniform throughout the depth.
Film wise condensation occurs on the inner surface of the glass cover.

III.2 GOVERNING EQUATIONS

The thermal performance is governed by energy balance equations for the basin, water, and glass cover. These equations account for solar radiation inputs and heat transfer via conduction, convection, radiation, and evaporation.

III.2.1 Basin Energy Balance:

The temperature change of the basin T_b is determined by the absorbed solar radiation minus the convective heat transfer to the water $Q_{cv,b-w}$ and heat losses to the ambient environment Ql [14].

$$\frac{dT_b}{dt} = \frac{I(t)A_b\alpha'_b - Q_{cv,b-w} - Q_l}{m_b C_b} \tag{1}$$

Where the heat transfer components and coefficients are calculated as follows: [15]:

$$Q_{cv,b-w} = h_{cv,b-w}A_b(T_b - T_w) \tag{2}$$

$$Q_l = U_b A_b(T_b - T_s) \tag{3}$$

$$U_b = \frac{1}{\left(\frac{x_{ins}}{k_{ins}} + \frac{1}{h_{t,b-s}}\right)} \tag{4}$$

$$h_{t,b-s} = 5.7 + 3.8V \tag{5}$$

III.2.2 Water Energy Balance:

The water temperature T_w is governed by the energy gain from the basin and solar radiation, balanced against heat losses to the glass cover $Q_{t,w-g}$ [14].

$$\frac{dT_w}{dt} = \frac{I(t)A_w\alpha'_w + Q_{cv,b-w} - Q_{t,w-g}}{m_w C_w} \tag{6}$$

The total heat transfer to the cover $Q_{t,w-g}$ includes convective h_{cv}, radiative h_r, and evaporative h_e components, derived using Dunkle's model: [16]

$$Q_{t,w-g} = \left(h_{cv,w-g} + h_{r,w-g} + h_{e,w-g}\right)A_w\left(T_w - T_g\right) \tag{7}$$

$$h_{cv,w-g} = 0.884 * \left[\left(T_w - T_g\right) + \frac{(p_w - p_g)T_w}{268900 - p_w}\right]^{\frac{1}{3}} \tag{8}$$

$$h_{r,w-g} = \varepsilon_{eff}\sigma\left(T_w + T_g\right)\left(T_w^2 + T_g^2\right) \tag{9}$$

$$h_{e,w-g} = 16.273\ x\ 10^{-3} * h_{cv,w-g}\left(\frac{p_w - p_g}{T_w - T_g}\right) \quad (10)$$

The saturation vapor pressure P at a specific temperature is calculated as: [17].

$$\mathrm{P} = \mathrm{e}^{\left(25.317 - \frac{5144}{\mathrm{T}}\right)} \quad (11)$$

III.2.3 Glass Cover Energy Balance:

The glass cover temperature T_g is derived by balancing the heat gained from the water against losses to the ambient air and sky via convection $Q_{cv,g\text{-}s}$ and radiation $Q_{r,g\text{-}sky}$ [14].

$$\frac{dT_g}{dt} = \frac{I(t)A_g\alpha'_g + Q_{t,w-g} - Q_{t,g-s}}{m_g C_g} \quad (12)$$

The associated heat transfer equations are: [15].

$$Q_{cv,g-s} = h_{cv,g-s}A_g(T_g - T_s) \quad (13)$$

$$h_{cv,g-s} = 2.8 + 3V \quad (14)$$

$$Q_{r,g-sky} = h_{r,g-sky}A_g(T_g - T_{sky}) \quad (15)$$

$$h_{r,g-sky} = \varepsilon_g\sigma(T_g + T_{sky})(T_g^2 + T_{sky}^2) \quad (16)$$

III.2.4 Optical Parameters and Performance Metrics

The effective absorptivity for the glass cover α_g, water α_w, and basin α_b are adjusted for reflections and absorption [18]:

$$\alpha'_g = (1 - R_g)\alpha_g \quad (17)$$

$$\alpha'_w = \alpha_w(1 - \alpha_g)(1 - R_g)(1 - R_w) \quad (18)$$

$$\alpha'_b = \alpha_b(1 - \alpha_g)(1 - R_g)(1 - R_w)(1 - \alpha_w)(1 - R_b) \quad (19)$$

The hourly freshwater productivity P_h and thermal efficiency η_h are calculated based on the evaporative heat transfer coefficient and latent heat of vaporization L_w:

$$P_h = \frac{3600 * h_{e,w-g}(T_w - T_g)}{L_w} \quad (20)$$

$$\eta_h = \frac{P_h L_w}{3600 * I(t)A_b} * 100 \quad (21)$$

III.3 MODIFIED BASIN MODEL WITH PCM, CUO NANO-COATING AND SPIRAL COPPER TUBE

This subsection extends the conventional thermal model to account for the integrated effects of CuO nanoparticle-enhanced absorptivity, paraffin wax PCM, and a copper spiral tube used in the MPSS.

The governing equations preserve energy conservation while introducing additional heat storage and transfer mechanisms responsible for the experimentally observed enhancement and extended night-time productivity.

III.3.1 Modified Basin Energy Balance

For the MPSS, the basin liner is coated with matt black paint mixed with CuO nanoparticles, which enhances solar absorptivity and thermal conductivity. In addition, thermal energy is transferred simultaneously to the basin water and to the PCM layer located beneath the basin. Accordingly, the transient energy balance of the modified basin is expressed as:

$$m_b c_b \frac{dT_b}{dt} = I(t)A_b\alpha_{b,eff}\tau_g - Q_{b-w} - Q_{b-PCM} - Q_{b-loss} \quad (22)$$

Where the effective absorptivity of the CuO-coated basin surface is given by:

$$\alpha_{b,eff} = \alpha_{paint} + \phi_{CuO}(\alpha_{CuO} - \alpha_{paint}) \quad (23)$$

$$Q_{b-w} = h_{b-w}A_b(T_b - T_w) \quad (24)$$

The heat transfer terms are defined as:

$$Q_{b-PCM} = h_{b-PCM}A_b(T_b - T_{PCM}) \quad (25)$$

$$Q_{b-loss} = h_{b-a}A_b(T_b - T_a) \quad (26)$$

The CuO nanoparticles improve the basin's ability to absorb and conduct heat, thereby accelerating heat transfer to both the basin water and the PCM layer.

III.3.2 Copper Spiral Tube Heat Transfer Model

A spiral copper tube immersed in the basin water acts as an additional heat absorption and redistribution element. The spiral tube receives solar energy through the CuO-coated surface and transfers it to the basin water by convection. The transient energy balance of the copper spiral is written as:

$$m_{coil}c_{Cu}\frac{dT_{coil}}{dt} = I(t)A_{coil}\alpha_{CuO} - Q_{coil-w} \quad (27)$$

Where the heat transfer from the spiral tube to the basin water is:

$$Q_{coil-w} = h_{coil}A_{coil}(T_{coil} - T_w) \quad (28)$$

The presence of the spiral tube increases the effective heat transfer area inside the basin, enhances temperature uniformity, and promotes faster charging of the PCM during peak solar hours.

III.3.3 Modified Water Energy Balance

Considering the additional heat supplied by the copper spiral tube, the basin water energy balance becomes:

$$m_w c_w \frac{dT_w}{dt} = Q_{b-w} + Q_{coil-w} - Q_{w-g} \quad (29)$$

The heat transfer from water to glass cover, $Q_{w\text{-}g}$, is calculated using Dunkle's correlations for convective, radiative, and evaporative heat transfer, as defined in Section III.2.

III.3.4 PCM Charging and Discharging

The paraffin wax PCM undergoes sensible heating, phase change, and sensible cooling depending on its temperature relative to the melting temperature T_m. The PCM energy balance is therefore modelled using a piecewise formulation.

(a) Daytime Charging Mode (I(t)>0)

Solid PCM($T_{PCM}<T_m$)

$$m_{PCM}c_{PCM,s}\frac{dT_{PCM}}{dt} = Q_{b-PCM} - Q_{PCM-loss} \quad (30)$$

Phase Change Region ($T_{PCM}=T_m$)

$$m_{PCM}L_{PCM}\frac{df}{dt} = Q_{b-PCM} \quad (31)$$

Liquid PCM($T_{PCM}>T_m$)

$$m_{PCM}c_{PCM,l}\frac{dT_{PCM}}{dt} = Q_{b-PCM} - Q_{PCM-loss} \quad (32)$$

Where f represents the liquid fraction of the PCM.

(b) Night-Time Discharging Mode (I(t)=0)

After sunset, the PCM releases stored thermal energy back to the basin and water, sustaining evaporation even in the absence of solar radiation. The basin energy balance during night-time becomes:

$$m_b c_b \frac{dT_b}{dt} = Q_{PCM-b} - Q_{b-w} - Q_{b-loss} \quad (33)$$

Where the heat released from PCM to basin is:

$$Q_{PCM-b} = h_{b-PCM}A_b(T_{PCM} - T_b) \quad (34)$$

During discharging, the PCM equations are written as:

Liquid PCM Cooling

$$m_{PCM}c_{PCM,l}\frac{dT_{PCM}}{dt} = -Q_{PCM-b} - Q_{PCM-loss} \quad (35)$$

Solidification Phase ($T_{PCM}=T_m$)

$$m_{PCM}L_{PCM}\frac{df}{dt} = -Q_{PCM-b} \quad (36)$$

This controlled release of latent heat maintains higher basin and water temperatures during evening and night hours, thereby extending the distillation period and explaining the experimentally observed enhancement in night-time productivity.

III.3.5 Contribution of the Modified Basin Model

The proposed modified basin model effectively captures the combined influence of CuO nanoparticle-enhanced absorptivity, improved internal heat transfer due to the copper spiral tube, and latent heat storage and release by the PCM. These coupled mechanisms explain the elevated basin and water temperatures, delayed thermal decay after sunset, and sustained evaporation rates observed in the MPSS. The model thus provides a physically consistent framework for predicting the enhanced thermal and productivity performance of the modified solar still.]

III.4 UNCERTAINTY ANALYSIS

An uncertainty analysis was performed to quantify the reliability of the measured data and the calculated results, typically following the methodology established by Holman. The overall uncertainty of a result (W_R), which is a function of independent measured variables (X_1,X_2,…,X_n), is computed using the general formula for the propagation of uncertainties:

$$W_R = \sqrt{\left(\frac{\delta R}{\delta X_1} W_1\right)^2 + \left(\frac{\delta R}{\delta X_2} W_2\right)^2 + \cdots + \left(\frac{\delta R}{\delta X_n} W_n\right)^2} \quad (37)$$

Where W_1, W_2…, W_n are the uncertainties associated with the independent measured parameters listed in the instrumentation Table 4. The errors in calculated parameters, such as the total freshwater distillate is typically found to be in the range of ±1.4% for productivity ensuring the credibility of the experimental findings.

IV. EXPERIMENTAL INVESTIGATION

This section describes the experimental methodology adopted to evaluate and compare the performance of the CSS and the MPSS. The experimental work was designed to ensure identical operating and environmental conditions for both systems so that the observed performance differences could be attributed solely to the proposed modifications. Details of the measuring instruments, test procedure, operating parameters, and data acquisition methodology are presented to ensure transparency, repeatability, and reliability of the experimental results.

IV.1 INSTRUMENTATION

Accurate measurement of thermal, meteorological, and productivity parameters is essential for reliable performance evaluation of solar stills. Therefore, calibrated measuring instruments with appropriate accuracy and resolution were employed to monitor the operating conditions of both the CSS and MPSS throughout the experimental duration. The measured parameters included basin temperature, water temperature, inner glass cover temperature, ambient temperature, solar radiation intensity, wind velocity, and freshwater yield. The instruments used, along with their specifications, are detailed below in Table 4.

Table 4: Specifications of the measuring instruments.

Instrument Name	Measured Parameter	Resolution	Range	Accuracy/Error
K-type Thermocouple with Digital Thermometer	Basin Surface Temperature (T_b), Water Temperature (T_w), Inner Cover Temperature (T_g), Ambient Temperature (T_a)	0.1°C	-50°C to 200°C	±1°C (±1%)
Solar Power Meter (Solarimeter)	Solar Radiation Intensity ($I(t)$)	1W/m^2 or 1 BTU / (ft^2*h)	0-1999W/m^2 or 0-634 BTU /(ft^2*h)	± 10W/m^2 [±3 BTU / (ft^2*h)] or ±5%, whichever is higher
Digital Vane Anemometer	Wind Velocity (V)	0.1 m/s	0-30 m/s	±5% or ±0.1 m/s whichever is higher
Calibrated Measuring Jar/Scaled Vessel	Hourly Distillate Productivity (m)	5 mL	0−1500 mL	±5 mL (±1%)

Source: Authors, (2026).

The experimental design investigated the influence of water depth on productivity by testing five distinct levels: 10 mm, 20 mm, 30 mm, 40 mm, and 50 mm over a 15-day period, with three days allocated to each depth to ensure data reliability. From July 3 to July 17, 2025, system performance was monitored hourly between 9:00 a.m. and 9:00 p.m.

During these intervals, internal and ambient temperatures (T_w, T_b, T_g, T_a) were recorded simultaneously, meteorological parameters including solar radiation intensity I(t) and wind velocity V, and the volume of freshwater distillate using calibrated vessels to determine the cumulative daily yield.

IV.2 EXPERIMENTAL PROCEDURE

The experimental procedure was systematically planned to investigate the influence of basin water depth on the thermal and productivity performance of the solar stills under real outdoor climatic conditions. Both the CSS and MPSS were tested simultaneously to eliminate the effect of day-to-day weather variations. The procedure followed during experimentation is described below. Prior to the commencement of experiments, both solar stills were thoroughly inspected to ensure airtight sealing, proper alignment of the glass covers, and correct placement of thermocouples. The basin surfaces, copper spiral tube (in MPSS), and glass covers were cleaned to remove dust and impurities that could affect heat transfer and condensation. The systems were then filled with saline water to the desired depth and positioned side-by-side in an open outdoor location to receive identical solar radiation and wind exposure. The experiments were conducted at five different basin water depths, namely 10 mm, 20 mm, 30 mm, 40 mm, and 50 mm, to assess their influence on still performance.

For each water depth, experiments were carried out over three consecutive days, and the average values were used for analysis to minimize the effect of transient environmental fluctuations. After completing tests for a given depth, the basin water was drained, and the next depth was set for subsequent experimentation. Each experimental run was conducted from 9:00 a.m. to 9:00 p.m., covering both peak solar hours and post-sunset periods to capture the thermal storage and discharge behaviour of the PCM in the MPSS. Hourly measurements of basin temperature (T_b), water temperature (T_w), inner glass cover temperature (T_g), and ambient temperature (T_a) were recorded using calibrated K-type thermocouples. Simultaneously, solar radiation intensity I(t) was measured using a solar power meter, and wind velocity was recorded using a digital vane anemometer. The freshwater distillate produced by each still was collected hourly in calibrated measuring jars placed at the outlet channels.

The collected distillate was measured and recorded to determine hourly productivity and cumulative daily yield. At the end of each day, the total distillate output was noted, and the measuring jars were emptied and reset for the next experimental run. The recorded experimental data were subsequently used for comparison with theoretical predictions and for evaluating the effects of water depth, PCM integration, CuO nanoparticle coating, and copper spiral absorber on the thermal and productivity performance of the solar stills.

V. RESULTS AND DISCUSSION

Before examining individual performance metrics, the experimental results are first interpreted in relation to the prevailing environmental conditions and the resulting thermal response of the solar stills. Since solar radiation and ambient temperature directly influence evaporation and condensation processes, analysing the hourly variation of basin, water, and glass temperatures provides a fundamental basis for understanding the observed productivity trends discussed in the following subsection.

V.1 HOURLY VARIATION OF ENVIRONMENTAL CONDITIONS AND STILL TEMPERATURES

The hourly variation of solar radiation, ambient temperature, and internal still temperatures were analysed to understand the thermal behaviour of both the stills. Solar radiation increased steadily during the morning hours, reaching a maximum around midday, which resulted in a corresponding rise in basin, water, and glass cover temperatures for both stills. Throughout the daytime operation, the MPSS consistently exhibited higher basin and water temperatures compared to the CSS. This enhancement is primarily attributed to the CuO nanoparticle-coated absorber surface, which increased effective solar absorptivity and accelerated heat transfer to the basin water. Moreover, the copper spiral tube promoted uniform heat distribution within the basin, reducing thermal resistance and enhancing evaporation.

As solar radiation declined during the late afternoon and evening hours, the CSS experienced a rapid temperature drop, whereas the MPSS maintained elevated temperatures due to the latent heat released from the paraffin wax PCM layer. This sustained thermal effect preserved a favourable temperature difference between water and glass cover, enabling continued evaporation beyond sunset. Theoretical temperature predictions obtained from the modified basin energy balance closely followed the experimental trends. Minor deviations observed during peak solar hours are attributed to transient environmental effects and unavoidable experimental heat losses, while overall agreement confirms the robustness of the proposed theoretical model. Figure 4 illustrates the hourly variation of solar radiation and the corresponding temperatures of the CSS and MPSS for experimental data.

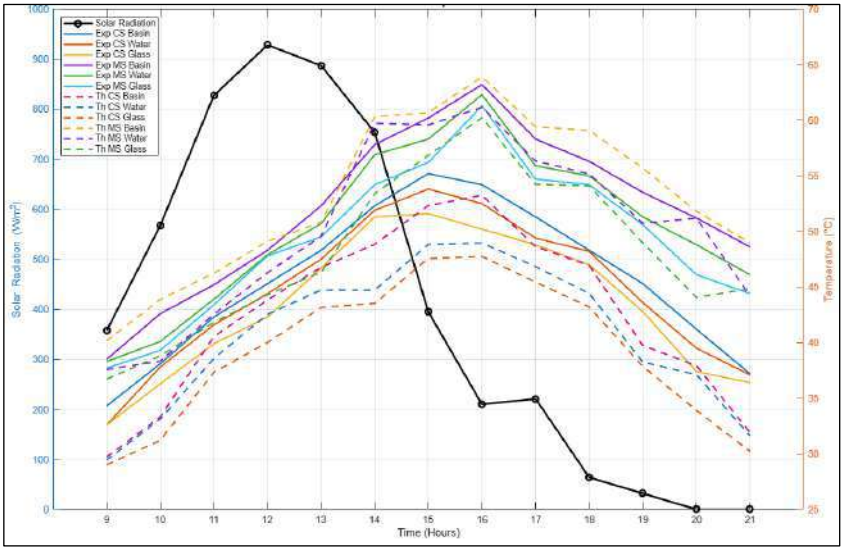

Figure 1: Graph of solar radiation vs temperature profile.
Source: Authors, (2026).

V.1.1 Validation of Theoretical Model with Experimental Data

The validity of the developed theoretical model was assessed by comparing the predicted basin, water, and glass cover temperatures with the corresponding experimental measurements for the MPSS. The theoretical results closely follow the experimental trends throughout the day, including peak solar hours and post-sunset conditions. The maximum deviation between theoretical and experimental temperatures was found to be within ±10%, which is acceptable for solar still thermal modelling considering environmental fluctuations and experimental uncertainties. The close agreement confirms that the modified basin energy balance, incorporating the effects of CuO nanoparticle-enhanced absorptivity, copper spiral tube heat transfer, and PCM charging–discharging behaviour, accurately represents the real thermal behaviour of the MPSS. This validation demonstrates that the proposed model can be reliably used for performance prediction and future parametric optimisation without extensive experimental trials.

V.2 COMPARATIVE PRODUCTIVITY AND EFFICIENCY ANALYSIS WITH VARYING WATER DEPTHS

The core objective of the experiment was to compare the freshwater productivity of the two solar stills across different water depths. The results, summarized in Figure 5, clearly demonstrate the significant benefits of the proposed modifications and underscore the critical role of water depth in system performance.

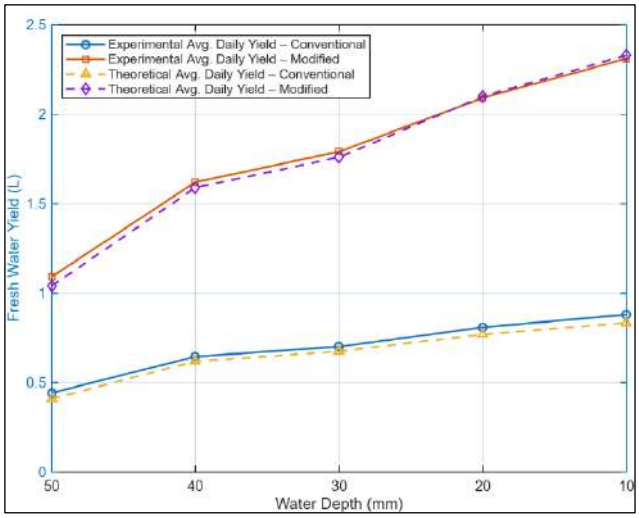

Figure 2: Summary of Daily Performance Metrics by Water Depth (Average of 3 Days).
Source: Authors, (2026).

The data reveals a clear and consistent trend: as the water depth decreases, the average daily yield of both the conventional and modified solar stills increases. The highest productivity for both stills was recorded at a water depth of 10 mm. This is a well-documented phenomenon in solar distillation, as a shallower water layer has less thermal mass, allowing it to heat up faster and reach a higher peak temperature during the day. The results show that the MPSS consistently outperformed the CSS at every water depth, with productivity enhancements ranging from an impressive 146.1% to 162.5%.

V.3 DISCUSSION OF FINDINGS AND UNDERLYING MECHANISMS

The experimental results clearly demonstrate that integrating PCM, CuO nanoparticle coating, and a copper spiral absorber significantly enhances the thermal and productivity performance of a pyramid solar still. Compared to previously reported studies employing individual modifications, the present system achieved a maximum productivity enhancement of 162.5%, indicating a strong synergistic effect among the combined techniques. The improved performance is attributed to enhanced solar absorption by the CuO-coated basin, accelerated internal heat transfer due to the copper spiral tube, and effective thermal energy storage and release by the PCM. These mechanisms collectively increase water temperature, maintain a favourable water–glass temperature difference, and sustain evaporation during post-sunset hours. The results confirm that reducing basin water depth further amplifies these benefits by lowering thermal inertia. Overall, the findings highlight the importance of integrated system design for achieving substantial and practically relevant performance improvements in passive solar desalination systems.

VI. CONCLUSIONS

The experimental results demonstrate that the MPSS, integrating paraffin wax PCM, CuO nanoparticle-enhanced absorber coating, and a copper spiral tube, consistently outperformed the CSS under all tested operating conditions. The maximum freshwater productivity was achieved at a water depth of 10 mm, where the MPSS produced 2.311 L/day, corresponding to a 162.5% enhancement compared to the CSS, confirming the strong influence of reduced thermal mass on evaporation performance. The incorporation of paraffin wax PCM effectively extended the distillation process into post-sunset hours by storing latent heat during peak solar periods and releasing it gradually, resulting in sustained basin and water temperatures. The CuO nanoparticle-coated absorber and copper spiral tube significantly improved solar energy absorption and internal heat transfer, leading to higher water temperatures, improved temperature uniformity, and increased evaporation rates throughout the day. The developed theoretical model, incorporating PCM charging–discharging behaviour and enhanced heat transfer mechanisms, showed good agreement with experimental data with deviations within ±10%, confirming its suitability for performance prediction and future system optimization.

This multi-faceted approach provides a viable and highly effective method for improving the performance of passive solar stills, presenting a more robust solution for water-stressed regions. Further investigation is recommended to optimize the system's design parameters, including the precise concentration of nanoparticles and the dimensions of the PCM layer and spiral tube. Future work could also involve a detailed thermodynamic analysis or computational fluid dynamics simulation to precisely model the internal heat and mass transfer phenomena and further refine the system's design for even greater efficiency.

ABSTRACT

Inconel-939 is a high-temperature superalloy comprising nickel and chromium. It has been extensively utilized in diverse applications within aerospace, automotive, and corrosive environments. The reason behind this is owed to its remarkable mechanical strength and thermal stability. Even though it has been the most popular choice for high-strength applications, it can be hard to machine the alloy effectively. Drilling the metal and creating high-quality holes using traditional methods has become extremely challenging due to its significant hardness and strength. Abrasive Water Jet Drilling (AWJD) provides a viable option for the machining of such challenging materials. The objective of the current investigation is to examine the AWJD material removal rate (MRR) with respect to the process parameters like Abrasive jet pressure (P_{aj}), traverse speed (V_t), stand-off distance (G_d), and abrasive mixture (A_m-garnet and silicon carbide). The experimental results depict that as P_{aj} reached its maximum value, the MRR indicated a rise by 32.66%. The ANOVA results further showed that P_{aj} is the most vital factor, accounting for 79.21% of the changes in MRR, while A_m also accounted for 6.43%. The results thus confirm that AWJD offers an efficient and controllable machining procedure for creating holes with minimal duration in Inconel-939 alloy.

I. INTRODUCTION

Inconel 939 (IN939) is a nickel-based superalloy manufactured for sustained performance at elevated temperatures (up to approximately 850 °C), providing superior resistance to creep, fatigue, corrosion, and oxidation. The γ (gamma) matrix is what makes it strong. The γ′ (gamma-prime) precipitates and carbides (MC, M23C6) make it even stronger [1-3]. Common uses include gas turbine blades and vanes, burner nozzles, and other hot-section parts in power generation and aerospace [4-6]. IN939 is hard to cut and wears down tools quickly, which might lead to a very rough surface finish. Like other the material alloys, IN939 is hard to machine due to it is exceptionally hard when heated, doesn't transmit heat well, and gets harder when you work with it. This makes cutting processes very hot, tools wear out quickly, and surfaces get damaged. These problems are further more important for additively created IN939, which has a thin, directionally cemented microstructure and is more likely to break, making chip-based cutting and welding harder [7-9].

Because of this, abrasive water-jet machining (AWJM) has become a popular non-traditional method for working with Inconel alloys, Shape memory alloys and advanced polymeric composites [10-13]. In AWJM, a high-pressure water jet (usually 200–400 MPa) speeds up abrasive particles that wear down the workpiece, allowing cutting or milling without a thermal-affected zone or contact between the tool and the workpiece. Various researchers proven that the AWJM can make cuts, pockets, and complex profiles efficiently in Inconel 600, 625, 718, and X-750 without causing too much wear on the tools. However, the surface roughness, kerf taper, Material Removal rate depth of cut depend on things like P_{aj}, V_t, G_d, and abrasive flow rate [14-16].AWJM is typically advised for the processing of nonconductive and conductive hierarchical material structures such as

Inconel alloy, titanium alloy, and metal fiber laminates. Inconel 625 machined using abrasive water jet technology by [17] The influence of process factors P_{aj}, G_d, A_m and V_t, on Ra and KA was analyzed. According to [18] conducted a comparative analysis of three non-traditional machining processes. The electric discharge machining process (EDM), laser beam machining process (LBM), and abrasive water jet machining (AWJM) are employed to process carbides and Inconel superalloys to attain improved material removal rates (MRR) and thickness. The results of this study indicated that AWJM surpasses laser cutting when processing thicker materials because to its capacity for deeper penetration. Furthermore, the AWJM exhibited a superior Material Removal Rate (MRR) compared to EDM, rendering it a more advantageous method for situations necessitating expedited material removal. These results underscore the benefits of AWJM in situations requiring high efficiency and the capacity to sever thick, resilient materials.

According to [19] investigated the performance attributes of Inconel X-750 Superalloy subjected to abrasive water jet (AWJ) machining, focusing on the variables. The combination of minimum G_d, minimum V_t, and P_{aj} has enhanced the machined surface quality (Ra). In [20] examined the influence of abrasive water jet parameters, including traverse rate, abrasive particle size, and number of passes, on the waviness of the titanium alloy Ti-6Al-4V. It was observed that at elevated traverse rates, surface roughness diminishes, whereas waviness escalates due to the reduced abrasive contact in the specified region. Balaji Vasudevan et al. examined the influence of abrasive water jet (AWJ) drilling parameters on the surface properties of Inconel 718 superalloy coated by Yttrium Stabilized Zirconia (YSZ). The variance of jet impact angle (0°–45°), abrasive flow rate (250–400 g/min), P_{aj} (175–325 MPa), on surface integrity was analyzed. Pressure was identified as the most significant factor. On Inconel 625, by [21] examined changes in water pressure, gap distance, and the abrasives (Sic and Garnet) in relation to surface roughness, kerf angle, and MRR. They observed pressure is predominate factor effect the responses.

II. MATERIALS AND METHODS

The studies were conducted using an abrasive waterjet machine of the MAXIEM 1515 type. The drilling operation is performed as depicted in Figure 1. Single pass techniques were used entire operation. The INX-939, having a thickness of 8 mm, is utilized for AWJD. Because this alloy is widely used in numerous industrial applications, it was chosen as the workpiece. Tables 1 and 2 describe the properties and composition of INX-939.

During the experiment, four various levels of parameters were modified, including P_{aj}, V_t, A_m, and G_d shown in Table 3 [14]. The RSM was used to perform rails. The trials were run at random [17] in order to decrease the influence of confounding variables, and two replications were obtained for each experiment. For MRR, W_1 is the beginning workpiece sample before machining, W_2 is after machining, the density of work =8.19 g/cm^3 is the cutting time (t) in minutes. as mentioned, equation (1)

III. RESULTS AND DISCUSSIONS

III.1 ANOVA ANALYSIS

The investigation employed a central composite Linear design including a total of L_{27} trials. Figure 2 (a-c) indicated correlation between actual, predicted, & residual values. It is observed all values in acceptable limits. Table 4 outlines the process parameters and their corresponding levels inside the L27 (Center point =3) orthogonal array, together with the response values for INX-939. The conclusive regression models for the analyzed variables, namely Material Removal Rate. Design Expert software (V13), was employed to analyze the impact of process variables on machining outcomes in the context of AWJD. The equations delineating the linear models of the input process parameters are shown in Equations (2). The model had a highly significant fit, evidenced by its substantial F-statistic (F=788.02), with a p-value below 0.0001, signifying its efficacy in predicting drilled MRR. The most significant individual influence of the different process parameters on material removal rate (MRR) was attributed to pressure (P_{aj}), which exhibited the highest sum of squares (SS) at 5379.5 and the greatest F-statistic (F=2514.32). Furthermore, the standoff gap (G_d), traverse speed (V_t), and abrasive mixture exhibited a statistically significant impact on material removal rate (MRR), evidenced by their respective F-statistics of 335.93, 55.15, and 204.28, all significant at $p<0.0001$. Moreover, the residual error was negligible (SS=47.07), indicating that pressure was the principal factor affecting MRR, whereas the complete array of process factors examined collectively influenced MRR.

$$(MRR) = +54.85613+0.15 * P_{aj} + 6.6 * G_d + 0.16 * V_t +2.57* A_m \quad (2)$$

Individual parameter percenatage contribution indicated in Figure 3. It is observed P_{aj} 69.29% predominant factor affect the MRR.

III.2 RSM ANALYSIS OF MRR

As shown in figure 4(a), it is clear how the pressure affects the MRR. When P_{aj} increased from 120 Mpa to 360 Mpa it observed 32.66% increased in MRR & Figure 4 (b) shows the Effect of G_d on MRR. When G_d reaches its higher value the MRR increased by 11.24% Furthur more combined effect of P_{aj} and G_d on MRR described in Fig figure 5(a), the distance from the workpiece surface affects the material removal rate (MRR) since it can be seen in this surface plot that an increase in pressure from 120 MPa up to 360 MPa has a very significant impact on MRR; especially when the distance from the workpiece surface is high (i.e., 1.5-2.0 mm).The obtained MRR almost reaches its highest point of approximately 153.57 mm³/sec. Figure 4(c), shows how the V_t affects the MRR. When V_t increased from 65 mm/min to 97 mm/min it observed 4.24% increase in MRR and Figure 5 (c) shows the trend of V_t and P_{aj} on MRR. Higher levels thesee parameters enhanced the MRR . Figure 4 (d) shows the effect of mixed abrasives on MRR described. It is observed Level 5 (100%SiC) higher MRR than the other mixture garnets (100%Gt, 75%Gt + 25%SiC, 50%Gt + 50%SiC and 25%Gt + 75%SiC). Combined efferets of Mixed abrasves and P_{aj} shows on Figure 5 (c). It is observed 100%SiC coupled with 100%SiC obtained high MRR.

IV. CONCLUSIONS

The study demonstrated the effectiveness of process parameter optimization for AWJD machining process for INX -939 through systematic evaluation of the key process parameters like pressure, Abrasive mixture, traverse speed and standoff gap. The Abrasive water jet drilling (AWJD) experimental investigation employed to enhance the material removal (MRR). This study showed that the MRR greatly enhanced by modifying the input parameters. During the investigation, the following particular observations were made:

- The ANOVA results show that the removal rate (MRR) is significantly influenced by the factors included in the model, and that the models are very reliable given the very high F-values and p-values less than 0.0001 for all parameters evaluated. P_{aj} was found to be the most influential parameter affecting the material removal rate. However, A_m, G_d, and V_t also have a significant impact on response variables.
- The ANOVA analysis described the variables influence on machining performance like P_{aj}> G_d > A_m > V_t >. Increasing Abrasive waterjet parameters linearly increases the MRR.

ABSTRACT

The Electric vehicle (EV) performance is critically dependent on the balance between speed and torque, which is managed through the ongoing development of motor technologies and control strategies. However, achieving high rotational speeds presents substantial challenges for conventional motor controllers due to issues such as switching losses, oscillations, and increased thermal loads. Furthermore, the integration of multi-speed transmission systems introduces additional complexity and weight, particularly concerning gear ratio selection and torque management. This study presents an innovative electric motor design for EV applications that eliminates the need for mechanical gearing and specialized controllers. The proposed design incorporates a synchronous permanent magnet input rotor that is magnetically coupled to a three-stage winding output rotor. This configuration facilitates high-speed operation, reduces acoustic noise and vibration, minimizes maintenance requirements, enhances reliability, and provides magnetic isolation between the input and output shafts. The novel integration of magnetic gearing with variable-stage windings enables the motor to sustain high efficiency across a wide speed range. Regardless of the motor type—whether Interior Permanent Magnet, Electrically Excited Synchronous, or C-core Hybrid Switched Reluctance—the proposed design achieves exceptional speed performance through simplified control and precise pole-pair determination. These findings indicate a promising direction for high-speed, gearless electric motor systems designed for next-generation EVs.

I. INTRODUCTION

The revolutions per minute (RPM) limit of electric motors in electric vehicles (EVs) can vary significantly based on the type of motor employed and the specific design requirements of the vehicle. EVs primarily utilize motors such as induction motors, brushless DC motors (BLDC), and permanent magnet synchronous motors (PMSM), each possessing distinct operational characteristics. For instance, PMSMs and BLDC motors are widely adopted due to their high efficiency and performance. These motors can operate at elevated RPM limits, typically ranging from 10,000 to 15,000 RPM in commercial EV applications, contingent upon the vehicle's design and manufacturer specifications [1], [2]. Surface-mounted PMSMs are capable of achieving rotational speeds up to 52,000 RPM, offering exceptional power density and compactness for EV traction systems.

However, they face challenges such as substantial rotor stress, eddy current losses, and reliance on costly rare-earth magnets, necessitating reinforced rotors, such as carbon-fiber sleeves, and advanced thermal management strategies [3]. Interior PMSMs (IPMSMs) can operate reliably at speeds up to 40,000 RPM, although commercial models typically restrict them to approximately 20,000 RPM due to increased bearing wear, vibration, and control complexity, despite their enhanced field-weakening capabilities [4]. Switched Reluctance Motors (SRMs) can surpass 100,000 RPM in specialized low-power applications, attributed to their robust rotor structure and magnet-free design [5]. Nevertheless, they generate high torque ripple and acoustic noise, requiring complex control and current shaping to ensure smooth operation, which limits their application in mainstream electric vehicles [6].

Synchronous Reluctance Motors (SynRMs) provide rare-earth-free operation and high efficiency, reaching around 14,000 RPM at 23 kW, but their torque density is generally lower, necessitating precise rotor geometry, which makes them less competitive in high-performance traction applications unless optimized [7]. Induction motors are also a prevalent choice for EVs and can similarly achieve high RPM levels, albeit generally exhibiting a broader RPM range due to their robust design and control flexibility. However, such motors may encounter challenges such as thermal management and efficiency decline at extremely high RPMs [1], [8]. Overall, while PMSMs dominate in high-performance EVs due to their efficiency and control precision, SRMs and SynRMs provide compelling alternatives when cost, simplicity, and rare-earth independence are prioritized, though at the cost of noise, control complexity, or reduced torque output [9-12]. The RPM limit in a particular EV model is largely influenced by the vehicle's design specifications, which encompass elements like the desired maximum speed, acceleration capabilities, and overall efficiency.

Electric motors in these vehicles are crafted to strike a balance among these performance aspects while ensuring reliability and reducing thermal stress during high-speed operations [13-18]. As velocity increases, motor controllers encounter challenges primarily due to elevated switching losses and oscillations. Soft switching technologies can address these issues by reducing the stress associated with high-frequency operations [19]. The implementation of a multi-speed transmission system introduces complexities, such as additional weight and the challenges of selecting appropriate gear ratios and managing torque interruptions during gear shifts [8]. High rotational speeds frequently result in increased heat generation, which can adversely impact the overall efficiency and lifespan of electric motors. Effective thermal management is essential for maintaining the performance of traction motors under high-speed conditions. This necessitates the implementation of innovative cooling solutions and the design of motors capable of handling increased thermal loads without a significant decline in performance [20].

Magnetic gears enable the transmission of power between input and output shafts without direct contact, thereby ensuring quiet operation and protection against overloads, in contrast to traditional mechanical gears [21-24]. High-speed magnetic gear motors are garnering considerable attention within the EV due to their capability to achieve rotational speeds surpassing 20,000 RPM without mechanical contact between the driving and driven components. This non-contact torque transmission mitigates wear, noise, and the necessity for lubrication, thereby enhancing the reliability and efficiency of these systems. Among the most promising designs for high-RPM performance are reluctance magnetic gears, which employ rotors composed entirely of iron to minimize eddy current losses and endure high centrifugal forces [25], and flux-switching magnetic gears, which incorporate multiple magnetic flux paths to sustain high torque density with improved thermal stability [26].

In advanced EV motor systems, magnetic multiple spur gear (MMSG) configurations are utilized to concentrate torque transmission within a compact space, facilitating both high-speed and high-power-density operation without compromising gear ratio flexibility [27]. Furthermore, the implementation of Halbach arrays in high-speed magnetic gears has been demonstrated to enhance air-gap flux density and reduce torque ripple, resulting in smoother and more efficient operation at extreme speeds [28]. The design and optimization of these high-RPM magnetic gear systems increasingly depend on nonlinear magnetic equivalent circuit (MEC) models, which offer precise and rapid predictions of magnetic behavior and torque characteristics without the computational demands of full finite element analysis (FEA) [29]. Collectively, these advancements support the integration of high-speed magnetic gear motors in next-generation EV drivetrains, where performance, efficiency, and durability are paramount.

This paper presents an innovative electric motor design for EVs, proposing the substitution of conventional motors with this new design rather than relying on advanced algorithms to achieve high-speed rotors. The proposed Variable Magnetic Gear Synchronous Motor (VMGSM) integrates a magnetic gear with a synchronous generator to facilitate high-speed operation without the need for mechanical gears, rendering it particularly suitable for EV applications. These systems employ three rotors in specific configurations to enable contactless torque transfer and speed enhancement. Our objective is to demonstrate that the proposed design is inherently capable of achieving high-speed rotors. It incorporates a multi-speed transmission system that can significantly enhance the vehicle's performance, improving acceleration and gradeability while also increasing energy efficiency.

II. TOPOLOGY OF PROPOSED VMGSM

Building upon the concept of high-performance magnetic gear as examined in [22], [23], our proposed design, illustrated in Figure 1, consists of a permanent magnetic inner rotor, a ferromagnetic rotor, and a variable electromagnetic output rotor equipped with stator winding.

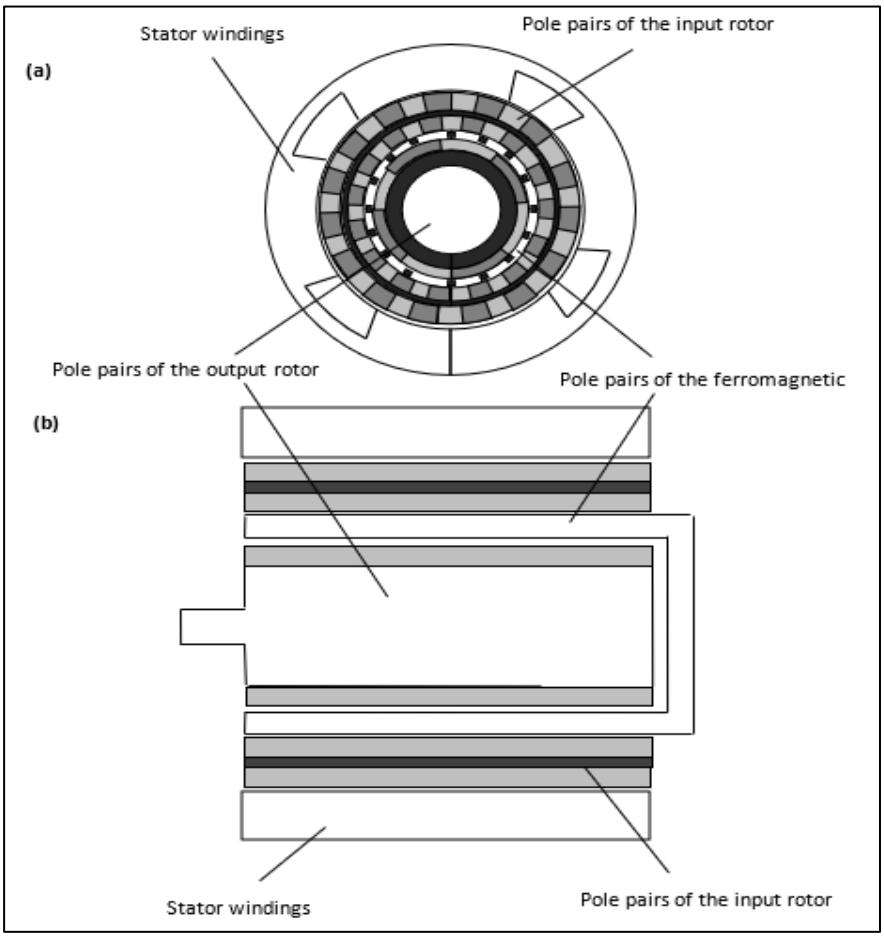

Figure 1: VMGSM (a) Radial cross section. (b) Axial cross section.
Source: Authors, (2026).

This configuration allows for the adjustment of the number of pole pairs in the output rotor. The stator's magnet winding interacts with the input rotor to generate electromagnetic torque, which is subsequently transmitted magnetically from the input rotor to the output rotor via ferromagnetic pole-pieces. This design enables the motor to operate efficiently across a range of speeds, rendering it particularly suitable for EVs. The stator windings interacts with the permanent magnetic pole-pairs pi of the input rotor to produce the electromagnetic torque:

$$T_e = \frac{3}{2} p_i \left(\varphi_{sd} i_{sq} - \varphi_{sq} i_{sd} \right) \tag{1}$$

The symbol φ represents the flux linkage, i indicates the current, s denotes the stator winding, and d and q refer to the dq reference frame. The three rotors are magnetically coupled according to the equation of motion [22], [23]:

$$\begin{cases} j_i \frac{d^2\theta_i}{dt^2} = T_e - T_{\max} \frac{p_i}{p_f} \sin(p_i\theta_i - p_f\theta_f - p_o\theta_o) \\ j_f \frac{d^2\theta_f}{dt^2} = -T_{\max} \sin(p_f\theta_f - p_i\theta_i - p_o\theta_o) \\ j_o \frac{d^2\theta_o}{dt^2} = T_{load} - T_{\max} \frac{p_o}{p_f} \sin(p_o\theta_o - p_f\theta_f - p_i\theta_i) \end{cases} \tag{2}$$

In this context, θ_i, θ_o, and θ_f represent the angular positions of the input, output, and ferromagnetic rotors, respectively. The symbol T_{load} is the load torque, T_{max} signifies the maximum torque that the magnetic gear can produce, and J_i, J_o, and J_f are the inertias associated with the input, output, and ferromagnetic rotors, respectively. The parameters p_i, p_o, and p_f represent the pairs-pole of the input, output, and ferromagnetic rotors. The equation governing these motions is expressed as follows [22], [23]:

$$p_f \cdot \omega_f = p_i \cdot \omega_i + p_o \cdot \omega_o \tag{3}$$

The speeds of the input, output, and ferromagnetic rotors are denoted by ω_i, ω_o, and ω_f, respectively.
It is evident that the rotor's speed is intrinsically connected to the number of pole pairs. The output rotor speed [22], [23]:

$$\omega_o = \frac{p_f}{p_o}\omega_f - \frac{p_i}{p_o}\omega_i \tag{4}$$

The output rotor is equipped with a winding that features variable pole pairs, enabling the adjustment of the number of pole pairs p_o. According to (4), it is evident that the speed of the output rotor ω_o is inversely related to the number of pole pairs, p_o. The torque is transferred magnetically from the input rotor T_i to the output rotor T_o, as described by the equation [22], [23]:

$$T_i = \frac{p_i}{p_o}T_o \tag{5}$$

The torque needed for the output rotor is not influenced by the rotor speeds; instead, it relies on the input torque applied and the gear ratio.

III. DYNAMIC INTERACTIONS AMONG THREE ROTOR

To elucidate the relationship between the input and output rotor speeds, we have selected two distinct gear ratios. The proposed VMGSM is directly powered by the stator winding. As depicted in Figure 2, the VMGSM is characterized by $p_i = 18$, $p_o = 8$, and $n_p = 26$. With these parameters, the input rotor achieves a speed of 200 rpm, while the output rotor operates at approximately 155 rpm.

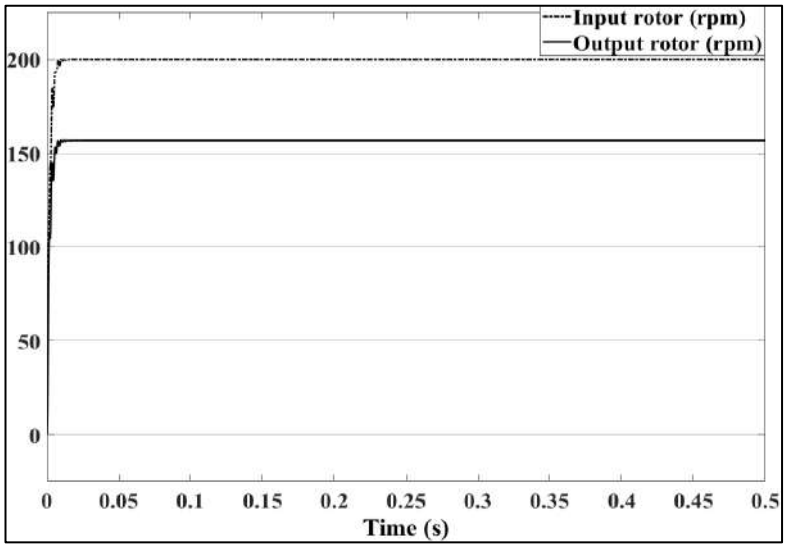

Figure 1: Rotors speed ($p_i = 18$, $p_o = 8$, and $n_p = 26$).
Source: Authors, (2026).

With the parameters p_i, p_o, and n_p set at 3, 16, and 24, respectively, the input rotor speed is documented at 1200 rpm. Consequently, this leads to an amplification of the output rotor speed to an estimated 12200 rpm.

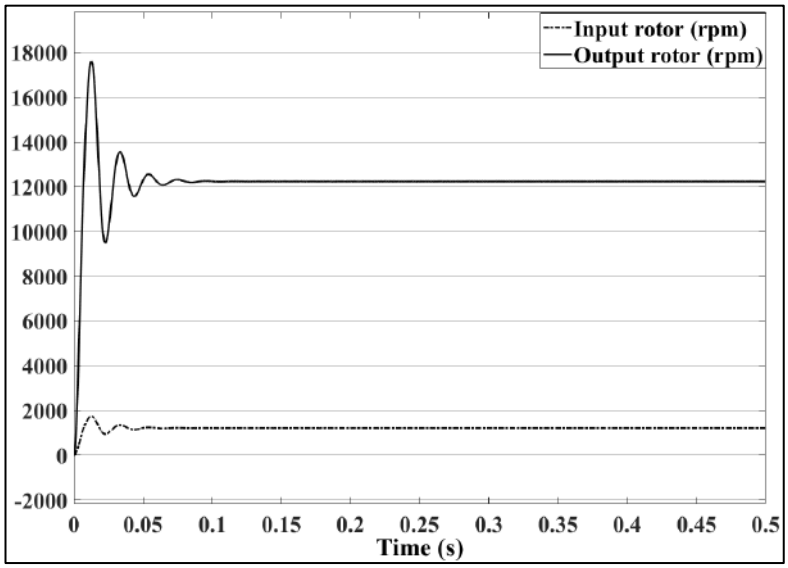

Figure 2: Rotors speed ($p_i = 3$, $p_o = 16$, and $n_p = 24$).
Source: Authors, (2026).

The rotational speed of the output rotor is not influenced by the torques of the rotors; instead, it is determined by the input speed and the gear ratio. The configuration of pole-pairs on both the input and output rotors, along with the number of ferromagnetic pole-pieces, significantly affects the resulting output speed.

Figure 4 illustrates a basic control system design that utilizes feedback mechanisms to regulate the speed and current of a 1.1 kW MGSM to their specified levels, without the reliance on completed algorithms. This closed-loop system continuously monitors the motor's actual speed and current through sensors, compares these measurements to the target values, and adjusts the motor's voltage to correct any deviations, thereby ensuring precise and stable operation.

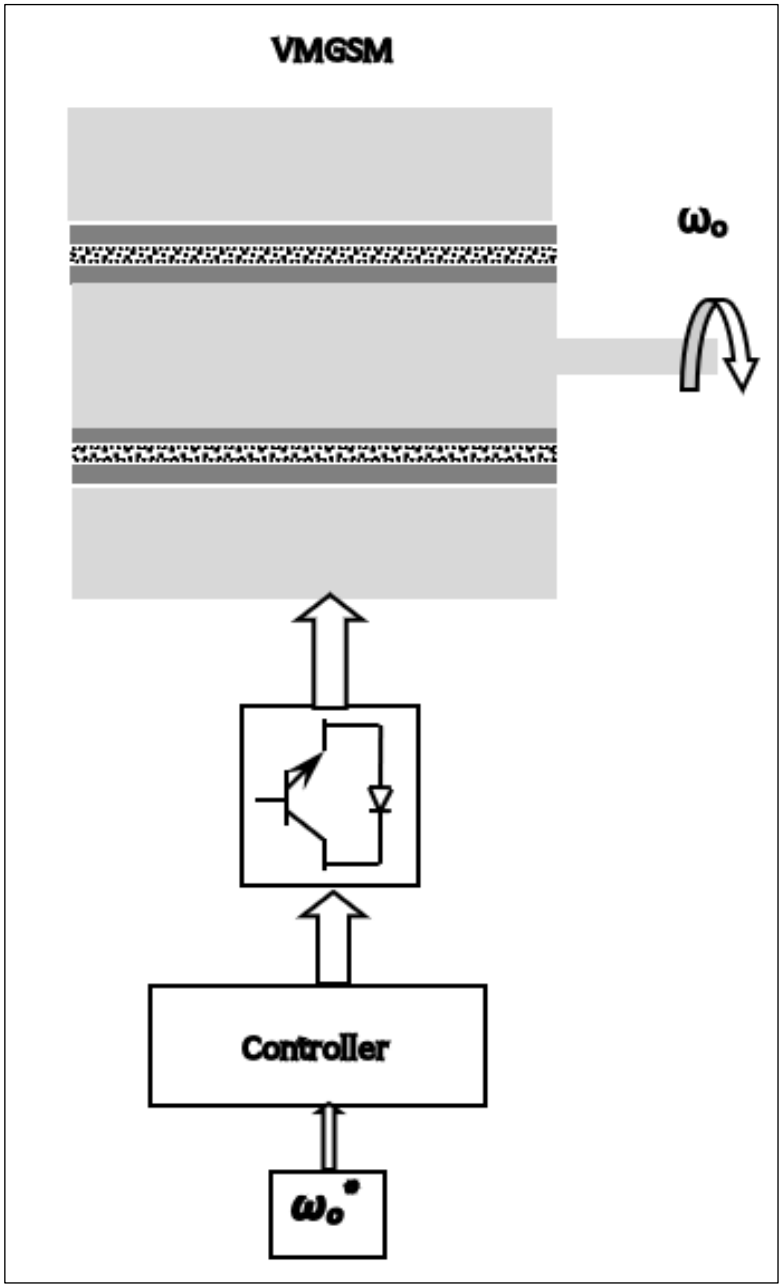

Figure 3: Control of proposed VMGSM.
Source: Authors, (2026).

Table 1 delineates the rated values of the VMGSM, which are regulated by a PWM inverter. The output from this inverter is transmitted through controlled voltage source before being applied to the stator windings of the VMGSM. Initially, the load torque on the machine's output shaft is set at 0 Nm, and then it increases to more than twice its nominal value of 7 Nm at t = 0.05s. A straightforward control strategy is employed, comprising two control loops: the inner loop regulates the stator currents of the motor, while the outer loop manages the motor's speed.

Table1: The rated values of the VMGSM.

Power	*1.1 (kw)*
voltage	*220 (v)*
p_i	*4*
p_o	*10*
n_s	*14*

Source: Authors, (2026).

As shown in Figure 5, setting the reference speed of the VMGSM's input rotor to 1900 rpm results in an output speed of 10,000 rpm, without the need for mechanical gears. This exemplifies the capability of this configuration to achieve high rotational speeds.

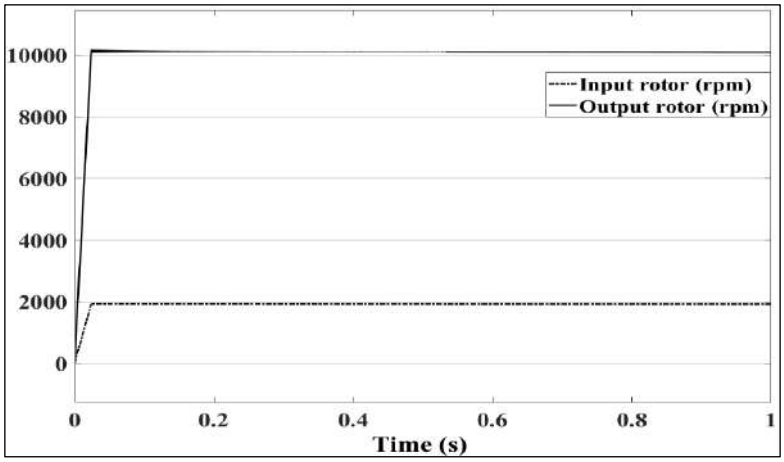

Figure 5: Input and output rotor speed.
Source: Authors, (2026).

Furthermore, Figure 6 the torque transmitted from the load via the output shaft surpasses the motor's rated value by 7 N.m, while the input rotor receives only 2.8 Nm. In this context, the VMGSM is subjected to a load that is 250% of its rated capacity.

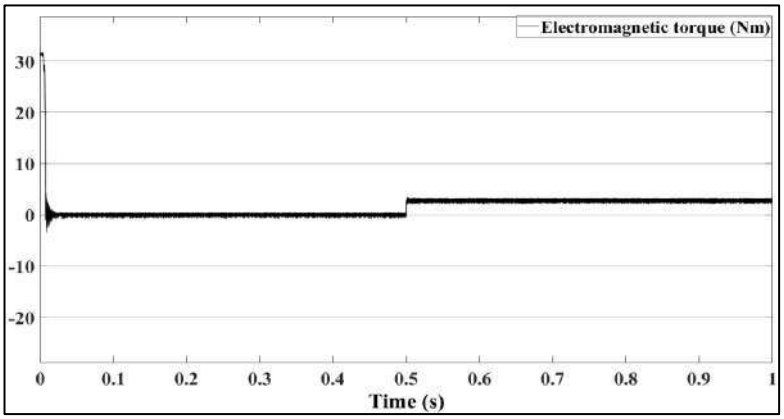

Figure 6: Electromagnetic torque.
Source: Authors, (2026).

IV. PRINCIPE OF OPERATION

To elucidate the correlation between the input and output rotor speeds of the VMGSM, the proposed VMGSM operates directly from a standard power source without the use of a controller Figure 7.

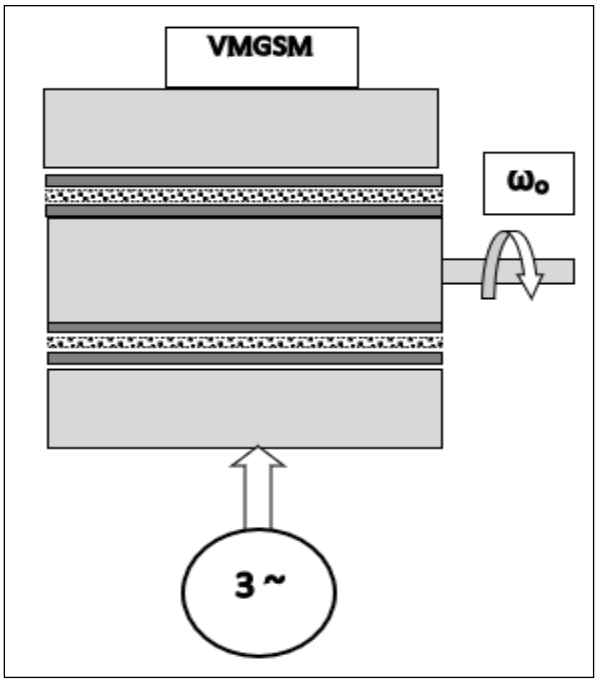

Figure 7: VMGSM with three-phase power supply.
Source: Authors, (2026).

We have chosen three distinct gear ratios, labeled as p_o, with values of 8, 12, and 16, corresponding to time intervals of 0 seconds, 1 second, and 2 seconds, respectively. As shown in Figure 8, the synchronous speed of the VMGSM (input rotor speed) is 900 rpm. Initially, this results in the output rotor reaching a speed of 3193 rpm for $p_o = 8$. At 1 second, the speed increases to 4214 rpm for $p_o = 12$, and finally, at 2 seconds, the system achieves a speed of 11311 rpm for $p_o = 16$. Without the integration of a controller, the output rotor of the VMGSM is capable of reaching a velocity that is 12.6 times the synchronous speed.

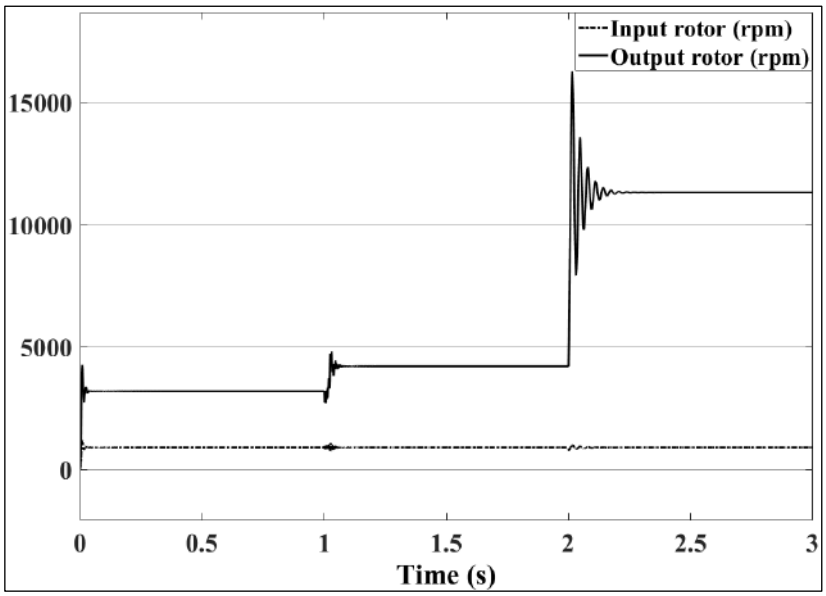

Figure 8: Input and output rotors speed with $P_i = 4$, $P_f = 14$, $P_o = 8$, 12 and 16.
Source: Authors, (2026).

We explore another scenario involving three distinct gear ratios: 4, 10, and 14, which align with time intervals of 0 seconds, 1 second, and 2 seconds, respectively. As shown in Figure 9, the synchronous speed of the VMGSM, acting as the input rotor speed, is established at 1800 rpm. Initially, this setup enables the output rotor to achieve a speed of 3193 rpm when the gear ratio of p_o, is 4. After 1 second, the speed escalates to 7976 rpm for a gear ratio of $p_o = 10$. Ultimately, at 2 seconds, the system reaches a speed of 30330 rpm for $p_o = 14$. The pronounced oscillation peak observed is attributed to the abrupt shift to a significantly higher speed, which is relevant solely in the context of speed gain.

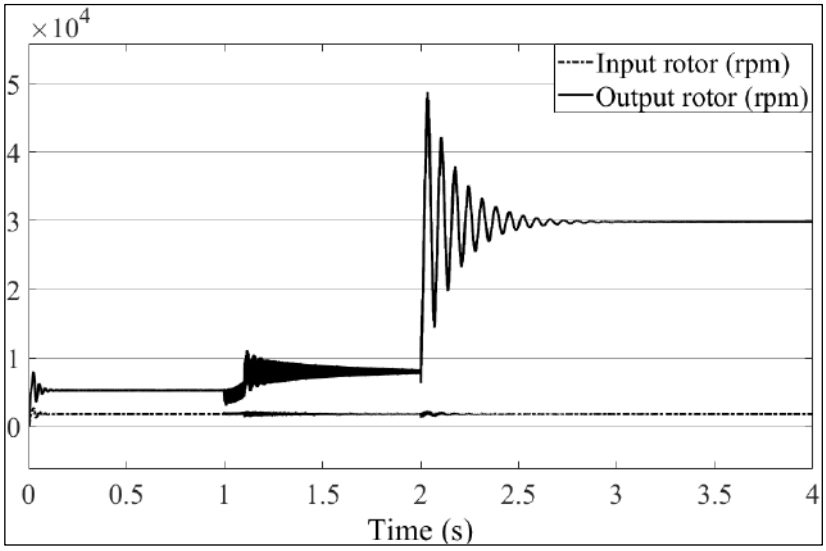

Figure 9: Input and output rotors speed with $P_i = 2$, $P_f = 12$, $P_o = 4$, 10 and 14.
Source: Authors, (2026).

As illustrated in Figure 8 and Figure 9, the rotational speed of the output rotor remains unaffected by the torques exerted by the rotors. Instead, it is determined by the input speed and the gear ratio. The configuration of pole-pairs on both the input and output rotors, in conjunction with the number of ferromagnetic pole-pieces, is instrumental in determining the final output speed. An important study investigates the connected C-core hybrid Switched Reluctance Motor (SRM), which incorporates inter-phase permanent magnets and an innovative magnetic configuration to enhance torque density and support high rotational speeds. Although the specific peak torque is not specified, the design achieves a significantly higher torque relative to magnet volume and is optimized for rotational speeds ranging from 10,000 to 15,000 RPM, rendering it highly suitable for compact, high-speed electric vehicle applications [30]. This level of speed performance was attained through the implementation of specific control strategies. Within the VMGSM framework, a rotational speed of 30,000 RPM was achieved by employing straightforward control techniques and a distinctive rotor design

V. RESULTS AND DISCUSSIONS

Table 2 shows the proposed control topology of 1.1 kw VMGSM in a simple closed-loop speed and current control. Table 2 outlines the rated values of the VMGSM, which are controlled by a PWM inverter. The inverter's output is transmitted through a controlled voltage source before being applied to the stator windings of the VMGSM. Initially, the load torque on the machine's output shaft is set at 0 Nm, then it increases to more than twice its nominal value of 7 Nm at t = 0.2 s. A straightforward control strategy is employed, consisting of two control loops: the inner loop regulates the motor's stator currents, while the outer loop manages the motor's speed. The reference speed of the VMGSM's synchronous speed is fixed at 1900 rpm, the gear ratio is increased from po = 4 to 10 and finally to 14 at 0 s, 0.5 s, and 1 s, respectively.

Table 2: Rated values of vmgsm.

Power	1.1 kw
Voltage	220 v
p_i	2
p_o	4, 10, 14.
P_f	12

Source: Authors, (2026).

As depicted in Figure 10, setting the reference speed of the VMGSM's input rotor to 1900 rpm results in output rotor speeds of 5544 rpm, 8450 rpm, and 32200 rpm, all achieved without the utilization of mechanical gears. This illustrates the VMGSM configuration's capability to attain high rotational speeds.

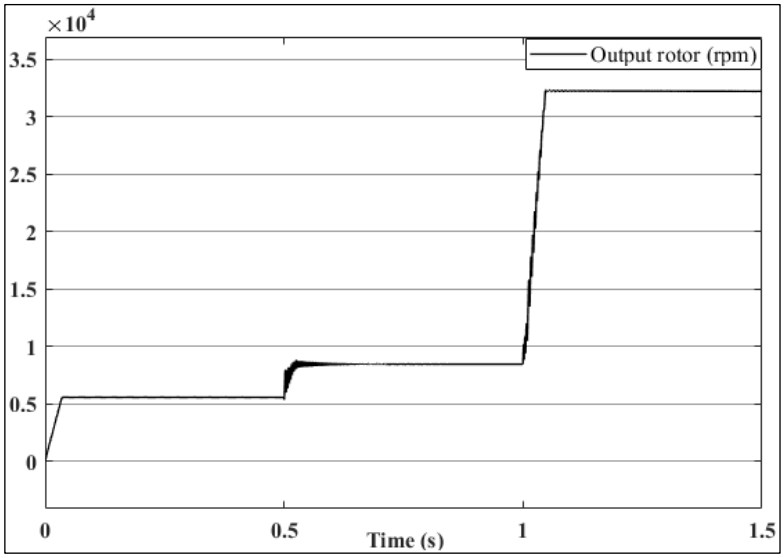

Figure 10: Output rotor speed.
Source: Authors, (2026).

As illustrated in Figure 11, the torque transmitted from the load via the output shaft exceeds the motor's rated capacity by 7 N.m. In contrast, the input rotor receives 3.5 Nm for $p_o = 4$, 1.4 Nm for $p_o = 10$, and 1 Nm for $p_o = 14$. In this context, the VMGSM is subjected to a load that is 250% of its rated capacity, yet the recorded electromagnetic torque is merely 1 Nm. The pronounced oscillation peak is attributed to the abrupt transition to a significantly higher speed, which occurs due to the absence of torque control in the controller.

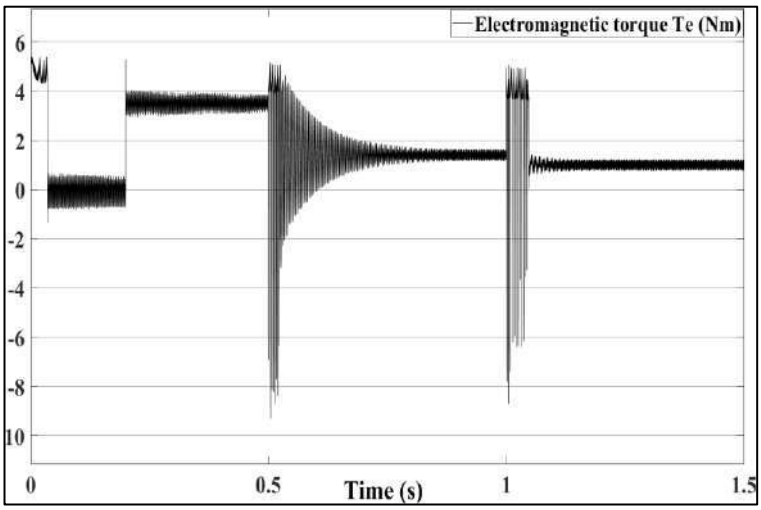

Figure 11: Electromagnetic torque.
Source: Authors, (2026).

Conversely, Interior Permanent Magnet (IPM) and Electrically Excited Synchronous Motors (EESMs) illustrate that the IPM achieves a maximum torque of 192 Nm at a constant torque speed of 6,559 RPM, whereas the EESM attains a higher peak torque of 232 Nm but operates at a lower constant-torque speed of 5,152 RPM [31]. This highlights the trade-off between torque and speed: although the torque required for the output rotor in VMGSM is independent of rotor speeds, it is dependent on the input torque applied and the gear ratio. In our case, the VMGSM is subjected to a load that is 250% of its rated capacity, yet the observed electromagnetic torque is merely 1 Nm.

VI. CONCLUSIONS

The present study investigates the performance characteristics of a variable magnetic gear synchronous motor across three distinct gear ratios, during which the output rotor speed progressively increases. The input rotor speed is consistently maintained at 1,800 rpm, serving as the baseline, while the output rotor achieves a maximum speed of 30,330 rpm. The output rotor speed is determined solely by the input rotor speed and the gear ratio, remaining unaffected by the electromagnetic torques produced by the rotors. These factors collectively establish the magnetic gear ratio and, consequently, the output speed. This decoupling of speed from torque underscores the variable magnetic gear synchronous motor's unique operational principle compared to conventional motors. The motor is subjected to a load exceeding 250% of its rated capacity, with the load torque transmitted through the output shaft surpassing the motor's nominal torque by 7 Nm.

Despite this substantial load, the electromagnetic torque generated by the variable magnetic gear synchronous motor remains high, recorded at only 1 Nm. In contrast, traditional motor types such as Interior Permanent Magnet (IPM) and Electrically Excited Synchronous Motors (EESMs) exhibit significantly lower speeds. The variable magnetic gear synchronous motor excels in achieving very high output speeds (up to 30,000 rpm) with simple control mechanisms and a specialized rotor design. The this substantial's design leverages a distinctive magnetic gear mechanism and straightforward control to enable high-speed operation, making it a promising candidate for applications where high rotational speeds are critical. This proposed motor eliminates the need for mechanical gears by incorporating a synchronous permanent magnet input rotor that is magnetically coupled to a three-stage windings output rotor.

This advanced design offers several advantages, including reduced weight and size, minimal maintenance requirements, operation without lubrication, an integrated cooling system, overload protection, and physical separation between the input and output shafts. It has been observed that the configuration of pole-pairs on the input and output rotors, along with the number of ferromagnetic pole-pieces, significantly influences the maximum torque transmission and output speed. The motor is capable of achieving high speeds, with the output rotor's rotational speed being determined by the input speed and gear ratio rather than the rotor torques. The arrangement of pole-pairs on both the input and output rotors, in conjunction with the ferromagnetic pole-pieces, is crucial in defining the output speed and torque load.

ABSTRACT

Circular economy which was a buzzword few years back is gaining momentum across the world. It is an economic system aimed at minimizing waste and mak- ing the most of resources. It is a model that contrasts with the traditional linear economy, which follows a 'take, make, dispose' approach. The circular economy involves designing products for longer use, promoting reuse, repair, refurbish- ment, and recycling to create a closed-loop system, thus reducing the need for new resources and minimizing environmental impact. This study aims at iden- tifying the publication trends related to the landscape of circular economy in India. Publications were searched from Dimensions data base. Software assisted bibliometric analysis was performed for bibliographic visualizations and exam- ining the knowledge creating networks. Total 221 publication items went into the analysis. Results reveal about the prominent journals, authors, organisations, and publications in the field. Advancing knowledge in circular economy requires interdisciplinary research and collaboration various disciplines, including busi- ness, environmental science, engineering, and policy studies. Focusing research on sectors related to the circular economy, such as agriculture, manufacturing, renewable energy, and e-waste management, while strengthening policy support through government initiatives, can promote sustainable and innovative solutions in India's circular economy.

I. INTRODUCTION

A circular economy involves the repurposing of goods that are nearing the end of their life cycle, thereby minimizing waste and closing loops within an industrial ecosystem [1-3]. Various studies have highlighted the importance of the circular economy as it can lead to economic growth, reduce the use of natural resources, offer environmental protection, and have positive social implications [4-7] . It is becoming an essential tool for activating sustainable development processes [8], [9] and is being prioritized by policymakers [10]. Academic research is also increasingly focused on the circular economy, particularly in areas such as product design [11], business models [12-14], agricultural waste management [15], [16], and sustainable supply chains [17]. Numerous studies have indicated that the global landscape of circular economy research is expanding, with environmental, economic, and social implications that necessitate the development of competencies and capabilities while offering a fertile ground for further research [5], [18-20].

The circular economy research is gaining traction in India also and is important for several reasons. Firstly, India is a rapidly growing economy with a large population and diverse industries, which puts significant pressure on resources and generates substantial waste. Embracing circular economy principles can help India address these challenges by minimizing waste, conserving resources, and promoting sustainable consumption and production patterns [21], [22]. Secondly, circular economy practices can contribute to India's sustainable development goals. By transitioning from a linear economy (where resources are extracted, used, and disposed of) to a circular economy (where resources are reused, recycled, and regenerated), India can achieve economic growth while reducing its environmental footprint.

Circular economy approaches can help decouple economic growth from resource consumption, leading to improved resource efficiency and reduced environmental impacts. Thirdly, circular economy research in India can foster innovation and create new business opportunities [23]. Circular economy practices promote resource efficiency, waste valorization, and sustainable business models, fostering the growth of green industries, creating employment opportunities, and improving competitiveness [24], [25]. Research in this area can provide insights into technological advancements, policy frameworks, and market opportunities that can support the growth of circular economy-oriented businesses in India. Moreover, circular economy research in India can contribute to global sustainability efforts. As one of the world's largest economies and a major contributor to global resource consumption and waste generation, India's adoption of circular economy principles can have significant environmental and social benefits.

Sharing research findings and best practices with the global community can inspire and inform circular economy transitions in other countries, promoting a more sustainable and inclusive future. Mapping the prominent journals, authors, organizations, and publications in the field of circular economy research in India through a rigorous bibliometric analysis is essential for several reasons. Firstly, it provides a comprehensive understanding of the current research landscape in India, identifying the key contributors and knowledge dissemination platforms. This information helps researchers and policymakers to recognize the most influential voices and sources of knowledge in the field, enabling them to stay informed about the latest developments and trends. Secondly, the mapping of prominent journals, authors, organizations, and publications facilitates knowledge exchange and collaboration.

By identifying the leading researchers, institutions, and publications, it becomes easier to establish connections and foster interdisciplinary collaborations. Researchers can leverage the expertise and networks of influential authors and organizations, leading to synergistic efforts and the generation of high-quality research outputs. Thirdly, the mapping of the circular economy research landscape aids in identifying research gaps and areas that require further exploration. By analyzing the distribution of publications across different topics and sectors, researchers can identify underrepresented areas and direct their efforts towards addressing those gaps. However, no such study has been conducted so far. Therefore, a bibliometric analysis of circular economy research in India is necessary to understand research trends, identify research gaps, and suggest future research directions. Such an analysis can aid policymakers and researchers in developing effective strategies to promote a circular economy in India and address challenges related to waste management and resource efficiency.

II. MATERIALS AND METHODS

For retrieving the publications, researcher searched for the items in Dimensions database on January 20, 2023. To populate the list of publications, terms "circular economy" and "India" were entered into the search field to search for them in 'title and abstracts' by using a Boolean "AND". Search resulted in total 368 documents, filter was applied to exclude the publication items which were not the research articles. Finally, 221 items went into the analysis. It is notable from Table 1 that the period between 2016 and 2023 witnessed a notable surge in publications on the circular economy in India, indicating a significant increase in research activity in this field. This can be attributed to several factors. Firstly, the global emergence and recognition of the circular economy concept prompted researchers to explore its applicability and implications specifically in the Indian context. Secondly, growing environmental concerns in India, such as pollution and resource depletion, have spurred a focus on sustainable approaches like the circular economy.

Thirdly, supportive policies and initiatives such as "National Mission on Sustainable Agriculture", National Policy of Plastic Waste Management", "National Mission on Sustainable Habitat" by the Indian government have encouraged research in this area. Additionally, the pressing need for sustain- able solutions in the face of population growth, urbanization, and resource scarcity has motivated scholars to investigate the circular economy's potential benefits. Lastly, research and funding opportunities have become available, attracting scholars to delve into this field. Collectively, these factors have contributed to the increased scholarly interest and research activity in the circular economy in India during this time frame. Table 2 classifies the publications on the basis of ANZRC categories of research and also on the basis of the sustainable development goal. Maximum number (74) of circular economy publications have been published in the area of "Engineering". The "Engineering" category of ANZRC covers a broad range of engineering disciplines, which allows for a diverse range of research topics related to circular economy.

For example, researchers may investigate the design and implementation of circular economy solutions in the manufacturing industry, or the development of sustainable building materials and infrastructure. Moreover, the circular economy is a relatively new concept in India, and research in this area is still in its nascent stage. The Engineering category of ANZRC may offer a suitable platform for researchers to explore and test circular economy concepts and practices in a variety of engineering fields. Overall, the large number of circular economy publications in the Engineering category of ANZRC in India suggests that the engineering community is taking an active interest in circular economy principles and is exploring ways to apply them in their respective fields of study. Software (VOSviewer) assisted bibliometric analysis is conducted by the researcher. Results include bibliographic coupling analysis of journals, research papers, and institutions, and co-citation analysis.

Table 1: Publication items and Percentages by Publication Years.

Publication Years	Publication items	Percentage of 221
2023	6	2.71
2022	83	37.55
2021	67	30.31
2020	46	20.81
2019	8	3.61
2018	5	2.26

III. RESULTS AND DISCUSSION

This section presents the results of the bibliometric analysis conducted to map the prominent journals, authors, organizations, and publications in the field of circular economy research in India. The analysis provides valuable insights into the current research landscape and highlights key contributors and influential entities in the field.

III.1 JOURNALS

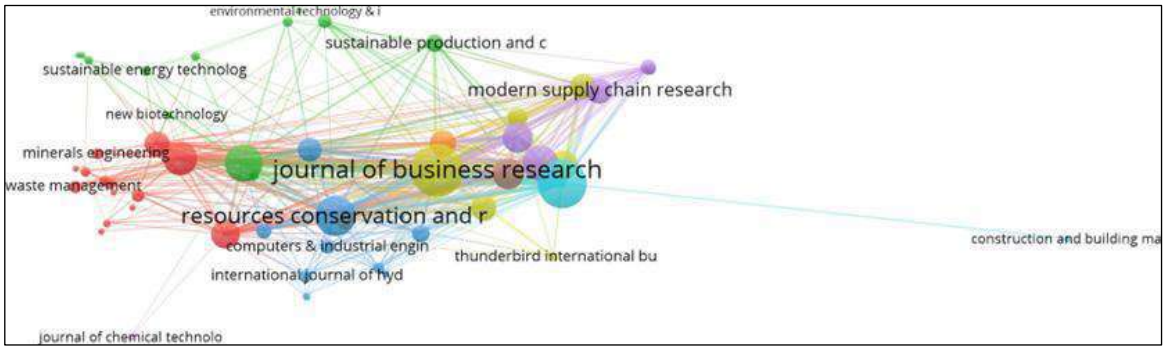

Figure 1: Network Visualisation of Journals (source: figure by authors).
Source: Authors, (2026).

Bibliographic coupling of the journals with network visualization is presented in Figure 1. Due to a smaller number of publications in the area, analysis included all the sources by keeping the number of documents of a source at minimum level 1, however the minimum number of citations of a source was set at 5 to get the most prolific journals. With these values, out of the 126 sources, 58 met the threshold, however the visualisation shows the largest set of connected items which consisted of 53 items. Bigger the size of a circle, higher the link strength of that journal. Top three journals in terms of total link strength are “Journal of Business Research”; “Journal of Cleaner Production”; and “Resources Conservation and Recycling”. “Journal of Cleaner Production” is at top in terms of number of papers published (17) and citations (479). Table 3 lists the top 15 journals. The Journal of Business Research has made a significant contribution to the field of circular economy in India by publishing a range of articles that explore various aspects of circular economy adoption by businesses, particularly SMEs.

These articles have provided insights into the barriers and drivers of circular economy adoption, identified gaps in current research, and proposed practical solutions for promoting circular economy practices in Indian industries. The journal has also contributed to the development of conceptual frameworks and models for understanding circular economy adoption by SMEs in emerging markets. Overall, the Journal of Business Research has helped to raise awareness and advance knowledge of circular economy practices in the Indian context. The Journal of Cleaner Production has made significant contributions to the field of circular economy in India by publishing research articles related to circular economy practices, challenges, and opportunities in various industries and sectors, such as agriculture, construction, manufacturing, and waste management. The journal has provided a platform for researchers to share their findings on circular economy-related topics, such as circular supply chain management, life cycle assessment, sustainable product design, and green innovation.

The articles published in the journal have helped in identifying the gaps in the existing circular economy practices and provided insights into the potential solutions and strategies to overcome these challenges. Resources Conservation and Recycling which is another leading journal in the field of circular economy and sustainability has made significant contributions to the circular economy landscape in India. The articles published in this journal have covered a wide range of topics related to circular economy, including the impact of COVID-19 on ship recycling, circular economy readiness in MSMEs, the role of blockchain in circular and modified linear economy, critical factors for remanufacturing, circular economy-induced employment shifts in apparel value chains, and advancing the assessment of circular economy strategies through material circularity and life cycle indicators. These articles have contributed to the development of knowledge and understanding of the circular economy in India, and have provided valuable insights for policymakers, researchers, and practitioners in the field. The inclusion of journals such as the Journal of Business Research, Journal of Cleaner Production, Resources Conservation and Recycling, Sustainability, Business Strategy and the Environment, and Environmental Science and Pollution Research highlights the multidisciplinary nature of circular economy research. It signifies that studies on circular economy in India encompass a wide range of topics, including business models, production processes, environmental conservation, sustainability practices, and waste management. Additionally, the presence of journals like Waste Management & Research, Journal of Environmental Management, Cleaner Logistics and Supply Chain, and Environment, Development and Sustainability indicates a specific focus on the circular economy within the waste management sector and the integration of sustainable practices across various industries.

Table 3: Top 15 Journals (criteria-total link strength).

Rank	Journal	No. of papers	Citations	Total link strength
1	Journal of Business Research	9	57	1238
2	Journal of Cleaner Production	17	479	1049
3	Resources Conservation and Recycling	6	372	628
4	Sustainability	12	116	561
5	Business Strategy and the Environment	3	46	468
6	Environmental Science and Pollution Research	8	161	419
7	Journal of Enterprise Information Management	1	7	343
8	Journal of Modelling in Management	2	24	332
9	International Journal of Productivity and Performance Management	1	7	287
10	Waste Management & Research the Journal for a Sustainable Circular Economy	6	12	287
11	Environment, Development and Sustainability	3	34	239
12	Modern Supply Chain Research and Applications	1	15	201
13	Journal of Environmental Management	6	106	196
14	Cleaner Logistics and Supply Chain	1	12	195
15	Management Decision	3	157	194

III.2 PROLIFIC AUTHORS

Table 4: Highly Cited Authors.

Rank	Author	Affiliation	Citations	Publications	Total link strength
1	Pradip Kalbar	IIT Mumbai	160	3	0
2	Rajesh Kumar Singh	MDI India	158	2	0
3	Sarat Kumar Jena	XIM University	120	2	2
3	Deepak Singhal	KIIT University	120	2	2
5	Rakesh D Raut	National Institute of Industrial Engineering	115	2	0
6	Sachin Kumar Mangla	O. P. Jindal Global University	108	4	13
7	Sudhanshu Joshi	Doon University	97	3	5
7	Manu Sharma	London Metropolitan University, UK	97	3	5
9	Purushothaman Chirakkuzhyil Abhilash	Banaras Hindu University	90	2	2
9	Priya Priyadarshini	Banaras Hindu University	90	2	2
11	Prem Vrat	The Northcap University	83	3	4
11	Ashwani Kumar	IIM Rohtak	83	2	2
13	Ayush Gautam	IIT Delhi	50	2	4
13	Ravi Shankar	IIT Delhi	50	2	4
15	Kannan Govindan	University of Southern Denmark, Denmark	42	3	5
15	Ashish Malik	University of Newcastle Australia	31	2	0
15	Rohit Panchal	National Institute of Industrial Engineering, India	30	2	2

Source: Authors, (2026).

In VOS minimum number of documents was set to two and minimum number of citations at five which resulted in 43 authors meeting the thresholds. A network of 43 authors has 903 possible co-authors (links) but in the network shown in Figure 2 only 44 links are present resulting in a very poor network density of 0.04<1(poorly knit network). A poorly knit network can have several implications. First, it suggests that researchers in the field have very few communication pathways to other authors, they are not working together and sharing their knowledge and expertise. This can result in duplication of efforts and missed opportunities for collaboration and innovation. Second, a lack of communication pathways can lead to limited dissemination of research findings and slower progress in the field.

Third, a poorly knit network may hinder the development of interdisciplinary research collaborations, which are crucial for addressing complex issues related to circular economy in India. Therefore, the low network density highlights the need for more collaboration and communication among researchers in the field of circular economy in India. This can be achieved through various means such as organizing workshops, conferences, and networking events, promoting interdisciplinary research collaborations, and fostering a culture of knowledge sharing and open communication. Such efforts can help to build a more robust research network and accelerate progress towards a sustainable circular economy in India. Table 4 summaries the results for top 15 most cited authors in the field along with their publications and total link strength.

It reveals that circular economy research in India is a multidisciplinary field, with contributions from researchers in diverse disciplines such as engineering, management, and sustainability. It also suggests that institutions such as IIT Mumbai, MDI India, and XIM University are leading research hubs in this field, with researchers affiliated to these institutions featuring prominently in the top 15 author list. Moreover, the presence of researchers from international universities such as London Metropolitan University, UK, University of Southern Denmark, Denmark, and University of Newcastle Australia in the top 15 author list suggests that circular economy research in India is gaining global recognition and attention. Researchers- Pradip Kalbar, Rajesh Kumar Singh, and Sarat Kumar Jena have made significant contributions to the field of circular economy research in India.

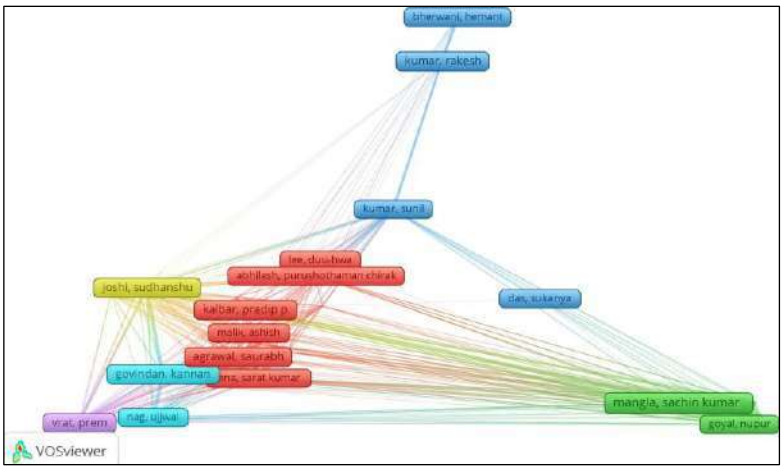

Figure 2: Clusters of author collaboration (source: figure by authors).
Source: Authors, (2026).

III.3 PROMINENT ORGANISATIONS

Network visualisation of organizations engaged in the field of circular economy research in India is presented in Figure 3. For analysis, value of minimum number of documents published by an organisation was set at three and minimum citations at five. Out of 248 organisations 27 met the threshold. It is clear that Indian Institutes of Technology (IIT) in Delhi and Mumbai, as well as Management Development Institute (MDI), are the top organizations in terms of citations and number of articles. This suggests that these institutions are actively involved in conducting research in the field of circular economy in India, and their research output is being cited frequently. Moreover, National Institute of Industrial Engineering, Amity University, Delhi University, Banaras Hindu University, and Graphic Era University are also among the top organizations, indicating that they too are actively involved in research in this field and have made significant contributions. It is worth noting that while some institutions have a higher number of articles, they may not necessarily have the highest number of citations. This may indicate that the quality of research output from these institutions may not be as impactful or influential as those with fewer articles but higher citations. Furthermore, from Table 5 it is interesting to observe the presence of international universities such as Aston University, Yonsei University, and University of Southern Denmark, among others, indicating collaboration between Indian and international scholars on circular economy research.

III.4 POPULAR PUBLICATIONS

For analysis, minimum number of citations of a document was set at 50, out of total 221 documents 17 met the threshold. Instead of all the items, only the largest set (14 items) of connected items has been shown in Figure 4. Table 6 lists the 15 top cited papers. Top cited article “Agricultural waste: Review of the evolution, approaches, and perspectives on alternative uses” provides a comprehensive review of the evolution, approaches, and perspectives on the alternative uses of agricultural waste in India. The author discusses the current state of agricultural waste management in India and highlights the challenges faced by the country in this regard. The article also highlights the potential benefits of converting agricultural waste into useful products such as biofuels, bioplastics, and animal feed. Furthermore, the author presents an overview of the various methods used for the conversion of agricultural waste, such as anaerobic digestion, pyrolysis, and fermentation. The article also reviews the policy framework related to agricultural waste management in India and highlights the need for a comprehensive policy that promotes the circular economy.

Overall, the article provides an insightful analysis of the circular economy landscape in India with respect to agricultural waste management and highlights the need for a holistic approach to address the challenges faced in this domain. Second top cited article “Waste-to-energy nexus for circular economy and environmental protection: Recent trends in hydrogen energy” by Surbhi Sharma (2020) discusses the potential of using waste-to-energy (WtE) technologies for the development of circular economies and environmental protection, with a focus on recent trends in hydrogen energy. The article presents a comprehensive review of various WtE technologies, their potential benefits and drawbacks, and explores the concept of circular economy and how WtE can play a crucial role in its development. The article also discusses the emerging trends in hydrogen energy production from WtE technologies and highlights its potential as a clean, efficient, and sustainable energy source for the future.

Table 6: Top Cited Research Papers.

Rank	Paper	First Author (Year)	Journal	Citations	Strength
1	Agricultural waste: Review of the evolution, approaches, and perspectives on alter- native uses	Monica D Acevedo (2020)	Global Economy and Conservation	190	2
2	Waste-to-energy nexus for circular economy and environmental protection: Recent trends in hydrogen energy	Surbhi Sharma (2020)	The Science of the Total Environment	180	6
3	Application of industry 4.0 technologies in SMEs for ethical and sustainable operations: Analysis of challenges	Ravinder Kumar (2020)	Journal of Cleaner Production	155	10
4	Valorization of agricultural waste for biogas based circular economy in India: A research outlook	Rimika Kapoor (2020)	Bioresource Technology	152	6
5	Circular economy business models in developing economies: Lessons from India on reduce, recycle, and reuse paradigms	Sandeep Goyal (2016)	Thunderbird International Business Review	127	3
6	Global E-waste management: Can WEEE make a difference? A review of e-waste trends, legislation, contemporary issues and future challenges	Shittu S Olanrewaju (2020)	Waste Management	115	6
7	To identify industry 4.0 and circular economy adoption barriers in the agriculture supply chain by using ISM-ANP	Shashank Kumar (2021)	Journal of Cleaner Production	113	16
8	Coupling material circularity indicators and life cycle-based indicators: A proposal to advance the assessment of circular economy strategies at the product level	Monia Niero (2019)	Resource Conservation and Recycling	110	13
9	Circular economy practices within energy and waste management sectors of India: A meta-analysis	Priya Priyadarshini (2020)	Bioresource Technology	90	15
10	When challenges impede the process	Yogesh Kumar Sharma (2019)	Management Decision	90	10

Source: Authors, (2026).

The study concludes by providing an outlook on the challenges and opportunities for WtE technologies in the context of circular economy and environmental protection. Third top article “Application of industry 4.0 technologies in SMEs for ethical and sustainable operations: Analysis of challenges” by Ravindra Kumar (2020) focuses on the application of Industry 4.0 technologies in Small and Medium Enterprises (SMEs) to achieve ethical and sustain- able operations. The paper analyzes the challenges that SMEs face in implementing these technologies and provides insights into how these challenges can be overcome. The study suggests that Industry 4.0 technologies can enable SMEs to adopt ethical and sustainable practices, improve productivity, and reduce costs. The paper also dis- cusses the role of government and industry associations in supporting SMEs in their adoption of these technologies. Overall, the paper highlights the potential benefits of Industry 4.0 technologies in promoting sustainability and ethical practices in SMEs. Based on the list of top cited articles in the field of circular economy in India, several insights can be made.

Firstly, it is apparent that there is a diverse range of research topics within the field of circular economy in India. The top cited articles cover a variety of themes, including waste management, energy, agriculture, and technology adoption. This suggests that the circular economy is not limited to one specific sector or area, but rather is a broad concept that can be applied across a range of industries and contexts. Secondly, it is interesting to note that several of the top cited articles focus on the challenges and barriers to implementing circular economy practices in India. This highlights the need for further research and understanding in this area, as well as the importance of addressing these challenges in order to promote sustainable and circular practices. Finally, it is worth noting that many of the top cited articles are authored by researchers based in India, indicating a growing interest and investment in circular economy research within the country. This is further supported by the fact that several of the top cited articles are published in Indian academic journals, indicating that there is a significant amount of research being conducted on this topic within India itself.

IV. CONCLUSION

This study significantly contributes to the existing literature on the circular economy landscape in India by mapping the prominent journals, authors, organizations, and publications through a rigorous bibliometric analysis. The findings offer valuable insights into the scientific research networks focusing on circular economy in India. Notably, esteemed Indian institutions such as IIT Delhi, IIT Bombay, and MDI Gur- gaon have emerged as influential knowledge producers in this field. Among the top journals, “Journal of Cleaner Production,” “Sustainability,” and “Journal of Business Research” have published a substantial number of papers, indicating their significance in the dissemination of research. The most prominent authors identified include Pradip Kalbar (IIT Mumbai), Rajesh Kumar Singh (MDI Gurgaon), and Sarat Kumar Jena (XIM University, Bhubaneshwar). Furthermore, highly cited research papers such as “Agricultural waste: Review of the evolution, approaches, and perspectives on alternative uses,” “Waste-to-energy nexus for circular economy and environmental protection: Recent trends in hydrogen energy,” and “Application of industry 4.0 technologies in SMEs for ethical and sustainable operations: Analysis of challenges” underscore the impact of these studies in shaping the circular economy discourse.

To advance knowledge in this field, fostering interdisciplinary research and collaboration among scholars from various disciplines such as business, environmental science, engineering, and policy studies is crucial. Targeting specific sectors related to the circular economy, such as agriculture, manufacturing, renewable energy, and e-waste management, for further research can address existing knowledge gaps. It is essential to strengthen policy support by continually enhancing and incentivizing circular economy practices, resource efficiency, and waste management through government initiatives. By integrating these recommendations, researchers, policymakers, and practitioners can collectively promote sustainable and innovative solutions in the circular economy domain in India.

ABSTRACT

Orthopedic surgical implants have traditionally been produced using conventional manufacturing techniques, with the output of these methods depending on the weight of the fabricated component and its biologically sourced materials. These hip implant composites, when exposed to physiological conditions over extended periods, particularly blood and adjacent soft tissues, are susceptible to gradual material degradation, manifesting as corrosion-induced damage and structural compromises. To address these challenges, this study focused on the development of titanium-containing composite material devices, primarily incorporating silicon carbide as a supporting component. The devices were cast via high-temperature sintering, facilitated by a specialized die assembly. The geometric design, material composition, and dimensional precision of these die sets are critical factors that determine the compressing efficiency and, consequently, the quality of the resulting sintered products. Therefore, this study emphasizes the design and application of a sintering die set optimized for cold uniaxial compression to produce cylindrical green packs characterized by a consistent layout and sufficient mechanical strength before the heated compression process. The compaction die set is a crucial component of the powder metallurgy method, which is responsible for shaping loose powder into the intended form. The die set was designed in accordance with the ASTM standards, and AISI D3 steel was used for its fabrication. This study also elaborates on the design factors, calculations, 2-D drawings, and 3-D models related to the die set. The die was manufactured using processes such as facing, turning, drilling, grinding, wire-cut electrical discharge machining (EDM), and heat treatment. The design was analyzed using SolidWorks 14 and ANSYS 2023R1. Following the evaluation of the safe load and production of the die set, the specimens were characterized. Scanning electron microscopy (SEM) evaluation identified the grain boundaries and porosity of the material, and mechanical tests demonstrated satisfactory hardness and biocompatibility..

I. INTRODUCTION

Globally, a significant number of individuals require bone replacements to treat injuries, trauma, and diseases. Historically, metal implants have been used in these patients. However, metal implants have certain limitations, including their weight, potential reactivity with human tissues and blood, and susceptibility to corrosion [1]. Corrosion can lead to implant loosening, requiring replacement, a procedure that can have substantial implications for human health. Implants are typically designed to last for a minimum of 15 years. However, recent findings suggest that some implants fail early because of fatigue corrosion. Therefore, further research on the fatigue corrosion of implants is essential, as such failures can occur within a month of implantation in the human body [2], [3]. Implant failures often result from the interaction between blood and implants, as blood is inherently corrosive in nature.

New materials are being developed for human implants, including ceramics. Ceramics, which have long been used in pottery and other applications, are also employed in various implants. When considering implants for hip replacement, factors such as the strength-to-weight ratio, corrosion resistance, and fatigue corrosion are critical. The initial research involved the use of finite element modeling to examine the design of the sintering die set and ceramic components. The uniaxial compaction process, which involves compressing powder under high pressure in a sealed chamber, was simulated using ANSYS Workbench software. The die set, which was oriented upwards, compressed the ceramic material. Pressures ranging from 350 to 1500 MPa are required for this treatment. Typically, temperatures of 1600°C are employed to shrink the mixed material within the circular die setup [4]. However, ceramic greens pose challenges when they are compressed.

Specifically, the interaction between the container's interior and the die's outer layer, as well as the interaction within the powder particles, is responsible for the permeation and round microcracking observed on the exterior of the green device. These factors can lead to surface imperfections, including restricted penetration scratches and radial microcracks, which are frequently observed in the outer areas of the compact [5]. Although these characteristics may appear detrimental, they can enhance the packing efficiency and, consequently, the material performance under specific conditions. Cold uniaxial compacting, employed across various forming methods, remains a valuable technique for molding ceramic powders by applying substantial compressive stress within a rigid die assembly. After shaping, the consolidated form is removed from the die and undergoes thermal processing, a phase that facilitates particle attachment and aggregation. This consolidation process generally occurs at high temperatures, and particle adhesion and neck growth are crucial for achieving mechanical strength, often in tightly controlled ammonia-rich environments [6]. To facilitate process development, the die-set layout and loading behavior were designed and assessed through numerical modeling using SolidWorks Software 14 and ANSYS Workbench 15.

The feasibility of the proposed method was confirmed by the successful production of green pellets incorporating alumina, zirconia, and hydroxyapatite. The load capacity during the compression phase was determined to be 800 kN, as estimated using a Universal Testing Machine (UTM) [7]. Concurrently, advancements in production and post-treatment techniques have enabled more precise monitoring of implant geometry, internal structure, and surface properties, thereby enhanced structural functionality and increased the potential for bone integration [8]. Advanced ceramic materials have become increasingly important in clinical settings, particularly in orthopedic prosthetics and surgical implants [9]. Bioceramics, specifically engineered for healthcare and orthodontic applications, are becoming increasingly prevalent as the demand for artificial substitutes rises in orthopedic applications. The fabrication of implants requires careful consideration, primarily because ceramic materials are susceptible to damage from environmental factors, particularly slow crack growth (SCG) in moist conditions [10].

This phenomenon is typically attributed to chemical reactions involving hydroxyl groups present in the atmosphere and highly stressed crack tips, which potentially compromise the metal–oxygen bond within the ceramic structure. Consequently, crack propagation may advance incrementally after a critical flaw dimension is reached, at which point a sudden fracture can occur without any prior macroscopic indications [11]. Among advanced ceramic systems, yttria-stabilized tetragonal zirconia polycrystals (Y-TZP) and alumina (Al_2O_3) have gathered sustained interest for implant-related applications, primarily because of their favorable combination of mechanical strength and structural reliability. Their high resistance to surface damage, coupled with a relatively strong fracture tolerance and elastic response, renders them suitable for demanding service conditions [12]. These attributes have encouraged their widespread application, particularly in biomedical settings [13], [14], where they are routinely employed. Beyond the clinical domain, the same material characteristics support their use in various engineering applications, including oxygen-sensing devices, protective thermal coatings for cutting and optical fiber tools, and functional elements within solid-oxide fuel cell technologies.[15].

II. MATERIALS AND METHODOLOGY

II.1 PROCESSING AND TESTING METHODS

Ti-6Al-4V titanium alloy was chosen as the main matrix material because of its established role in structural and biomedical fields, where it offers a good mix of mechanical strength, corrosion resistance, and biocompatibility. To alter the mechanical properties of the matrix, SiC was added as a ceramic phase to boost stiffness and surface hardness while ensuring that the dimensional stability remained within acceptable limits. The reinforcement strategy aimed to improve the load-bearing capacity without significantly reducing the ductility. In the chosen formulations, additional oxide-based components, such as alumina, zirconia, and hydroxyapatite, were included to evaluate their functional roles in the glass. Alumina was selected for its wear and thermal degradation resistance, whereas zirconia was selected for its stress-induced transformation behavior, which is often associated with enhanced fracture toughness. Hydroxyapatite was incorporated to encourage biological interactions at the material interface of the scaffold. During powder processing, polyvinyl alcohol served as a temporary binder to aid in the formation of the green compact. To ensure consistency between the experimental data and numerical models, the elastic behavior of the titanium–silicon carbide composite was characterized using a Young’s modulus of 180 GPa and a Poisson’s ratio of 0.27.

II.2 POWDER PREPARATION AND BLENDING

Composite samples were created using a powder metallurgy method, which was chosen to ensure precise control over the phase distribution during the manufacturing process. Ti-6Al-4V and SiC powders were measured according to specific compositions to maintain a uniform reinforcement ratio within the metal matrix. For ceramic systems based on oxides, alumina was mixed with unstabilized zirconia in different proportions to study the effects of the composition. The powders were homogenized through ball milling, which facilitated close interactions between the metal and ceramic components while reducing clumping. This step was deemed essential for achieving an even particle distribution and minimizing density variations during the subsequent compaction and sintering stages.

II.3 COMPACTION PROCESS

Cylindrical green compacts were created by cold uniaxial pressing of the mixed powder blends. The die–punch setup facilitated the production of pellets with uniform geometries and consistent dimensions. Figure 1(a) illustrates the tooling used for compaction, depicting the two-dimensional design of the die assembly, which was developed according to the ASTM B925-08 standards. To minimize the friction between the powder and die wall, a suitable lubricant was applied during pressing, ensuring a more uniform pressure distribution and reducing density variations within the green bodies.

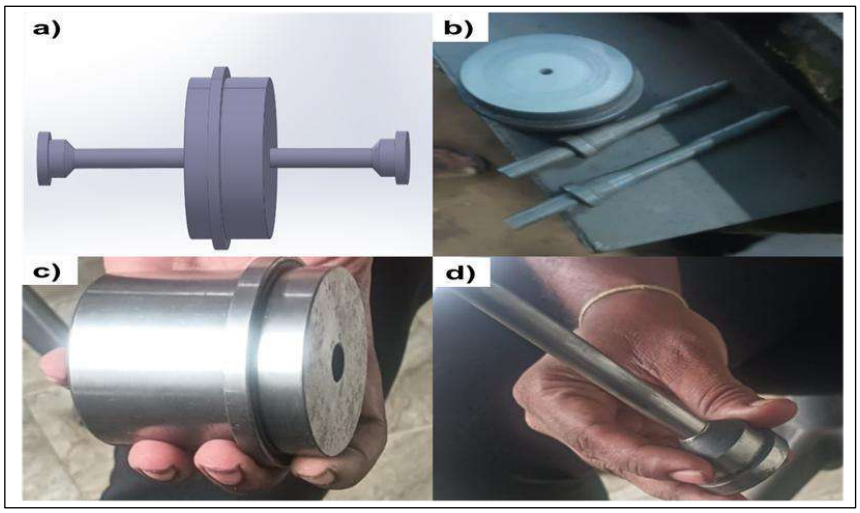

Figure 1: shows a) Model of the Die Set b) Sintering Die Set c) Die Set d) Punch.
Source: Authors, (2026).

II.4 DESIGN AND FABRICATION OF THE SINTERING DIE SET

The die system designed for sintering was formed to meet the dual requirements of high compaction forces and prolonged exposure to elevated temperatures during its use. Its design, which includes a central die body and opposing punch components, was developed using SolidWorks 14 to ensure structural strength and precise dimensions. A 0.5 mm clearance was intentionally set between the punch, and die bore to minimize friction and reduce wear over time. AISI D3 tool steel was selected for its high chromium content and excellent wear resistance. The manufacturing process involved material removal techniques such as facing, turning, drilling, and boring, all of which were carried out using CNC lathe systems, as shown in Fig. 1(b). Following the completion of the main machining operations, the die components were subjected to a carefully achieved through heat treatment process that included stress relief, hardening, and subsequent tempering. These procedures were implemented to improve the mechanical reliability while preserving dimensional accuracy. Surface finishing was performed using a combination of cylindrical and flat grinding techniques to achieve the desired surface quality. The final die assembly and corresponding punch elements, ready for use in pellet production, are shown in Figures 1 (c) and 1 (d), respectively.

II.5 MECHANICAL PROPERTIES OF TITANIUM AND SILICON CARBIDE

Table 1 provides an overview of the methods used to assess essential physical characteristics, such as the volume of the specimen, porosity, thermal conductivity, and related thermal expansion coefficient. These data were then used to investigate how the SiC reinforcement affects the overall physical behavior of the material system. The mechanical properties of the material, including microhardness, tensile strength, elastic modulus, wear characteristics, and fracture toughness, were assessed and compared with those of monolithic Ti-6Al-4V, as detailed in Table 2.

Table 1: Titanium silicon carbide composite Physical Properties.

Property	Ti-6Al-4V	Ti-6Al-4V + 10% SiC	Remarks
Density (g/cm³)	4.43	4.40–4.42	Slight reduction due to SiC (3.21 g/cm³)
Porosity (%)	1–2	0.5–1.5	Decreases with better sintering
Thermal Conductivity (W/m·K)	6.7	8–10	Increases with SiC
Coefficient of Thermal Expansion (µm/m·K)	8.6	7.8	Lower expansion improves dimensional stability

Source: Authors, (2026).

Table 2: Titanium silicon carbide composite Mechanical Properties.

Property	Pure Ti-6Al-4V	Ti-6Al-4V + SiC (10 wt%)	Remarks
Microhardness (HV)	340–360	420–480	~25–30% increase due to SiC
Ultimate Tensile Strength (MPa)	950–980	1050–1150	Improved load transfer via SiC
Elastic Modulus (GPa)	110	125–135	Enhanced stiffness
Wear Rate (mm³/N·m)	4.5×10^{-5}	1.8×10^{-5}	Better wear resistance
Fracture Toughness (MPa√m)	55	52	Slight reduction (brittleness due to ceramic phase)

Source: Authors, (2026).

In crafting the experimental strategy, ensuring uniformity in procedures was prioritized throughout the different phases of material preparation, which included powder-based processing, the creation of in-house tools, and the use of advanced consolidation techniques. Traditional furnace sintering and spark plasma sintering were employed to investigate the effects of variations in thermal exposure and consolidation kinetics on microstructural evolution. Consistent protocols for specimen preparation and assessment of physical and structural properties further minimized variability. The material properties derived from the experimental data were integrated into the computational framework to bolster the reliability of the finite element simulations. Overall, the chosen methodology provides a structured approach for examining the relationships between processing conditions, changing microstructures, and the resulting functional response, as discussed in the following sections.

II.6 POWDER PROCESSING

In this study, a powder metallurgy technique was employed to fabricate uniform blends of Ti-6Al-4V and SiC particles. Additionally, the research yielded ceramic compounds such as alumina, zirconia and hydroxyapatite.

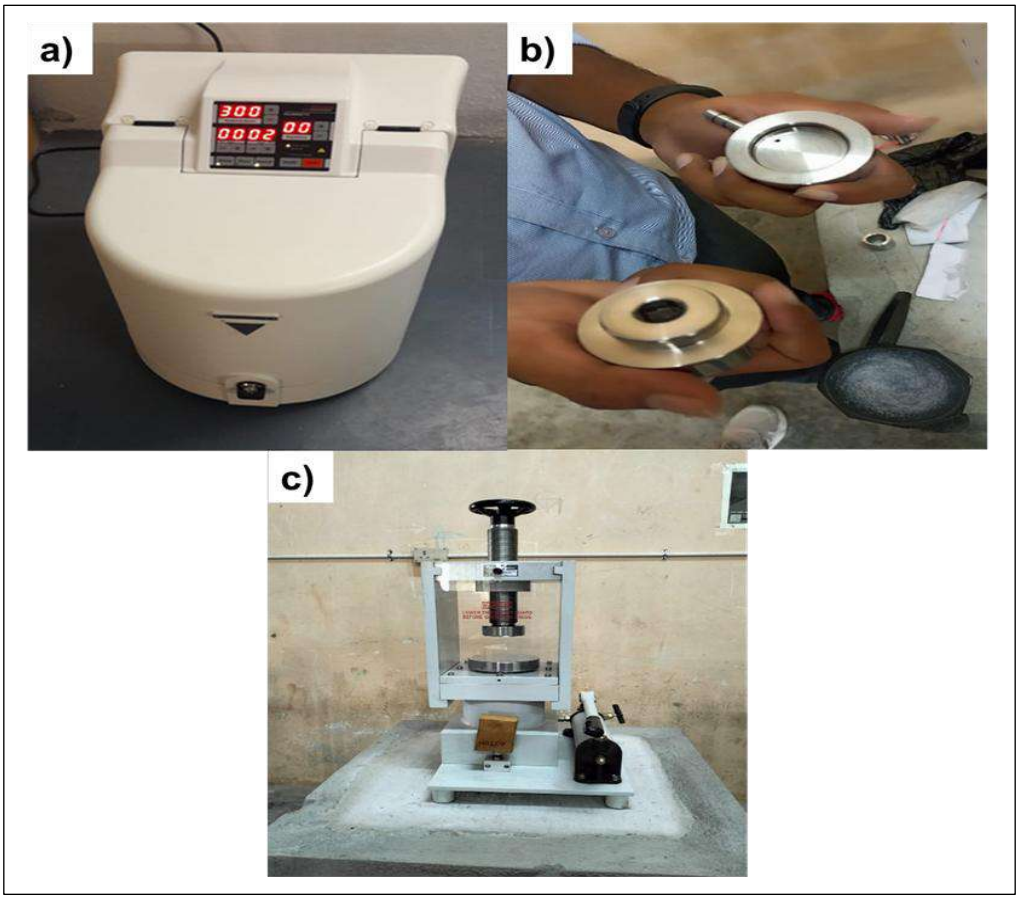

Figure 2: a) Ball milling machine, b) Steel dia punch, c) Pallet machine.
Source: Authors, (2026).

As illustrated in Figure 2 (a), ball milling was used to break up agglomerates and ensure an even particle distribution before compression. Surface analysis verified the absence of macroscopic fragmentation, indicating that the selected grinding time and rotational speed were effective in creating a homogeneous mixture. The cold compression grinding process, using a specially designed steel die and pressing equipment (Figure 2 (b)), resulted in green pellets with adequate dimensional stability and handling strength, with no visible breakage or boundary fractures after their ejection. The observed movement suggests that lubrication was successful and that the weight was distributed evenly throughout the crushing process. This was further enhanced by employing high-power compression equipment (Figure 2 (c)), which applied consistent pressure, resulting in a uniform green density.

III. RESULTS AND DISCUSSION

III.1 SEM ANALYSIS

The SEM image, taken at an increased frequency of 20 kV and a magnification of 5,000×, reveals the external morphology of the Ti–6Al–4V/SiC composite material after sintering. The surface structure is marked by a spread of fine, relatively evenly distributed grains interspersed with a few larger geometric features, especially noticeable in the upper-right section of the image. The presence of grains of similar size, generally measuring between 1 and 3 µm, may indicate a largely uniform recrystallization process during thermal consolidation. In contrast, the appearance of larger grains could indicate localized regions with higher titanium concentrations, which experienced accelerated grain growth during partial sintering. As for particle distribution, the disordered, bright, and angular features seen within the titanium substrate are likely due to silicon carbide atoms. Their larger atomic size would likely result in increased contrast in the SEM image analysis, as shown in Figure 3 (a) & (b).

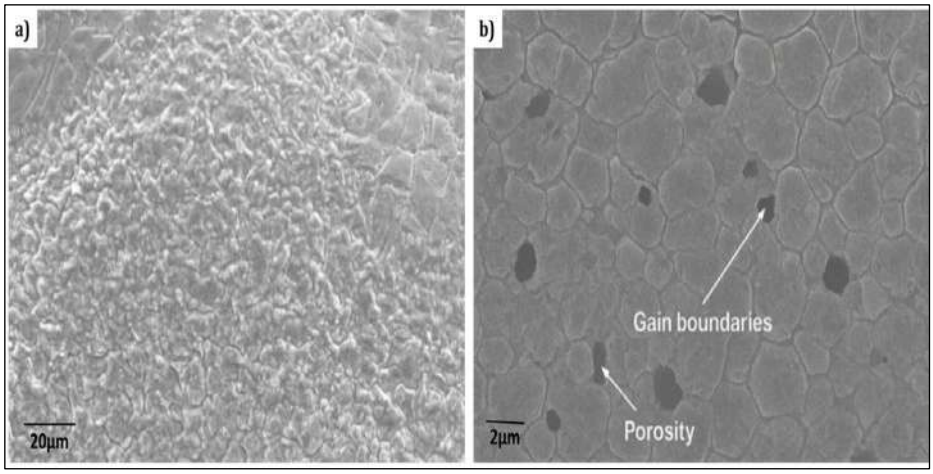

Figure 3: SEM Analysis.
Source: Authors, (2026).

Analysis of the SEM image revealed that the Ti–6Al–4V/SiC material reached a satisfactory level of consolidation, as evidenced by a microstructure characterized by fine and densely packed features. The SiC reinforcement was distributed within the titanium matrix without noticeable segregation, and the observed morphology suggests a sintering result that could enhance the mechanical strength and wear resistance, although such connections should not be exaggerated.

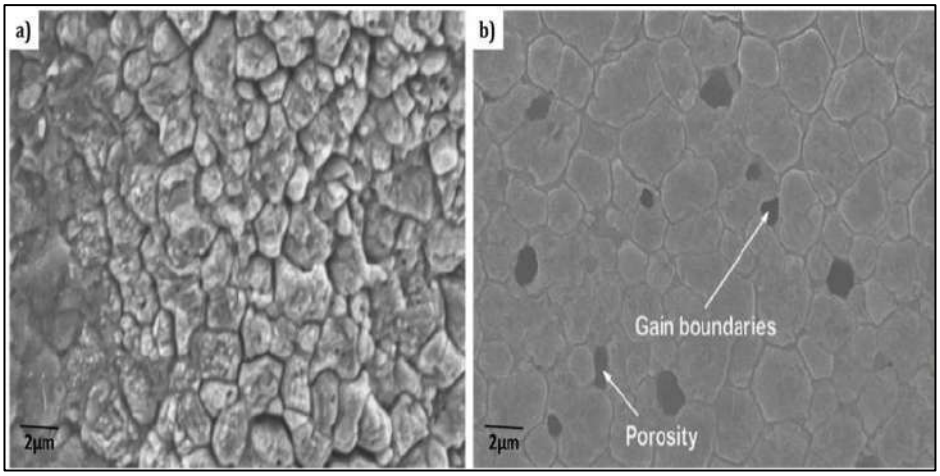

Figure 4: SEM Analysis of Titanium Silicon carbide.
Source: Authors, (2026).

Figure 4(a) & (b) shows the thermally treated surface morphology of the Ti–6Al–4V–SiC composite captured at a higher magnification. Imaging was conducted at 15,000× magnification with an accelerating voltage of 20 kV, allowing for a detailed examination of the microstructural arrangement formed during thermal processing. SEM Microscopic analysis revealed that the finer areas of the microstructure consisted of densely packed polygonal shapes with distinct edges. The typical size of these shapes ranged from approximately 0.3 to 1.2 µm. This consistency can be considered an indication of relatively controlled grain development during the sintering process, which was carried out at temperatures between 1200 and 1300 °C. Importantly, the lack of significant voids or cracks indicates a high degree of consolidation and minimal remaining porosity, characteristics often linked to meticulously manage sintering conditions and, in some instances, processing methods similar to hot pressing. The grains exhibited a predominantly uniform shape, which might be linked to the nearly isotropic elastic properties of the material. Slightly curved grain boundaries were also observed, suggesting partial diffusion bonding and a relatively stable grain boundary network. Furthermore, the SiC nanoparticles present at the grain interfaces likely played a role in refining the grain size by hindering boundary movement, aligning with the Zener-type pinning mechanism that is commonly noted for preventing excessive grain growth during thermal exposure.

III.2 SURFACE INTEGRITY

In the analyzed areas, there were no signs of microcracking, particle detachment, or separation at the interfaces, and the bond between the reinforcement particles and the matrix was strong. Consequently, the material is linked to relatively high hardness levels of approximately 450–470 HV, along with a noticeable enhancement in resistance to corrosive damage.

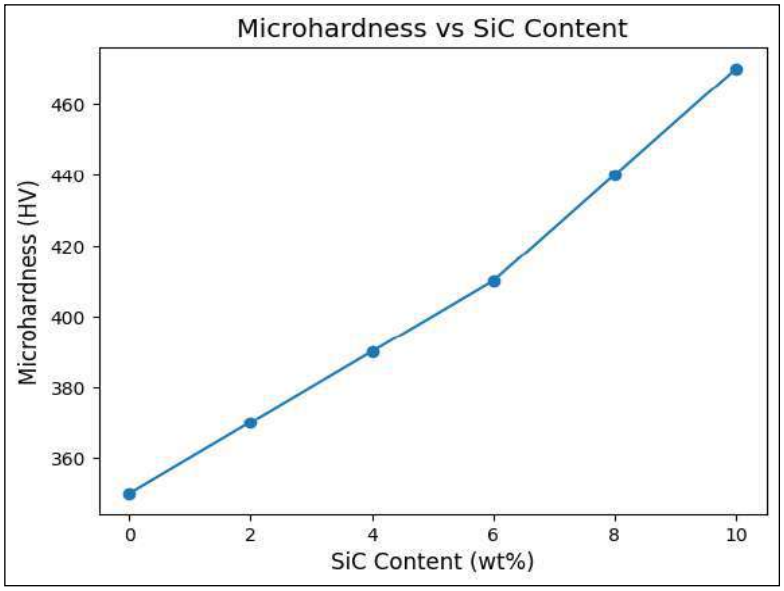

Figure 5: Graph hardness vs Silicon content.
Source: Authors, (2026).

Table 3 Inferred Material Characteristics.

Property	Observation	Implication
Grain size (μm)	0.3–1.2	Fine-grained → higher hardness & strength
Porosity	<1% (no visible voids)	High densification
Interfacial bonding	Strong (no particle detachment)	Efficient load transfer
Expected Microhardness (HV)	450–480	~30% improvement over Ti-6Al-4V
Fracture Mechanism	Ductile–brittle mixed	Grain-boundary strengthening with SiC

Source: Authors, (2026).

III.3 FINITE ELEMENT ANALYSIS OF HIP IMPLANT AND SINTERING DIE SET

Simultaneously, the numerical evaluation of the hip implant setup (Fig. 6) revealed that the total deformation under conditions representing physiological loads was minimal, a reaction typically deemed advantageous for orthopedic components that bear weight. Numerical analysis showed that the maximum deformation remained at approximately 10^{-7} m, indicating significant structural rigidity and only slight localized movement. The analysis of stress and strain patterns demonstrated a generally even distribution, with no noticeable areas of concentration, suggesting efficient load distribution and a reduced likelihood of fatigue initiation. Applying the same analytical approach to the sintering die assembly under various loads revealed that the stress and deformation levels remained well within the elastic range of AISI D3 tool steel. Across all the tested loading scenarios, the die set consistently exhibited elastic behavior, supporting its appropriateness for repeated compaction tasks rather than single-use applications. For better understanding, Figure 6 shows the geometric design of the sintering die set from multiple angles.

III.4 MICROSTRUCTURE-DRIVEN MECHANICAL AND BIOMECHANICAL PERFORMANCE

Through a combined evaluation of experimental data and numerical modeling, it is evident that the processing approach significantly affects the internal structure and subsequent performance of the studied material systems. Employing controlled powder conditioning alongside electrically assisted rapid consolidation promotes the formation of refined and evenly distributed structural features, potentially enhancing hardness and reducing residual porosity. In this framework, Ti–SiC composite systems exhibited a desirable balance of mechanical stiffness and environmental stability, making them suitable for applications subjected to mechanical stress and chemically active environments. Additionally, metallic samples consolidated via spark plasma sintering exhibited a high degree of structural continuity, suggesting that rapid sintering methods effectively reduce microstructural heterogeneity. From an engineering standpoint, finite element simulations indicated that deformation levels under load conditions similar to physiological scenarios would be minimal, which is a favorable outcome for materials intended for load-bearing biomedical applications. However, it is crucial to note that these computational predictions cannot be directly applied to long-term biological system assessments. Overall, the combination of microstructural uniformity, empirically measured mechanical performance, and resistance to environmental degradation provides preliminary support for further investigation of titanium-based composite systems in orthopedic-implant research [19-25].

IV. CONCLUSIONS

This study investigated the behavior of titanium-based composite materials has examining the effects of different fabrication methods on their internal structure and functional performance. Instead of using only monolithic alloys, SiC was added as a reinforcing phase to alter the properties of Ti-6Al-4V, and the resulting materials were compared with those produced through spark plasma sintering. The hybrid samples were formed using a powdered production technique in which the ceramic component was integrated during the initial material preparation phase. This approach allowed the formation of compressed bodies that maintained their structural integrity before exposure to high temperatures. After thermal processing, the subsequent substrate showed a uniform internal structure with fewer deficiencies than the untreated substrate. Additionally, the inclusion of SiC has affected the interaction dynamics within the composite, leading to improved material uniformity and reduced structural cracking during fabrication. Elemental analysis revealed a uniform distribution of the constituent elements within the composite system, indicating successful material integration.

During processing, phase evolution at the matrix–reinforcement interface may involve the formation of Ti-rich phases along with limited carbide or silicide reaction products. In the stability of the interfacial region, which is characterized by controlled reaction layers, is crucial for maintaining structural continuity. Based on this, a hybrid implant material by combining a titanium alloy with silicon carbide was developed, offering benefits such as reduced weight and enhanced compatibility. Microstructural evaluation revealed steady grain features, strong interfacial bonding between the metallic matrix and ceramic reinforcement, and low residual porosity, all of which support efficient stress transfer and mechanical reliability. The increased hardness can be attributed to the inclusion of the ceramic phase, which refined the internal structure. These findings were also supported by numerical modeling, which predicted minimal deformations and a favorable distribution of stress when subjected to loads like those in the body.

ABSTRACT

Technology in business field has helped solve problems that involve card fraud or commercial transactions; however, it has also generated a great need to guarantee the security of customer data. The use of neural networks has emerged as an indispensable tool to address this type of problem. In this study, a systematic review was developed of 64 articles from Scopus and Web of Science, to identify the type of business data, the neural network architecture used, and the influence on a type of analyzed business problem. Search strategies such as PICO and PRISMA2020 were combined for the selection. Based on inclusion and exclusion criteria, this paper seeks to answer the research question: How the neural network models optimize enterprise data security? Four metrics were identified: Accuracy, Precision, Recall, and F-Score, to compare the efficiency of neural network models such as CNN, DNN, LSTM, or their variants. These models outperformed other current techniques in the identification of card or transaction fraud; however, their implementation remains limited in small and medium-sized enterprises due to restrictions in technological infrastructure and computational capacity.

I. INTRODUCTION

The current financial risk landscape poses a persistent challenge, driven by economic expansion and technological advances [1], [2]. The ongoing digitalization of financial services has increased the incidence of fraudulent activities, adversely affecting financial institutions, regulatory bodies, and end-users [3], [4]. For instance, direct losses from credit card fraud are estimated to amount to billions of dollars annually, excluding indirect losses which are more difficult to quantify [5], [6]. In 2023, global losses reached USD 33.83 billion, slightly exceeding the USD 33.45 billion recorded in 2022. Conventional detection methods, relying primarily on manual scrutiny and rule-based systems, are insufficient to counter the complexity of modern fraud schemes [7], [8]. This situation necessitates the development of more innovative anti-fraud solutions capable of thwarting malicious actors. Various machine learning algorithms as support vector machines, linear and logistic regression, decision trees, random forests, and k-nearest neighbors, have also been employed for fraud detection and corporate data security [9], [10].

However, their accuracy and scalability are often constrained by class imbalance and the need to process large data volumes. Advances in technology and internet accessibility have established deep learning models as significant contributors to optimizing the security and protection of financial, commercial, customer, operational, and human resources data. Architectures such as Convolutional Neural Networks (CNNs), Deep Neural Networks (DNNs), and Dual-Channel Graph Attention Networks (DGANs) achieve superior accuracy compared to traditional approaches. Furthermore, Long Short-Term Memory (LSTM) networks, Recurrent Neural Networks (RNNs), and hybrid structures demonstrate a considerable potential for countering sophisticated attacks in fraud detection. These models learn data representations to identify malicious patterns, anomalous behaviors, or fraud attempts [8], [11]. Other brain-inspired architectures, such as Spiking Neural Networks, Chaotic Coupled Neural Networks, and graph-based approaches, offer additional potential by detecting dynamic and chaotic patterns, thereby adapting to evolving fraudulent behaviors over time [12-16].

Financial institutions face sustained economic risks stemming from inadequate information protection. This challenge has driven the scientific community to design and implement new defensive measures against fraudulent systems [17]. Nevertheless, despite progress in deep learning, comprehensive studies analyzing the capacity of diverse neural network architectures to enhance corporate data security remain scarce. This article presents a comprehensive and up-to-date review of the principal neural network architectures applied to corporate data security. Guided by the PICO strategy and the PRISMA2020 (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) framework for study search, selection, and analysis, the review systematically categorizes information based on data type, addressed problem, applied neural network architecture, and reported evaluation metrics. This rigorous methodological approach provides a deep understanding of the strengths, limitations, and opportunities for future research in corporate fraud prevention.

II. METHODOLOGY

This study was conducted as a systematic literature review, a methodology characterized by the evaluation and synthesis of relevant information on a specific topic. This review aims to identify neural network models used to analyze corporate data security. To this end, the following research question was formulated: How do neural network models optimize corporate data security?

II.1 PICO STRATEGY

A guided approach based on specific questions from the PICO strategy was employed. Originally applied in medical fields, this tool is now used to identify the Problem (P), Intervention (I), Comparison (C), and Outcomes (O) in any area of study [18], [19]. To address the research question, the comparison component was excluded, allowing for the evaluation of all types of neural networks. Consequently, only three components (P-I-O) were assessed. Table 1 presents the questions and associated keywords for each PIO component. The first question focuses on identifying the types of corporate data analyzed using neural networks; the second addresses the type of neural network used for processing corporate data. Finally, the third question evaluates the influence of neural networks on data analysis. Thus, these three questions determined the research objective.

Table 1: PIO Strategy Components.

Component	Associated Question	Keywords
Problem (P)	What types of corporate data are analyzed using neural networks?	Business Data, Enterprise Data, Company Data, Financial Risk, Fraud Detection
Intervention (I)	What neural network architectures are applied to corporate data?	Neural Networks, Neuronal Networks, NN
Outcomes (O)	How do neural networks influence corporate data security?	Security, Safety, Protection, Confidentiality, Privacy, Analyses

Source: Authors, (2026).

Using the keywords described in Table 1, an exhaustive search was conducted in two high-impact scientific databases: Scopus and Web of Science (WoS) [20], [21]. The search strategy began in Scopus, forming three blocks joined by the logical operator AND. In each block, the *Article title, Abstract, Keywords* option was selected, and the keywords associated with PIO were entered, connected by OR. As a result, the following search string was obtained (as of May 3, 2025):

(TITLE-ABS-KEY ("business data" OR "enterprise data" OR "company data" OR "financial risk" OR "fraud detection") AND TITLE-ABS-KEY ("neural networks" OR "neuronal networks" OR NN) AND TITLE-ABS-KEY (security OR safety OR protection OR confidentiality OR privacy OR analyses)) AND PUBYEAR > 2019 AND PUBYEAR < 2026 AND (LIMIT-TO (DOCTYPE , "ar")) AND (LIMIT-TO (LANGUAGE , "English")) AND (LIMIT-TO (OA , "all"))

For the WoS search, the same PIO strategy keywords (see Table.1) were used, placed in three blocks with the *Topic* option, interlinked by the AND connective. The same filters were applied for both Scopus (FS) and WoS (FW). These filters are presented in Table 2.

Table 2: Filters Applied to the Search String.

Filter	Description
FS1: PUBYEAR > 2021 AND PUBYEAR < 2025 **FW1: 2022 or 2023 or 2024 (Publication Years)**	Limits the search to documents published within a specific date range
FS2: LIMIT-TO (LANGUAGE , "English") **FW2: English (Languages)**	Selects documents only in the chosen language
FS3: LIMIT-TO (DOCTYPE,"ar") **FW3: Article (Document Types)**	Restricts results to original articles
FS4: LIMIT-TO (OA , "all") **FW4: All Open Access (Open Access)**	Filters for open access documents

Source: Authors, (2026).

II.2 PRISMA2020 PROTOCOL

For the selection of documents that formed the basis of this review's results, the PRISMA2020 protocol was applied. This is a widely recognized methodology in the scientific community for conducting bibliometric studies, reviews, and meta-analyses [22]. Specific inclusion and exclusion criteria were applied to minimize bias (see Table 3).

Table 3: Inclusion and Exclusion Criteria.

Filter	Description
CI1: Studies that apply neural networks to the analysis of corporate data in any sector	CE1: Studies not focused on corporate data
CI2: Studies that describe or compare different neural network architectures applied to corporate data	CE2: Studies that do not present clear results on the use of neural networks
CI3: Studies that report performance metrics or impact on business processes or data protection	CE3: Studies that do not provide information on data security through the use of neural networks
CI4: Studies accessible in full text.	CE4: Studies identified as retracted

Source: Authors, (2026).

Figure 1 presents a PRISMA2020 flow diagram to document and visualize the study selection process in a structured manner. This diagram details the stages of search, inclusion, and exclusion of studies, providing a clear framework for the strategy employed in this review. Initially, 221 studies were identified from Scopus (151) and WoS (70). After removing 40 duplicate records, a total of 181 remained. Subsequently, 89 were excluded after analyzing titles and abstracts, reducing the number to 92 articles. All of these were successfully retrieved in full text. During the evaluation phase, 28 articles were excluded based on the exclusion criteria (CE) established in Table 2. Finally, a total of 64 studies were selected for the review analysis.

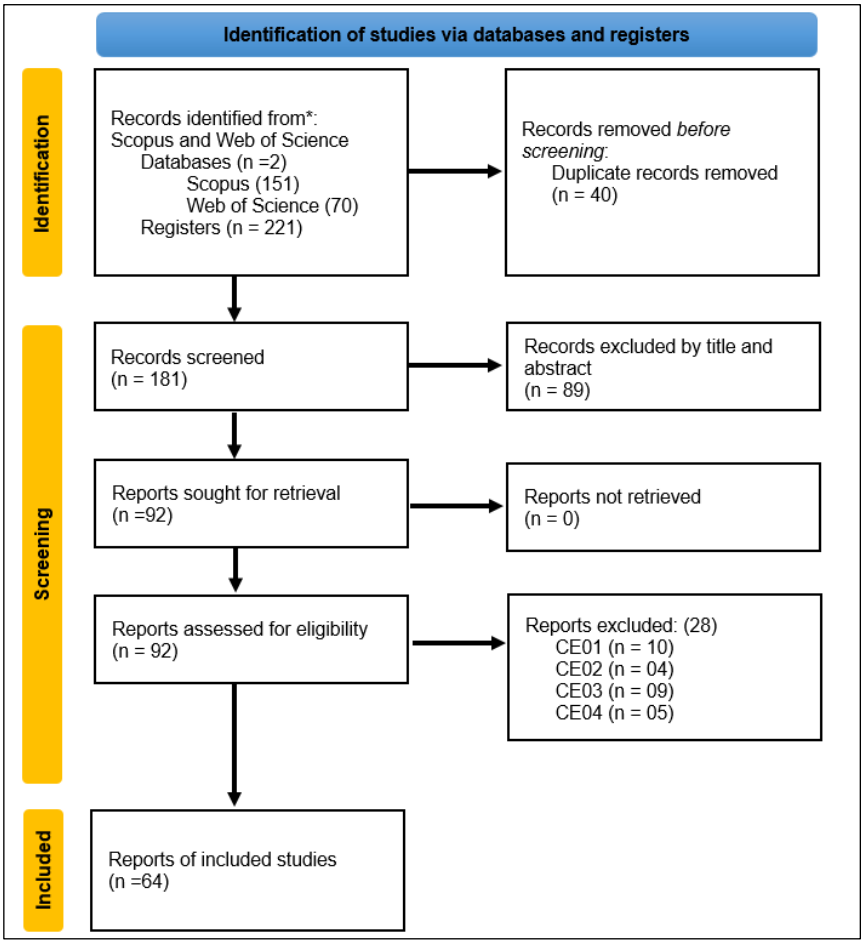

Figure 1: PRISMA Flowchart.

III. RESULTS AND DISCUSSIONS

III.1 BIBLIOMETRIC RESULTS

To present a general report of the articles included in the analysis, journals were classified by quartile type, calculated using the SCImago Journal Rank indicator (SJR 2024). 21articles correspond to quartile 1 (Q1), 25 to Q2, 15 to Q3, and only 3 articles mention Q4-type journals. Figure 2 describes the percentages associated with each quartile. These results indicate that over 70% of the analyzed studies originate from high-impact Q1 and Q2 journals, demonstrating the editorial quality of the selected studies.

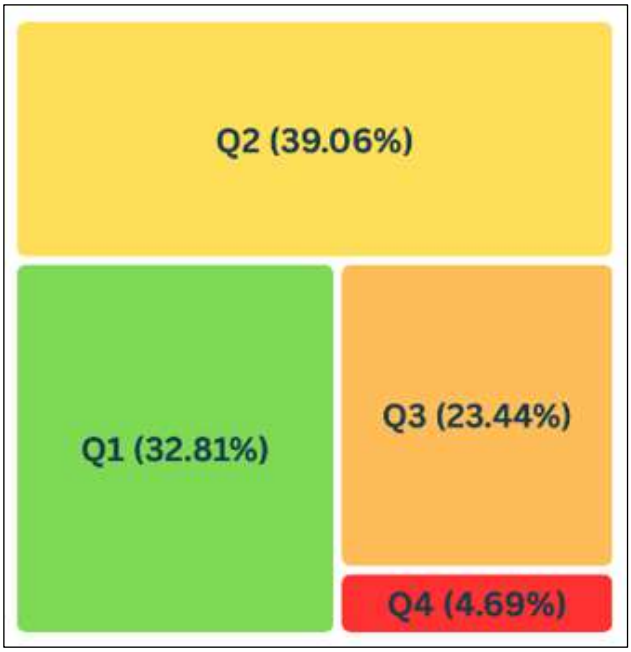

Figure 2: Articles classified by journal quartile.
Source: Authors, (2026).

The most prominent publisher is the Multidisciplinary Digital Publishing Institute (MDPI) with 11 articles, followed by the Institute of Electrical and Electronics Engineers Inc. (IEEE) with 9 articles, whose main journal is IEEE Access (7).

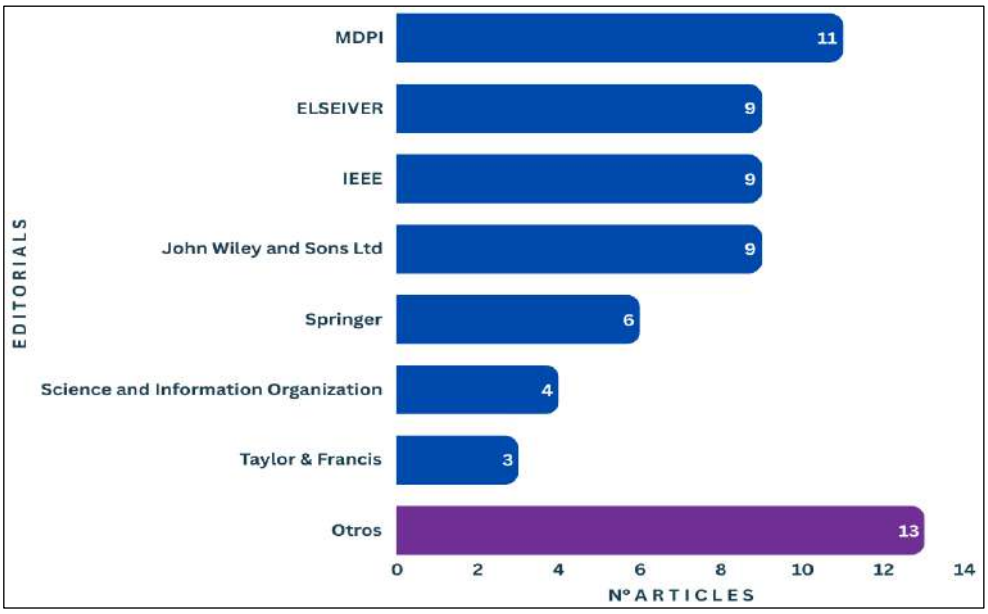

Figure 3: Articles classified by journal publisher.
Source: Authors, (2026).

Studies were also categorized by research field. Computer science stands out in this classification with 69.2%, encompassing artificial intelligence, machine learning, and natural language processing. The information systems area accounts for 12.3%, followed by Finance and Economics with 10.8%. Other represented disciplines are Engineering, with 4.6%, and Mathematics, with 3.1%. This distribution highlights a strong interdisciplinary link in the analyzed works. The following sections will address the questions related to each component of the PIO strategy (see Table 1).

III.2 WHAT TYPES OF CORPORATE DATA ARE ANALYZED USING NEURAL NETWORKS?

One of the main challenges in the corporate sphere is managing the control of large data volumes. Data preparation is one of the initial stages of the process and involves collecting and organizing raw data for efficient analysis [23]. Therefore, using neural networks to analyze such data in real-time has become a necessity to provide timely responses in milliseconds, preventing fraud and increasing customer confidence [24]. Of the 64 selected articles, 87.5% (56 studies) detail some type of corporate data analyzed using neural networks, with commercial transaction data standing out in 25 studies. This type of transaction involves banks processing thousands of transfers per day, which is impossible for a human to supervise, let alone in real time [25].

With the widespread use of credit cards in online and offline transactions, fraud has become a major challenge for the financial sector. Wu et al. in [6], demonstrate that brain-like computing can significantly contribute to improving the security and efficiency of fraud detection systems. On the other hand, with countries like China entering the international market, competition is becoming increasingly complex. Added to this, companies often have gaps in their financial structure, generating significant risks in their international trade [26]. Likewise, financial-type data were identified in 14 studies involving companies that use technological innovation to offer services and products. Liu, T. and Yang L. in [27], used financial data for their analysis, accurately identifying companies with different risk levels, particularly in the low and medium-risk categories. In [28], five financial indicators were identified: (i) interest-bearing debt/total invested capital, (ii) quick ratio, (iii) accounts payable turnover ratio, (iv) proportion of goodwill, and (v) goodwill, demonstrating that these factors have a greater impact on the identification results of many neural network models, reflecting a significant role in identifying financial fraud. Another relevant dataset comprises operational and logistical data (12 articles). This type of data is generated by the various modules of an Operational Management System [29]. Accurately predicting the volatility of financial asset prices has profound theoretical and practical importance, especially for generating early warnings of financial market risks. Identifying the type of data to be analyzed for a problem is fundamental to applying more effective detection methods. If working with imbalanced data, where class distribution is not uniform, it can lead to suboptimal predictive performance, especially for the minority class [30]. Table 4 describes the types of corporate data analyzed using neural networks, detailing the problem studied and the sector of application.

Table 4: Types of corporate data.

Data type	Problem	Sector	Ref.
Commercial Transactions	Anomaly identification in payments, transfer classification	E-commerce	[16], [25], [26], [31], [32], [33], [34], [35], [36], [37], [38], [39], [40], [41], [42], [43], [44], [45], [46], [47], [48], [49], [50], [51], [52].
Financial Data	Fraud detection, credit risk prediction	Microfinance, fintech	[6], [16], [23], [24], [27], [28], [53], [54], [55], [56], [57], [58], [59], [60].
Operational Data	Demand forecasting, quality control	Manufacturing	[15], [29], [61], [62], [63], [64], [65], [66], [67], [68], [69], [70].
Customer Data	Market segmentation	Marketing, e-commerce	[40], [46], [71], [72].
Human Resources Data	Turnover prediction, job performance, absenteeism	Human talent management	[73], [74], [75], [76].

Source: Authors, (2026).

Based on this component, the corporate data analyzed using neural networks correspond mainly to transactional and financial information. This reflects the need to manage data in real-time to prevent fraud or detect anomalies, as noted by previous studies [3],[6]. The literature also makes clear that, with technological advances and the increase in electronic operations, companies seek to implement more robust models to minimize credit risk [4]. Despite the effectiveness demonstrated by neural networks in data analysis, challenges exist related to integrating unstructured sources, such as text or customer behavior. Furthermore, in sectors like manufacturing and logistics, various studies describe the ability of these techniques to improve industrial efficiency through demand forecasting and quality control [61],[63]. However, their adoption in small and medium-sized enterprises remains limited, revealing a technological gap for future research. On the other hand, these models are also applied in customer and human resources management, primarily in marketing and human talent areas [40],[46],[75]. In general, this review shows the frequency of neural network usage in the corporate environment, although their adoption depends on the data type, learning architecture, and interpretability of the implemented models.

III.3 WHAT NEURAL NETWORK ARCHITECTURES ARE APPLIED TO CORPORATE DATA?

Deep learning methods based on artificial intelligence techniques have generated better results for extracting, analyzing, and expressing data compared to traditional methods. Many researchers have gradually applied deep learning technologies to their research, particularly in topics related to corporate financial early warning [34]. 42.19% of the articles selected for this research (27) describe the type of neural network used to analyze a corporate-type problem. Table 5 describes the neural network type, the selected dataset, the corporate problem being solved, the metrics used to measure efficiency, and the reference article. Based on the 27 articles involved for component (I), 26.63% use CNN to solve problems of financial risk, fraud detection, or identification of fraudulent transactions. Unlike other models, CNN methods reflect a significant advantage due to their nonlinear adjustment capability, data processing ability, and generate greater accuracy and discrimination in predictions [34]. According to [31], developed a CNN model to detect and mitigate fraudulent activities in smart contracts. Textual and transactional data from smart contracts from Google BigQuery Ethereum were analyzed.

This dataset includes essential attributes such as sender addresses, recipient addresses, transaction value, and timestamp. On the other hand, inspired by brain-like computing, Wu et al. in [6], implemented an optimized CNN network, known as Continuous Coupled Neural Network (CCNN) for credit card fraud detection, managing to reduce data imbalance through random oversampling techniques. Another type of neural network is the DNN. In [33], establishes that the financial early warning model trained by DNN generates an effective financial early warning for the company. However, due to the hidden layers of these models, uncertainty in their analysis can be generated. For example, fraudsters change their strategies, and consequently, DNNs encounter observations not generated by the same process; another factor is due to the time-consuming process and very few transactions are verified in a timely manner by professional experts to update the DNNs. In [51], three uncertainty quantification (UQ) techniques called "Monte Carlo dropout," "ensemble," and "ensemble Monte Carlo dropout" are proposed, demonstrating that UQ methods provide additional information about point predictions, thereby improving the fraud prevention process.

Other research combines DNN and RNN, resulting in a model called FinAnalytixs [45] for stock performance prediction and fraud detection. This architecture allows DNN to capture complex relationships between various financial indicators, such as the interaction between market trends, company finances, and macroeconomic factors. Other models were identified, such as Graph Neural Networks (GNN), specifically designed to work with graph-structured data [15]. The Backpropagation Neural Network (BPNN), a model built based on blockchain technology for financial data analysis [52]. The NAG (Neural Aggregates Generator) model, which faithfully mimics the structure of state-of-the-art manual function aggregates. This strategy relates any transaction to its recent past by calculating statistics on those transactions similar to the current one [77]. The CRAFIC (Complex Relationship Analysis for Fraud Identification and Cost management) framework [37] achieves a significant performance improvement in complex fraud detection tasks by combining CNN and LSTM in feature extraction and time series analysis. The analysis of architectures adopted in the corporate sector shows a marked preference for deep and hybrid learning models, capable of optimizing pattern detection and reducing uncertainty in complex financial environments [4], [8].

In particular, CNNs and their composite variants, such as CNN-LSTM and CNN-Transformer-Wavelet, stand out for their robust generalization capability in fraud prevention and financial risk prediction. However, DNNs, BiLSTM, and GRU-LSTM present better performance in handling temporal dependencies, positioning themselves as effective alternatives for financial trend prediction [4], [29], [70]. On the other hand, graph-based approaches stand out for their high potential to capture nonlinear relationships and complex structures between entities and transactions, identifying anomalies that often go unnoticed by conventional methods [15], [16]. The different approaches indicate that there is no universal architecture; rather, its choice depends on the data type and the complexity level of the problem. Although trends point towards hybrid models, challenges still exist related to uncertainty, computational efficiency, and class imbalance in fraud scenarios. Furthermore, their implementation remains limited in small and medium-sized enterprises due to technological infrastructure and computational capacity restrictions.

Table 5: Neural Network Architectures Applied to Corporate Problems.

Neural Network	Dataset and/or Sample	Corporate Problem	Metrics	Ref.
Bi-LSTM	Wind database	Exchange and protection of financial data	Accuracy, AUC	[75]
BP/ARIMA	Not specified	Financial risk prediction	Profitability metric	[26]
BPNN	Shanghai Index and Shenzhen 200 Index (CSI 200)	Commercial transactions with blockchain technology	MAE, MSE, RMSE, Training times	[52]
BPNN	Companies in the financial sector of Shanghai and Shenzhen in the third quarter of 2022	Prediction of financial risks for listed companies	Accuracy, Recall, F1-Score	[27]
CCNN	Kaggle Credit Card Fraud Detection (CCFD)	Security and efficiency of fraud detection in the financial industry	Accuracy, Precision, Recall, F1-Score	[6]
CNN	Google BigQuery Ethereum dataset	Detection and mitigation of fraudulent activities within smart contracts	Accuracy	[31]
CNN	Not specified	Financial risk prediction	Accuracy	[44]
CNN-IKOA	Data from 100 Internet companies	Prediction of risks for Internet companies	MSE, MSPE, MAE, MAPE	[78]
CNN-LSTM	279 companies with net profits of <0 for two consecutive years in Shanghai and Shenzhen A-shares, listed from 2019 to 2023	Corporate financial risk management	Accuracy, Precision, Recall , F1-Score	[34]
CNN-LSTM	Data generated by the Sparkov tool from Brandon Harris, simulating transactions between 01-01-2019 and 31-12-2020	Identification of fraudulent credit card transactions	Accuracy, Precision Recall, F1-score, AUC	[55]
CNN-LSTM	Global supply chain from DataCo and IEEE-CIS fraud detection data	Network transaction security and reduction of socioeconomic problems caused by fraudulent behavior	Accuracy	[37]
CNN-Transformer-Wavelet	Three financial datasets: (i) Standard Poor's 500 Index-SPX500, (ii) West Texas Intermediate-WTI, (iii) London Metal Exchange Gold Price-LGP	Prediction of financial risk in companies	Accuracy, Precision, Recall, F1-Score	[38]
DNN	Kaggle website: Credit card transactions of European cardholders generated over 2 days in 2013	Detection of fraudulent credit card transactions	Accuracy, F1-Score	[73]
DNN	PaySim dataset	Credit card fraud detection	Accuracy, F1 Score, Precision, Recall, AUPRC	[70]
DNN	Vesta Corporation	Credit card fraud detection	UAcc, UPre, USen:, USpe	[51]
DNN-DL	Not specified	Analysis of early warning of corporate financial risks	Accuracy	[33]
DNN-RNN	Not specified	Comprehensive analysis of complex financial data	Accuracy, Precision, Recall, F1-score	[45]
FNN	Ninth "TIPDM Cup" financial analysis competition for listed companies	Detection of fraudulent financial data	Accuracy, Precision, Recall, F1-score	[59]
GNN-Autoencoders	Pakistani private banks (Meezan Bank and UBL)	Reduction of fraudulent activities in large organizations	Accuracy, Precision, Recall, F1-Score	[15]

HNN	Mobile advertising platform in China	Identification of fraudulent applications for mobile advertising	Average Precision (AP), AUC	[68]
GRU-LSTM	Three financial datasets: (i) Standard Poor's 500 Index-SPX500, (ii) West Texas Intermediate-WTI, (iii) London Metal Exchange Gold Price-LGP	Prediction of financial asset price volatility	MAE, MSE	[29]
MLP-ANN	Companies listed on the Shenzhen and Shanghai stock exchanges between 2016 and 2020	Stock market forecasting	Accuracy, Z-score	[64]
MOE-DNN-Smote	Kaggle Credit Card Fraud Detection (CCFD)	Improvement of fraud detection performance	Accuracy, TPR, TNR, FPR, MCC	[57]
MS-HGNN	Public data from Amazon and Yelp	Online fraud detection	Recall, AUC	[16]
NAG	Wordline dataset and a public dataset	Credit card fraud detection	Precision-recall curve (AUCPR)	[77]
SVM-FFNN	Kaggle dataset	Detection of fraudulent activities	Accuracy, Precision, Recall	[40]
TH-LSTM	Real-world transactions provided by a Chinese financial institution	Automatic detection of fraudulent transactions	Precision, Recall, F1-Score	[60]

III.4 HOW DO NEURAL NETWORKS INFLUENCE CORPORATE DATA SECURITY?

To address this question, 16 articles (25%) were identified that quantitatively report any of the following 4 metrics: Accuracy, Precision, Recall, F-Score. These metrics provide a comprehensive assessment of the model's classification effectiveness [6], obtained as:

$$\text{Accuracy} = \frac{\text{TP} + \text{TN}}{\text{TP} + \text{TN} + \text{FP} + \text{FN}},$$

$$\text{Precision} = \frac{\text{TP}}{\text{TP}+\text{FP}},$$

$$\text{Recall} = \frac{\text{TP}}{\text{TP}+\text{FN}},$$

$$\text{F-Score} = \frac{2 \cdot \text{Precision} \cdot \text{Recall}}{\text{Precision}+\text{Recall}},$$

Where TP: True Positives, TN: True Negatives, FP: False Positives, and FN: False Negatives. Figure 4 shows the metrics recorded for the 16 articles, identifying the type of neural network used. Labels A1-A16 were used for these articles, which are mentioned in Table 6.

Table 6: Articles labeled for component O.

Label	Reference	Label	Reference
A1	[75]	A9	[73]
A2	[27]	A10	[70]
A3	[6]	A11	[33]
A4	[44]	A12	[45]
A5	[34]	A13	[59]
A6	[55]	A14	[15]
A7	[37]	A15	[40]
A8	[38]	A16	[60]

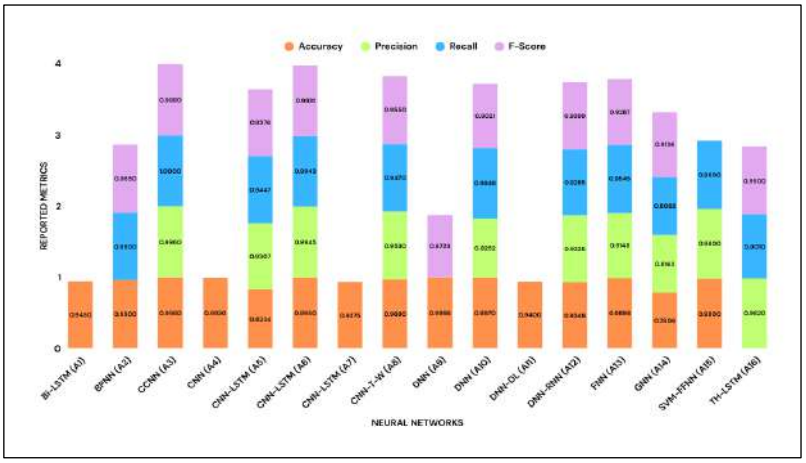

Figure 4: Metrics used by articles employing neural networks.
Source: Authors, (2026).

The results shown in Figure 4 highlight the effectiveness of CCNN in handling the complexity and subtlety of fraud detection, where small and non-obvious patterns often indicate fraudulent behavior [6]. The CNN simulation system based on the scientific node selection method greatly improved the accuracy of financial risk assessment [44]. A CNN model has significant advantages in processing complex financial data; it can perform in-depth mining and feature extraction from massive financial data by simulating the human brain's processing mode [34]. Another suggested approach combining CNN and LSTM outperformed other current techniques and achieved the highest accuracy of 99.5% in identifying credit card fraud [55]. According to [33], demonstrated that the prediction accuracy of the DL network after sample training reached 94%, being superior to other prediction models. The financial early warning model used by Li is based on DL with DNN and can be fully applied to corporate financial risk early warning.

On the other hand, less recurrent models have been of great importance in addressing corporate problems. In [15], they concluded that financial institutions are using deep learning with business intelligence to control money laundering. Their work was based on fraud detection with Graph Neural Networks and anomaly detection using Autoencoders in Credit Cards. Models based on Support Vector Machines (SVM) and Feedforward Neural Networks (FFNN) are used in [40] to distinguish between classes and capture complex patterns and relationships, respectively. The model shows promise in fraud detection with greater accuracy and precision. According to [60] propose a new representation for each transaction record based on users' historical transactions to accurately capture fraudulent patterns. Their proposal is based on an improvement of the LSTM model with a time-aware gate (TH-LSTM), which can capture behavioral changes caused by users' consecutive transactions.

Experimental results demonstrated a clear distinction between legitimate and fraudulent behaviors, achieving better fraud detection performance compared to state-of-the-art methods. In general, models based on neural networks influence corporate data analysis very positively. These statistical indicators show the potential of neural networks in decision-making in corporate contexts, especially for identifying anomalous behaviors and reducing false positives [34],[44]. However, these metrics can be biased by the data type and architecture design, showing limitations against changing scenarios not contemplated in training and testing [15],[40]. Consequently, corporate data security should be evaluated not only by model performance but also by its robustness and adaptability in real-world environments [33],[55].

IV. CONCLUSIONS

This review study organized and systematized the available scientific evidence on the use of neural networks in optimizing and protecting corporate data. The PICO and PRISMA2020 strategies guided the search, selection, and analysis process of information from 64 articles. Specifically, the scientific background was systematized based on answering three specific questions and one general question, which were the focus of the research. The main findings are as follows:

- 87.5% of the studies detail some type of corporate data analyzed using neural networks, with commercial transaction data (25), financial data (14), and operational data (12) being the most prominent.
- 42.19% describe the type of neural network used to analyze a corporate-type problem. In particular, CNNs and their composite variants, such as CNN-LSTM and CNN-Transformer-Wavelet, stand out for their robust generalization capability in fraud prevention and financial risk prediction. Other network types, such as DNNs, BiLSTM, and GRU-LSTM, demonstrate better performance in handling temporal dependencies.
- The different approaches indicate that there is no universal architecture; rather, its selection depends on the type of data and the complexity level of the problem.
- Based on metrics such as Accuracy, Precision, Recall, and F-Score, a positive influence is evidenced in applying neural networks to solve problems involving corporate data. The 25% of articles using these types of metrics mention that models such as CNN or DNN combined with LSTM have significant advantages in processing complex financial data. These models outperformed other current techniques in identifying credit card fraud.

Diesel Engine

ABSTRACT

The current study compares the combustion, performance and emission properties of the compression ignition engine using Diesel, GABME B20 (Green Algae Biofuel Methyl Ester blend) as well as their corresponding mixtures with cerium oxide (CeO_2) nanoparticles at a concentration of 50 ppm. The experiment aims at the study of in-cylinder combustion behaviour, BTE, BSFC and controlled emissions (CO, HC, NOx and smoke) under different brake power operation (0 -4.4 kW). The results of the combustion analysis showed that GABME/CeO_2 had the highest peak cylinder pressure (70 - 72 bar) and heat release rate maximum (68 - 72 J/ ° CA), which means that the oxidation rate and oxygen buffering capacity of CeO_2 nanoparticles were improved and the premixed combustion was enhanced. The performance outcomes indicated that Diesel/CeO_2 had the highest maximum BTE of 30.4% at full load and GABME/CeO_2 had 29.5% which is an improvement of 2 - 6% compared to the respective base fuels. At full load, GABME/CeO_2 (0.32 kg/kWh) had the lowest BSFC and was better fuel utilising. The analysis of emissions shown that CO, HC, smoke and smoke opacity decreased knowingly (up to 20%) with the addition of nanoparticles and NOx increased somewhat (5 -15%) by the increase in combustion temperature. On the whole, the addition of 50 ppm of CeO_2 nanoparticles into the biodiesel blocks of algae led to a important increase in the combustion efficiency and the decrease of the unfinished combustion emissions, which is why its application is one of the promising ways of operating diesel engines in a sustainable and cleaner manner.

I. INTRODUCTION

The high rate at which deposits of fossil fuel are being depleted as well as the increasing worry over emission of greenhouse gases has increased the scope of global research on the development of alternative fuel that can replace fossil fuel that is used in compression ignition (CI) engines, which is cleaner and more sustainable. Transportation, agricultural and industrial industries remain dominated by diesel engines because of the high thermal efficiency and longevity. The strong environmental policies require new methods to mitigate the emission of carbon monoxide (CO), unburnt hydrocarbons (HC), nitrogen oxides (NOx) and PM. Biodiesel is one of the promising alternatives to replace the currently used diesel fuel due to its biodegradability, oxygenation and its ability to fit in the already developed diesel engine infrastructure [1]. Microalgae-produced 3 rd -generation biodiesel has received important interest because it produces high lipid content, grows quickly and does not interfere with food crops. In comparison to the first- and second-generation biodiesel feed, microalgae can be cultivated in the non-arable land using wastewater or saline water, which is why it is a sustainable alternative in the long term. Algae based biodiesel especially Green Algae Biofuel Methyl Ester (GABME) has good combustion characteristics due to its natural oxygen content which improves oxidation during combustion.

However, its increased viscosity, reduced calorific value and possible rise in NOx emissions are some of the constraints that limit its use in CI engines [2]. Consequently, the enhancement of physicochemical and combustion properties of the algae biodiesel is a field of research that is still active [3]. The recent developments in nanotechnology have also proposed the concept of nanoparticle additives that are effective to be used as combustion catalysts in biodiesel-diesel mixtures [4]. CeO2, Al2O3, CuO and TiO2 are metal oxide nanoparticles that have been confirmed to enhance fuel atomization, facilitate micro-explosion phenomena and enhance the oxidation kinetics [5]. Of them, cerium oxide nanoparticle is especially appealing because of the distinctive property of oxygen storage and release (Ce3+/Ce4+ redox cycle), which enables oxidation of precursors of CO and soot to continue throughout the combustion. This is an oxygen buffering process that enhances combustion efficiency and at the same time minimises incomplete combustion emissions [6]. A number of scientists have examined the role of CeO2 nanoparticles on blends of biodiesel. Research indicates that nanoparticle fuels that are blended with fuels enhance BTE and low BSFC because of the increased heat release properties and a decreased ignition delay [7]. Experimental research on algae biodiesel additives of CeO2 has shown a high peak CP and HRR, which show that there is more premixed combustion. Also, a decrease in CO, HC and smoke opacities has been extensively documented due to enhanced oxidation reactions and soot burnout mechanisms [8]. There is often a moderate level of increase in NOx emissions and this is mainly explained by high in-cylinder temperature due to the increased combustion reactivity.

The source also emphasises the effect of the size of nanoparticles, concentration, injection pressure, compression ratio and hydrogen enrichment on combustion and emission properties in recent literature [9]. Specifically, the Variable Compression Ratio (VCR) engines offer a flexible platform to study combustion behaviour under different conditions of thermodynamic conditions. Compression ratio adjustment has a direct impact on peak pressure, temperature, ignition delay and heat release dynamics in general [10], [11]. Although a lot of research has been done on nanoparticle-blended biodiesel in conventional CI engines, there has been limited research on thoroughly examining the combustion parameters, including CP and HRR and performance and emission characteristics in a VCR engine using algae biodiesel of the third generation [12-14]. In addition, the vast majority of available studies concern binary fuel mix (diesel-biodiesel or biodiesel-nanoparticle systems). It is necessary to have more understanding regarding the thermochemical interactions in tertiary blends of diesel, third-generation biodiesel and metal oxide nanoparticles under different load conditions [15], [16]. The synergies of the innate oxygen concentration of algae biodiesel and the catalytic oxygen buffering ability of CeO2 nanoparticles have the potential to induce a profound change in combustion phasing and emission patterns.

The literature on the systematic experimental confirmation of such collective effects is not adequately covered [17], [18]. The other point of weaknesses in previous research is the lack of sufficient correlation between combustion features and emission formation processes [19-21]. Although results of BTE betterment and cuts in CO and smoke are well known, little effort has been made to identify the relationship between peak CP, HRR and the generation of pollutants under different loads. In the case of high-impact journal articles, a combined combustion-performance-emission strategy is necessary towards explaining the underlying mechanisms in the nanoparticle-aided biodiesel combustion [22], [23]. In that regard, the current research project examines the combustion, performance and emission of a VCR diesel engine using a ternary blend of Diesel, GABME B20 and CeO2 nanoparticles at the concentration of 50 ppm. Under different brake power conditions, detailed study of CP, HRR, and controlled emissions (CO, HC, NOx and smoke opacity) are scrutinised [24-26]. The innovation of the present study is the assessment of the third-generation algae biodiesel and CeO2 nanoparticles synergistic combustion enhancement in a VCR engine context, which offers more findings on the aspects of combustion phasing and trade-offs between emissions.

Even though the possibility of nanoparticle-blended bio-diesel fuels is confirmed by the previous studies, there is still a distinct research gap in correlating combustion intensity parameters (CP and HRR) to efficiency and formation of emissions in algae-based ternary fuel under controlled conditions of compression [27], [28]. Further, there is a paucity of research on the use of third-generation biodiesel with cerium oxide nanoparticles in VCR engines [29]. Accordingly, the study at present is going to fill the gap in the experimental quantification of the mechanism that increases the combustion and its overall effect on the engine efficiency and environmental performance. Cerium oxide nanoparticles have been chosen because of their excellent redox performance, catalytic efficacy in oxidation of soot, thermal stability and compatibility with biodiesel fuels. Similarly, algae biodiesel of the third generation is selected because of its sustainability benefits and the high level of oxygen content that supplements the oxygen release catalytic process of CeO2. Through the combination of these two new and improved fuel technologies, the study aims at offering a viable way forward towards enhancing the efficiency of diesel engines and reducing the effects of incomplete combustion as a remedy to sustainable production of energy and cleaner operation of CI engines.

II. MATERIALS AND METHODS

II.1 PREPARATION OF GREEN ALGAE BIOFUEL METHYL ESTER (GABME20

Microalgae ability to absorb nutrients and sunlight to create biomass that is high in lipids has led to their current popularity as a feedstock for renewable energy. Because of its rapid growth, ecological tolerance and oil-enhanced production, Chlorella vulgaris is the most researched microalgae [23]. These characteristics make C. vulgaris a feasible feedstock for the commercialisation of biofuel, both as a replacement for conventional fossil fuels and in terms of environmental factors like carbon capture and waste management. In order to create GABME20, a 20% biodiesel blend composed of Chlorella vulgaris, this study will examine the use of a base-catalyzed transesterification technique. In order to achieve a rapid pace of transformation while meeting quality standards for the biodiesel fuel category used in engines, the transesterification process was optimised. The established applications of C. vulgaris in nutrition and medicine provide further financial advantages for employing it as feedstock, bolstering the viability of an integrated algal biorefinery.

II.2 PHYSICOCHEMICAL CHARACTERIZATION

In accordance with ASTM standards, the physicochemical properties of the produced GABME20 product were carefully examined to ensure that the fuel fulfilled predetermined quality criteria.

Spec. gravity, viscosity, boiling range, cetane number, flash point and energy content were among the characteristics that were investigated. For precision, every physicochemical characteristic was measured three times and the average results were published. Table 2 summarises the features of generated GABME20 that were contrasted with ASTM limits and neat diesel fuel. Added GABME20 + CeO_2 the powder and sem image is shown in Figure 1.

Table 1: Fuel Properties of Diesel, GABME20 and GABME20 + CeO_2 Nanoparticles.

Property	**Diesel**	**GABME20**	**GABME20 + CeO_2**
Physical state	Liquid	Liquid	Liquid
Specific gravity @ 16 °C	0.86	0.90	0.848
Stoichiometric air–fuel ratio	14.5	13.2	13.8
Kinematic viscosity @ 40 °C (mm²/s)	2.42	4.1	3.9
Boiling range (°C)	160–366	185–365	180-340
Cetane number	51	55	53
Flash point (°C)	59	162	73
Calorific value (kJ/kg)	44,000	39,700	40,250

III. EXPERIMENTAL SETUP

Figure 3: Experimental set up.
Source: Authors, (2026).

The experiment examined the effects of adding (CeO_2) nanoparticles to green algae-based biodiesel (GABME20) on emissions and engine performance using a basic diesel engine shown in Figure 3. Current information from sensors installed to measure an engine's crankshaft angle, chamber temperature, and piston pressure was collected using a data gathering system. The internal airflow was assessed using a laser-based method. Pure diesel, GABME20, and GABME20 mixed with 50 ppm of CeO_2 nanoparticles uniformly distributed in the fuel by ultrasonication were among the many fuel mixes assessed for the engine study. The engine was continually operated with variable loads and at a constant speed of 1800 rpm.

IV. RESULT AND DISCUSSION

IV.1 CYLINDER PRESSURE (CP)

Figure 4 shows cylinder pressure with crank angle at full load which is compared to that of Diesel, Diesel/CeO_2 (50 ppm), GABME and GABME/CeO_2 (50 ppm). The highest pressure of the pure Diesel was noted 67 - 68 bar that was reached at 8 -10° ATDC. Induced of 50 ppm CeO_2 nanoparticles to Diesel slightly decreased the peak pressure to approximately 65 - 66 bar, which can be explained by enhanced control of premixed combustion and decreased ignition delay. The peak pressure of GABME was a at 68 -69 bar and this can be attributed to the fact that it contains some natural oxygen content that facilitates better combustion. It is worth that GABME/CeO_2 (50 ppm) had the highest peak cylinder pressure of 70 -72 bar which shows it has a better combustion intensity because of the catalytic properties of the cerium oxide nanoparticles. The enhanced oxygen buffering property of CeO_2 increases the reaction of oxidation in the premixed step resulting in increased combustion pressure. It was confirmed that the nanoparticle blended biodiesel had a 3 - 5% higher peak pressure than pure Diesel and this value increased the combustion properties without causing the unusual pressure change.

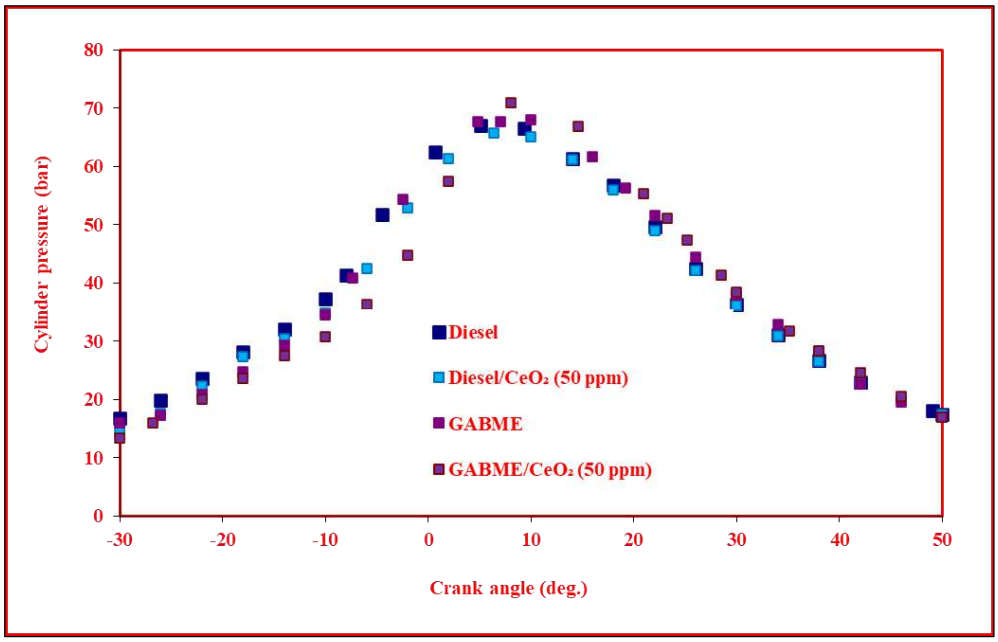

Figure 4: CP Characteristics of Diesel/GABME/CeO_2.
Source: Authors, (2026).

IV.2 HEAT RELEASE RATE (HRR)

The tested fuels have notice in their properties of heat release rate that shows the existence of premixed and diffusion combustion stages shown in Figure 5. Pure Diesel had a peak HRR of 62 - 65 J/ ° CA, which slightly before TDC (62° to 70° CA), which a strong premixed burning phase. The highest HRR of 60 -63 J/ ° CA with Diesel/CeO_2 (50 ppm) was similar but slightly reduced indicating that the combustion was controlled through catalytic oxidation. GABME exhibited a peak HRR of almost 58 - 60 J/ ° CA which is slightly lower than the values of Diesel which the concept by the higher viscosity and shorter ignition delay of GABME. GABME/CeO_2 (50 ppm) shows the peak of the HRR of around 68 - 72 J/ ° CA, which is nearly 10 -15 per cent higher than that of pure Diesel. The high HRR is explained by the better atomization, decreased ignition delay and the better micro-explosion phenomena promoted by CeO_2 nanoparticles. The diffusion combustion stage of nanoparticle blends was more gradual and sustained which means that the heat was well dispersed and the combustion was level.

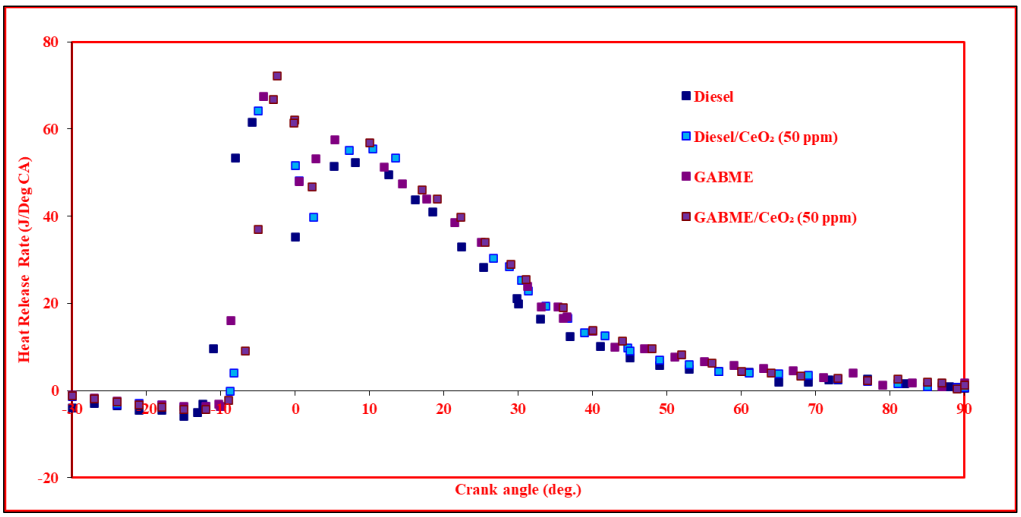

Figure 5: HRR Characteristics of Diesel/GABME/CeO_2.
Source: Authors, (2026).

IV.3 BRAKE THERMAL EFFICIENCY

The BTE improved gradually with brake power of all the tested fuels and followed the same trend as the combustion improvement of CP and HRR characteristics shown in Figure 6. Diesel had 13.9% BTE at 1.1 kW, Diesel/CeO_2 (50 ppm) increased to 14.6 and GABME B20 had 13.5 and GABME/CeO_2 had 14.1. At 2.2 kW the efficiencies rose to 22.5% with Diesel, 24% with Diesel/CeO_2, 22% with GABME B20 and 23.3% with GABME/CeO_2. Another increase was noted at 3.3 kW with 26.9% and 28.5% and 26.4 and 27.8 respectively. At 4.4 kW, Diesel/CeO_2 reached 30.4% and GABME/CeO_2 reached 29.5%, pure Diesel reached 28.6 and GABME B20 reached 27.9. The steady increase of around 2 -6% with the addition of CeO_2 is explained by the increased combustion reactivity, the increased oxidation reactivity and the increased use of heat, which resulted in the high energy conversion efficiency in comparison to the corresponding base fuels.

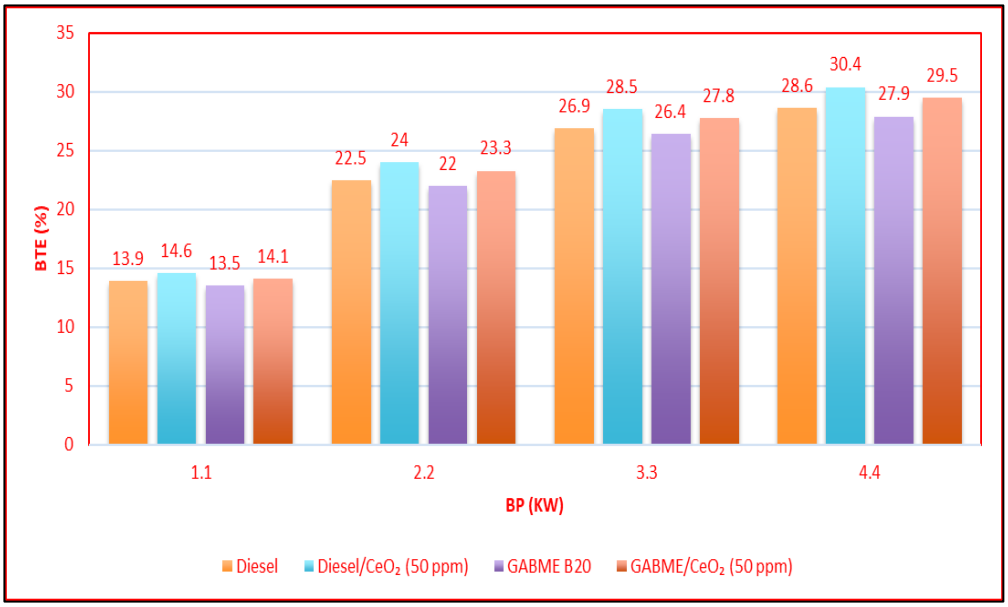

Figure 6: BTE of Diesel/GABME/CeO_2.

IV.4 BRAKE SPECIFIC FUEL CONSUMPTION

The BSFC also declined with the brake power of all the tested fuels, which implies the enhanced fuel usage at higher loads shown in Figure 7. Diesel had a BSFC of 0.792kg/kWh at 1.1 kW, Diesel/CeO_2 (50 ppm) had 0.762 kg/kWh and GABME B20 was 0.81 kg/kWh and GABME/CeO_2 was 0.776 kg/kWh. When the BSFC values dropped further to 0.497, 0.472, 0.51 and 0.486 kg/kWh respectively at 2.2 kW. At 3.3 kW, Diesel and Diesel/CeO_2 had 0.375 and 0.353 kg/kWh, respectively and GABME B20 and GABME/CeO_2 had 0.34 and 0.365 kg/kWh, respectively. Diesel was found to have 0.374 kg/kWh at full load (4.4kW), Diesel/CeO_2 was lower at 0.353 kg/kWh, GABME B20 was found to be 0.38 kg/kWh and lowest BSFC was realised with GABME/CeO_2 at 0.32 kg/kWh. The steady decrease in BSFC by addition of CeO_2 (around 4 - 8% when compared to the base fuels) can be linked to the increase in combustion efficiency, oxidation kinetics and fuel - air mixing leading to more efficient conversion of energy and the consumption of less fuel per unit brake power.

IV.5 CARBON MONOXIDE (CO)

CO emissions rose to full load with all the fuel mixtures because the richer the mixture the higher the brake power, but addition of nanoparticles caused a substantial lowering of CO formation shown in Figure 8. Diesel produced 0.129% at no load and Diesel/CeO_2 produced 0.1145% and GABME B20 produced 0.114 and GABME/CeO_2 produced the lowest of that was 0.1012%. CO was reduced at 1.1 kW as 0.124% (Diesel) to 0.1092% (Diesel/CeO_2) and GABME B20 and GABME/CeO_2 produced 0.1078% and 0.096, respectively. Diesel produced more at full load (4.4 kW) of 0.211%, but Diesel/CeO_2 decreased it to 0.1796; GABME B20 produced 0.19 and GABME/CeO_2 further lowered the figure to 0.162. This is because the decrease of 10 -20 percent by addition of CeO_2 is attributed to the enhanced oxidation of CO into CO2 owing to the ability of the cerium oxide nanoparticles to buffer oxygen.

Source: Authors, (2026).

IV.6 HYDROCARBON (HC)

The emission of unburned hydrocarbons rose with the load with all fuels mainly because the combustion in high fuel injection rates was incomplete shown in Figure 9. Diesel produced 38 ppm at no load, Diesel/CeO_2 produced 33 ppm, GABME B20 produced 38 ppm and GABME/CeO_2 produced 34 ppm. HC emissions at 2.2 kW were 45, 42, 48 and 43 ppm (Diesel, Diesel/CeO_2, GABME B20 and GABME/CeO_2) respectively. Diesel gave a high figure of 53 ppm at full load (4.4 kW), followed by 48 ppm with Diesel/CeO_2, 58 ppm with GABME B20 and 50 ppm with GABME/CeO_2. The uniform reduction of almost 8-12 per cent by the addition of nanoparticle is evidence of increased completeness of combustion and better flame propagation behaviour.

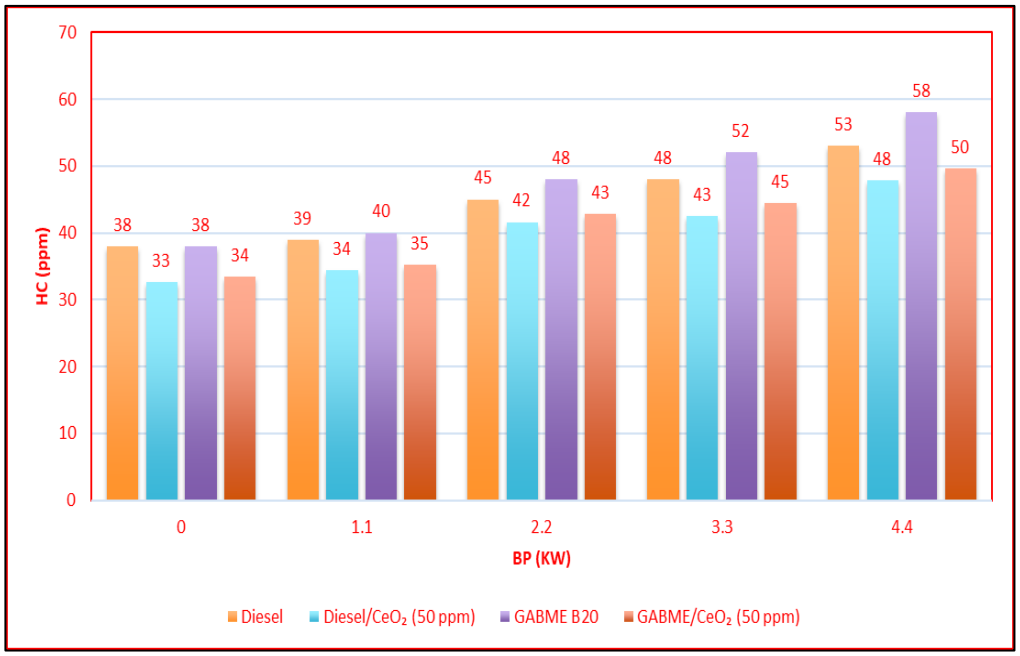

Figure 9: HC of Diesel/GABME/CeO_2.
Source: Authors, (2026).

IV.7 NITROGEN OXIDES (NOX)

Emissions of NOx were increasing with the load because of an increase in combustion temperature and the availability of oxygen shown in Figure 10. At zero load, both Diesel and Diesel/CeO_2 gave 295 ppm and GABME B20 and GABME/CeO_2 gave 310 ppm and 317 ppm, respectively. At 2.2 kW, the levels of NOx went to 429 ppm (Diesel), 456 ppm (Diesel/CeO_2), 463 ppm (GABME B20) and 488 ppm (GABME/CeO_2). Diesel produced maximum NOx of 4.4 kW, i.e., 574ppm, DIscet/CeO_2 was 605ppm, GABME B20 was 670ppm and GABME/CeO_2 was highest of 710ppm. The rise of 5 -15 percent on the addition of nanoparticles is attributed to the increase in the combustion temperature and the kinetics of oxidation favouring the formation of thermal NOx.

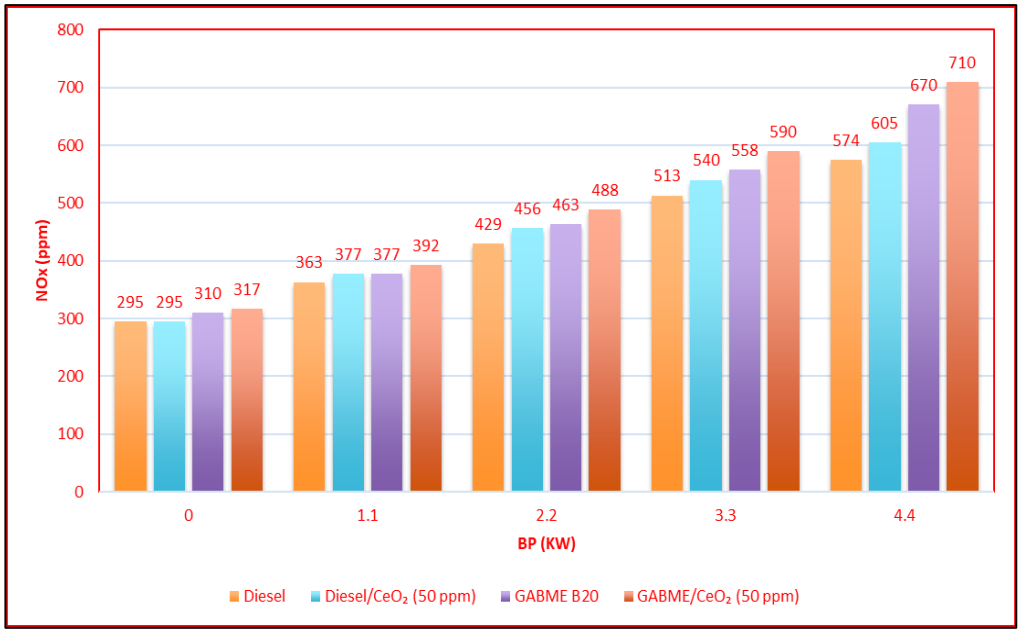

Figure 10: NOx of Diesel/GABME/CeO_2.
Source: Authors, (2026).

IV.8 SMOKE OPACITY

All fuels showed an increment of smoke emissions with load because of increased fuel accumulation during the diffusion combustion stage shown in Figure 11. Diesel produced 11% at no load, Diesel/CeO_2 reflected 10%, GABME B20 reflected 8% and GABME/CeO_2 reflected 8%. Smoke opacity was 25% (Diesel), 22% (Diesel/CeO_2), 21% (GABME B20) and 19% (GABME/CeO_2) at 3.3 kW. Diesel produced 35 percent at full load (4.4 kW), Diesel/CeO_2 produced 30 percent, GABME B20 produced 27 percent and GABME/CeO_2 was the lowest with 24 percent. This cutting down by almost 10 -20 percent of addition of CeO_2 is attributed to the presence of better oxidation of the soot and an increase in the air-fuel mixing, leading to cleaner burning than the base fuels.

V. CONCLUSION

This paper has shown that addition of cerium oxide (CeO_2) nanoparticles of concentration of 50 ppm concentration have a substantial effect on the combustion and performance properties of GABME B20 and Diesel fuels in a compression ignition engine. Improved reactivity of combustion and reduction of the ignition delay of nanoparticle-blended fuels are verified by the increased peak cylinder pressure and high rate of heat release. Thermal efficiency with the brakes increased steadily in all loading conditions but Diesel/CeO_2 attained 30.4% and GABME/CeO_2 at full load reached 29.5%. It was found that a important decrease in the BSFC was achieved, especially with GABME/CeO_2 (0.32 kg/kWh) with regard to improved energy conversion efficiency. Emissions Emission properties showed large reductions in CO, HC and smoke opacities because of enhanced oxidation and soot removal processes, but there were small increases in NOx emissions because of elevated in-cylinder temperature. In general, the outcomes establish that the enriched algae biodiesel blends with CeO_2 nanoparticles can be a valid route to improve engine efficiency and reduce unfinished combustion emissions. Such nanoparticle-enhanced biofuels with optimised NOx control measures can be an efficient and viable substitute to regular diesel fuel in the future low-emission diesel engine use.

ABSTRACT

This paper investigates the adaptation and the application of one of the recently proposed meta-heuristic optimization algorithm namely Manta Ray Foraging (MRFO) algorithm to solve the Optimal Power Flow (OPF) problem with the presence of wind power generation. The wind generation cost model includes direct cost, expected penalty cost and expected reserves cost to account for wind power generation imbalance. The methodology for maximizing voltage stability margin in the system is also presented in this study and the line voltage stability index is used as indicator to investigate voltage stability assessment. The effectiveness of the proposed methodology is tested on IEEE 30-bus power system for different objective functions. The obtained results are compared with the recently published methods in the case of conventional OPF as well as in the case of OPF incorporating wind sources. The comparison study demonstrates the effectiveness of the proposed methodology.

I. INTRODUCTION

The integration of renewable energy, especially wind power, in power systems has become a new task for researcher. The integration of wind generation in power systems has been continuously increased in recent years due to the environmental benefits. The insertion of such energy sources into modern power systems has introduced new kind of challenges for operating and managing the power systems [1]. Optimal power flow (OPF) is one of the widely used tools in the planning and managing of the power systems. Its main goal is to optimize a specified objective function while satisfying a set of equality and inequality constraints. However, in last years, solving the OPF problem has become more convoluted with immense integration of renewable energy resources. A variety of optimization techniques have been successfully used to solve the OPF problem with incorporating of wind power generation. Authors in [2] proposed the use of Gravitational Search Algorithm (GSA) to solve the economic emission load dispatch problem for system with thermal power and wind generators. OPF solution of power grid incorporating stochastic wind power with the implementation of Gbest guided artificial bee colony algorithm is addressed in [3]. According to [4] proposed a new optimization algorithm called Modified Bacteria Foraging Algorithm (MBFA) and introduced Doubly Fed Induction Generator (DFIG) model in OPF problem. Authors in [5] used concepts from the fuzzy set theory with a new cost model in OPF problem. The cost model is based on the addition of a penalty cost in the classical economic dispatch problem representing compensation payment to private owners of wind farms for not using the available wind power capacity. In the same way, a supplementary cost term for overestimation of the available wind power has been added in OPF problem along with use probability functions to describe the wind speed profiles [6], [7]. According to [8] Modeled the uncertainties of wind power penetration in the power system through probability density functions and solved the economic emission load dispatch problem with genetic algorithm. Authors in [9] used a new hybrid flower pollination algorithm with time-varying fuzzy selection mechanism to solve the OPF problem incorporating wind power, emission and valve-point loading effect of generators. Quantum-inspired particle swarm optimization algorithm is proposed by [10] for OPF problem solving considering wind power uncertainty and carbon tax.

According to [11] employed entropy weight–TOPSIS method to comprehensively assess the performance of different power producers, based on which a multi-objective security-constrained economic dispatch model. In [12] proposes an Enhanced Moth-Flame Optimization (EMFO) algorithm for solving the non-convex economic dispatch problem with valve point effects and emissions. In this paper, the wind-thermal OPF problem with voltage stability enhancement is solved using a recently proposed optimization algorithm named Manta Ray Foraging Optimization (MRFO). The wind generation cost model is introduced into the conventional OPF program as objective function, and voltage stability improvement is investigated as well. The OPF objective function includes: the fuel cost of thermal units, the cost of wind power and the line voltage stability index (L_{mn}). In turn, wind power cost includes: the expected cost of wind power to be purchased, the expected penalty cost for not exploiting available wind power and the expected reserve cost due the shortage of wind power [10]. The proposed method is tested on IEEE 30-bus test system. The simulation results show the efficiency of the proposed method compared to other methods available in literature. The rest of the paper is organized as follows. Section 2 deals with the OPF problem with wind energy subject to equality and inequality constraints. The general framework of MRFO and its implementation for solving the OPF problem is discussed in Section 3 whereas Section 4 illustrates the simulation and results of the proposed method. Finally, conclusions are given in Section 5.

II. PROBLEM FORMULATION

The wind–thermal economic dispatch problem with voltage stability improvement can be formulated mathematically as the following constrained nonlinear optimization problem with some equality and inequality constraints.

II.1 THERMAL GENERATORS COST FUNCTION

Generation cost or the total fuel cost can be expressed in terms of the real power output by the quadratic function and hence the fuel cost function to be minimized can be described as:

$$f_1 = \min \sum_{i=1}^{NG} f_i = \sum_{i=1}^{NG} \left[a_i + b_i P_i + c_i P_i^2 \right] \quad (\$/h) \tag{1}$$

Where f_1 is the fuel cost of the i_{th} generator, a_i, b_i and c_i are the basic, the linear and the quadratic cost coefficients of the i_{th} thermal generator, P_i represents the power output of the i_{th} thermal generator; NG denotes the number of generating units

II.2 WIND GENERATORS COST FUNCTION

Considering the influence on power system produced by the uncertainty of wind power, the operating cost of wind power can be divided into three parts: direct cost, underestimated cost and overestimated cost. Typically wind power units are owned by private parties and grid operators pay for wind power purchased from wind farm operator based on the power purchase agreement. A direct cost for power derived from the wind generators is given by Equation (2) [3].

$$WPCost_{dir.j} = d_j w_j \tag{2}$$

Where $WPCost_{dir.j}$ is the direct cost for generation of wind power, which is directly proportional to output wind power; d_j is the direct cost coefficient for j_{th} wind farm. The underestimation cost is considered when available power of wind farm is not used and it can be computed using the following equation

$$WPCost_{ue} = \sum_{j=1}^{m} (C_{pwj} \times E(Y_{ue.j})) \tag{3}$$

Where

$$E\left(Y_{ue.j}\right) = \begin{cases} w_j \left\{ 1 - \exp\left(-\left(v_{IN} / c \right)^k \right) + \exp\left(-\left(v_{OUT} / c \right)^k \right) \right\} \\ + \left(\left(w_R v_{IN} / v_R - v_{IN} \right) + w_j \right) \left(\exp\left(-v_{IN}^K / c^K \right) - \exp\left(-v_j^K / c^K \right) \right) \\ + \left(\left(w_R c / v_R - v_{IN} \right) \right) \left(\Gamma\left[1 + 1/K, \left(v_{IN} / c \right)^K \right] - \Gamma\left[1 + 1/K, \left(v_j / c \right)^K \right] \right) \end{cases} \tag{4}$$

$WPCost_{ue.j}$ is the scaled average cost of underestimation for j_{th} wind turbine; C_{pwj} is the cost coefficients for underestimation; $E(Y_{ue.j})$ is the expected value of wind power underestimation for j_{th} wind turbine; w_j is the available active power from j_{th} wind power source; w_R is rated wind power output; v_R is rated velocity of wind; v_{IN} is cut in velocity of wind; v_{OUT} is cut-out velocity of wind. The overestimation cost is calculated for buying power from alternate sources (reserves) or load shedding. It can be expressed as follow

$$WPCost_{oe} = \sum_{j=1}^{m} (C_{rwj} \times E(Y_{oe.j})) \tag{5}$$

Where

$$E\left(Y_{oe.j}\right)=\begin{cases} w_j\left\{1-\exp\left(-\left(v_{IN}/c\right)^k\right)+\exp\left(-\left(v_{OUT}/c\right)^k\right)\right\} \\ +\left(\left(w_R v_{IN}/v_R-v_{IN}\right)+w_j\right)\left(\exp\left(-v_{IN}^K/c^K\right)-\exp\left(-v_j^K/c^K\right)\right) \\ +\left(\left(w_R c/v_R-v_{IN}\right)\right)\left(\Gamma\left[1+1/K,\left(v_{IN}/c\right)^K\right]-\Gamma\left[1+1/K,\left(v_j/c\right)^K\right]\right) \end{cases} \quad (6)$$

Where $WPCost_{oe}$ is the scaled average cost of overestimation for j_{th} wind turbine; C_{rwj} is the cost coefficients for overestimation of j_{th} wind turbine. Similarly, $E(Y_{oe.j})$ is the expected value of wind power overestimation for j_{th} wind turbine. The total cost of wind-generated power from the wind farm can be represented as the sum of the direct, underestimation and overestimation costs:

$$f_2=\min\sum_{j=1}^{m}\left(WPCost_{dir.j}+WPCost_{oe.j}+WPCost_{ue.j}\right) \quad (7)$$

II.3 VOLTAGE STABILITY INDEX

It is perspicuous that a power system operating at the pinnacle of the unstable condition is conspicuously referring to the voltage magnitude approaching to its limit and it is presented by the voltage stability indices [13]. Several methods have been introduced to assess the voltage stability and to determine the stability margins. In this part voltage stability enhancement is considered through optimization of the line voltage stability index (L_{mn}) [14]. The L_{mn} index is defined as follows:

$$L_{mn}=\frac{4XQ_r}{\left[V_s\sin(\theta-\delta)\right]^2}\le 1.0 \quad (8)$$

Where X is the line reactance, Q_r is the reactive power at the receiving end, V_s is the sending end voltage, θ is the line impedance angle and δ is the angle difference between the supply voltage and the receiving voltage.
The value of L_{mn} index ranges from 0 (no load) to 1 (voltage collapse) and it must be less than 1 for stable systems. The improvement of the voltage stability of the system can be reached by minimization of the line voltage stability index at all branches in the system.
The function described the line voltage stability index is expressed as follows [15]:

$$f_3=\min\sum_{k=1}^{NB}L_{mn} \quad (9)$$

Where NB is the number of power system branches.

II.4 ACTIVE POWER LOSSES MINIMIZATION

The first objective aims to minimize the total active P_{loss} by optimally adjusting the control variables. This objective can be defined mathematically as follows:

$$f_4=\min\left(P_{Loss}\right)=\min\left[\sum_{i=1}^{N_L}G_{ij}\left(V_i^2+V_j^2-2\times V_i\times V_j\cos\delta ij\right)\right] \quad (10)$$

The total objective function including thermal generation cost, wind generation cost, voltage stability enhancement and active power losses minimization is expressed as follows:

$$F=f_1+f_2+f_3+f_4 \quad (11)$$

The OPF objective is subject to system equality and inequality constraints. Equality constraints: equality constraints are the power balance equations where the generated real and reactive powers must be equal to the demand and losses.

$$P_{gi}-P_{di}-V_i\sum_{j=1}^{NB}V_j\left[G_{ij}\cos(\delta_{ij})+\mathrm{B}_{ij}\sin(\delta_{ij})\right]=0 \quad (12)$$

$$Q_{gi}-Q_{di}-V_i\sum_{j=1}^{NB}V_j\left[G_{ij}\sin(\delta_{ij})+\mathrm{B}_{ij}\cos(\delta_{ij})\right]=0 \quad (13)$$

Where, P_{gi} and Q_{gi} are real and reactive powers of ith generator, whereas P_{di} and Q_{di} is real and reactive load of i_{th} bus, respectively. $\delta_{ij}=\delta i-\delta_j$ is the voltage angle difference between buses i and j. G_{ij} and B_{ij} are the ij branch conductance and susceptance, respectively. Inequality constraints: The inequality constraints of the OPF reflect the limits on physical devices present in the power system as well as the limits created to guarantee system security. These inequality constraints are as follows

$$P_{gi}^{\min} \le P_{gi} \le P_{gi}^{\max} \tag{14}$$

$$Q_{gi}^{\min} \le Q_{gi} \le Q_{gi}^{\max} \tag{15}$$

$$P_{wi}^{\min} \le P_{wi} \le P_{wi}^{\max} \tag{16}$$

$$Q_{wi}^{\min} \le Q_{wi} \le Q_{wi}^{\max} \tag{17}$$

$$V_{gi}^{\min} \le V_{gi} \le V_{gi}^{\max} \tag{18}$$

$$T_{i}^{\min} \le T_{i} \le T_{i}^{\max} \tag{19}$$

$$Q_{Ci}^{\min} \le Q_{Ci} \le Q_{Ci}^{\max} \tag{20}$$

P_{wi} and Q_{wi} represent the real and reactive powers output of ith wind turbine generator, respectively; V_{gi} represents the voltage magnitude of ith generator bus; T_i represents the tap settings of ith transformer; Q_{Ci} represents the ith shunt VAR compensation.

III. IMPLEMENTATION OF MRFO ALGORITHM IN OPF PROBLEM

Manta rays are marine organisms distinguished by a flattened body and a pair of expansive pectoral fins Figure 1. They mostly consume plankton due to the absence of sharp teeth. The Manta Ray Foraging Optimization (MRFO) method is derived from the distinctive foraging habits demonstrated by manta rays in its native environment [16]. These activities are exemplified by three primary foraging mechanisms: the chain, the cyclone and the somersault. The MRFO method commences by initializing a population of candidate solutions that are randomly dispersed inside the search space, as articulated by the subsequent equation [16]:

$$X_i(t) = X_{\min} + r \times (X_{\max} - X_{\min}) \tag{21}$$

Where Xmin and Xmax denote the bounds of the design parameters, respectively, and r represents an arbitrary number uniformly distributed between 0 and 1. Subsequent to the initialization procedure, the three foraging techniques are implemented in succession to replicate the feeding behavior of manta rays, as elaborated in the following subsections [16].

Figure 1: Picture of the manta ray.
Source: Authors, (2026).

III.1 CHAIN FORAGING

This strategy indicates that manta rays navigate towards areas with the greatest abundance of plankton. In this procedure, manta rays arrange themselves in a line, creating a chain structure to enhance foraging efficiency. With the exception of the foremost individual, each manta ray in the population advances concurrently toward the direction of the food source and the person directly ahead of it. This synchronized action facilitates efficient information exchange and alignment towards ideal feeding areas. The chain foraging mechanism of The MRFO method can be theoretically articulated as follows [16]:

$$X_i^d(t+1) = \begin{cases} X_i^d(t) + r(X_{best}^d(t) - X_i^d(t)) + \alpha(X_{best}^d(t) - X_i^d(t)), i = 1 \\ X_i^d(t) + r(X_{i-1}^d(t) - X_i^d(t)) + \alpha(X_{best}^d(t) - X_i^d(t)), i = 2,3,...,N \\ \alpha = 2r\sqrt{|\log(r)|} \end{cases} \tag{22}$$

$X_i^d(t)$ represents the position of the i_{th} manta ray at iteration t in dimension d. X_{best} denotes the individual exhibiting the optimal fitness. r represents a random variable inside the interval [0,1], N signifies the population size, and α denotes the weight coefficient. The chain hunting procedure is shown in Figure 2 [16].

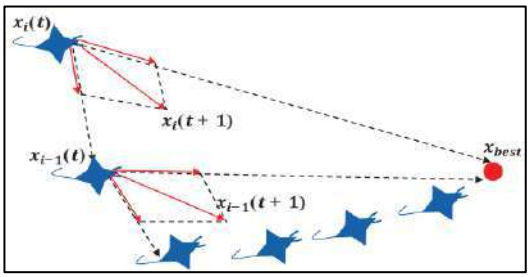

Figure 2: The chain foraging strategy.
Source: Authors, (2026).

III.2 CYCLONE FORAGING

In this phase, every manta ray executes two fundamental tasks to discover food effectively. Initially, it navigates towards the plankton-abundant zone, adhering to a spiral path that mimics the natural vortex movement characteristic of authentic manta ray behavior. Secondly, it concurrently advances towards the individual situated immediately in front inside the sequence [17]. This synchronized movement improves local search functionality and signifies the exploitation phase of the MRFO algorithm, whereby solutions are optimized in proximity to favorable areas inside the search field. The cyclone foraging behavior can be defined as follows [16]:

$$X_i^d(t+1)=\begin{cases} X_{bext}^d(t)+r(X_{best}^d(t)-X_i^d(t))+\beta(X_{best}^d(t)-X_i^d(t)), i=1 \\ X_{best}^d(t)+r(X_{i-1}^d(t)-X_i^d(t))+\beta(X_{best}^d(t)-X_i^d(t)), i=2,...,N \\ \beta=2e^{r_1\frac{t_{max}-t+1}{t_{max}}}\times\sin(2\pi r_1) \end{cases} \quad (23)$$

Where β represents the weight coefficient, r_1 is an arbitrary number within the interval [0,1], and t_{max} signifies the extreme number of iterations. To enhance their foraging ability, manta rays conduct a global search for a new feeding location, distancing themselves from the present optimal site. This mechanism can be articulated analytically as follows:

$$X_i^d(t+1)=\begin{cases} X_{rand}^d(t)+r(X_{rand}^d(t)-X_i^d(t))+\alpha(X_{rand}^d(t)-X_i^d(t)), i=1 \\ X_{rand}^d(t)+r(X_{i-1}^d(t)-X_i^d(t))+\alpha(X_{rand}^d(t)-X_i^d(t)), i=2,...,N \\ X_{rand}^d(t)=LL^d+r\times(UL^d-LL^d) \end{cases} \quad (24)$$

Where X_{rand} denotes a random point within the search space, while LL_d and UL_d signify the boundaries of dimension d. Figure 3 illustrates the cyclone foraging method [16].

III.3 SOMERSAULT FORAGING

In this procedure, each manta ray navigates around the food location and does a somersault to reach a new food spot. They consistently adjust their locations toward the area with the largest quantity of plankton.

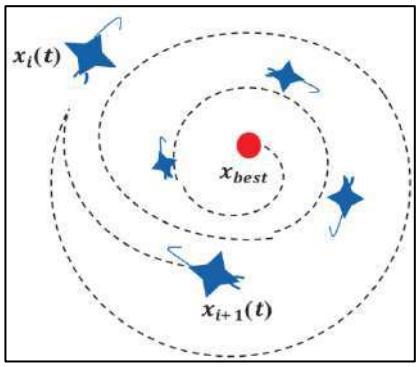

Figure 3: The cyclone foraging strategy.
Source: Authors, (2026).

The mathematical representation of somersault foraging is as follows [16]:

$$X_i^d(t+1)=X_{rand}^d(t)+SF(r_2X_{best}^d(t)-r_3X_i^d(t)), i=1,...,N \quad (25)$$

Where r_2 and r_3 are stochastic variables inside the interval [0,1]. SF represents the somersault factor, which is set at a value of 2 as advised in [16]. Figure 4 illustrates the somersault foraging mechanism.

IV. RESULTS AND DISCUSSIONS

In this section, the MRFO algorithm is applied to solve the OPF problem on standard and modified IEEE 30-bus test system for three case studies.

Case 1: Optimal power flow without incorporating wind power

In this case, the performance of the MRFO algorithm is tested on the standard IEEE 30-bus test system without incorporating wind power where the objective is to minimize the fuel cost of thermal generators given by Equation 1. The test system contains six thermal generators at buses 1, 2, 5, 8, 11 and 13 interconnected with 41 branches [18]. The cost characteristics and power limits of the thermal generators are shown in Table 1. The OPF problem is solved and the total cost obtained under the constraint optimization is **798.9211 $/h**. Figure 5 depicts the convergence characteristic of MRFO algorithm during this case. The simulation results obtained by MRFO algorithm are compared with other optimization algorithms reported in the literature. These optimization algorithms include Sine-Cosine Algorithm (SCA) [19], Modified Sine-Cosine Algorithm (MSCA) [19], Gbest guided Artificial Bee Colony (GABC) [3], (SF-DE) [20] and (GAME) [21]. The results of this comparison are given in Table 1. It is clearly seen from this Table that the proposed method gave better results in the terms of fuel cost and power loss minimization.

Case 2: Optimal power flow with wind power

This case aims to simultaneously optimize the fuel cost of thermal generators and the cost of wind power. The IEEE 30-bus system is modified by replacing the thermal power plants located at buses 5, 11, and 13 with wind farms. The wind farm at bus 5 consists of ten wind turbine generators with a total capacity of 60 MW. Similarly, the wind farms at buses 11 and 13 each consist of ten wind turbines with a total capacity of 60 MW. Cost coefficients associated with the wind farms are reported in [22]. The convergence characteristic of MRFO for this case is shown in Figure 6. The best cost and real power losses calculated by MRFO algorithm are **798.7147 $/h** and **4.8862 MW**, respectively. The corresponding system total cost and real power loss are relatively low compared with the system without wind farms. In other words, buses 5, 11 and 13 are the fittest integrated positions from viewpoint of system total cost and power loss reduction. Analyzing and interpreting the results is part of the discussions, their importance, achievements and limitations, highlighting the innovative aspects of the practical applications of the study and the conclusions derived from them, delimiting unresolved issues. If necessary, recommendations can be proposed.

Case 3: Optimal power flow with wind power and voltage stability enhancement

With the same simulation conditions given in case 2, after considering voltage stability improvement, the total cost and the active power transmission losses are found to be **799.606$/h** and **4.9512 MW**, respectively. The convergence characteristic of MRFO is shown in Figure 7. Compared with the obtained results without considering voltage stability improvement, it can be observed that the total cost and the power losses are increased with **0.8913$/h** and **0.065 MW**, respectively. However, in the terms of voltage magnitudes and L_{mn} index, the results achieved are better compared with the obtained results without considering voltage stability index as shown in Figure 8, 9 and 10. Detailed comparison of the optimal obtained results under the studied cases is represented in Table 2. The results achieved in case 3 displays that the active power losses are greatly reduced compared to the case 1 as well as the $\sum L_{mn}$ index is decreased compared to the case 1 and 2, thus, the distance to the collapse point is enhanced.

V. CONCLUSIONS

This paper presents the solution of OPF problem incorporating wind power generation and voltage stability enhancement using one of the most recently proposed optimization algorithms namely Manta Ray Foraging Optimization (MRFO) algorithm. This method used to optimize the power flows in the system in order to minimize the operating cost and to enhance the voltage stability. The efficiency of the proposed MRFO algorithm has been tested through its application to the IEEE 30-bus power system. The results demonstrate that the proposed algorithm to solve OPF incorporating wind power and line voltage stability index decreases the operating cost and improves the voltage stability of the power system.

ABSTRACT

The success of post-operative and post-traumatic therapy, as well as rehabilitation of disorders involving major joints, often necessitates ongoing passive mobility of those joints. Exercises used in physiotherapy are performed to heal broken joints. These can also be utilised by paralysed persons. Some technologies, such as Continuous Passive Motion (CPM), are routinely used to assist people suffering from paralysis, osteoarthritis, or other knee injuries. However, the current CPM gadget only conducts a specific common flexion and extension exercise, which aids in muscle tissue regeneration. Humans walk bipedally, which is an important attribute. Therefore, following physiotherapy, the human knee regains its flexibility, but it takes some time for the muscle to retrain itself to function in the gait cycle. This study facilitates the integration of precise gait cycle biomechanics into training mechanisms, enabling patients to replicate the exact gait motion during CPM machine exercises. As a result, the gait cycle not only lengthens the time it takes for patients to recuperate but also takes into account how easily people walk.

I. INTRODUCTION

In recent scenario injuries related to human musculoskeletal system plays a vital role and it is increasingly at faster rate. One of the most significant issues with occupational health in both developed and developing nations is musculoskeletal illnesses. Among the different musculoskeletal system, most common injuries and defects that occur in the knee joint [1]. The complex interactions between these disparate structures—each of which is dependent upon the others for correct function power the musculoskeletal system, which is made up of muscles, ligaments, tendons, intervertebral discs, and the nerves and blood arteries that connect them. [1]. The musculoskeletal system's tissues can experience damage from abrupt overloads as well as from repeated or prolonged loading. Conversely, insufficient exercise can cause the health of bones, cartilage, tendons, ligaments, and muscles to deteriorate. This may be induced by the following: pathological alterations in the knee joint (e.g., modifications due to pharmacological interventions or conditions such as diabetes), congenital anomalies, injuries and microtrauma incurred over a lifetime (e.g., minor injuries resulting from high-impact sports that excessively strain the knee joint, such as football, skiing, or skating), and overload-induced degenerative changes arising from the aging process of the human body [2]. In severe instances, a patient may require surgery, during which the surgeon does a total joint replacement (knee arthroplasty) or substitutes the damaged components of the joint with prosthesis (implant) [3]. Most of the knee injuries or disease ends up in surgical resections or reproductive surgeries, while surgical resection deals with removal of damaged parts of the joint and latter involves in replacing the damaged parts with new set of joints. Treatment steps often involve treating meniscus injury, treating degenerative changes surgically, and treating patellar instability. Coastal and offshore regions offer significant opportunities for wind energy utilization; however, conventional fixed offshore wind turbine installations are associated with high costs, complex structural demands, and maintenance challenges [4], [5]. To address these limitations, floating wind energy systems and buoy-supported platforms have been introduced as practical solutions, allowing power generation in deeper waters and remote marine locations.

These systems are particularly advantageous for supplying energy to independent offshore applications such as navigation lights, marine sensors, and environmental monitoring equipment.

II. LITERATURE REVIEW

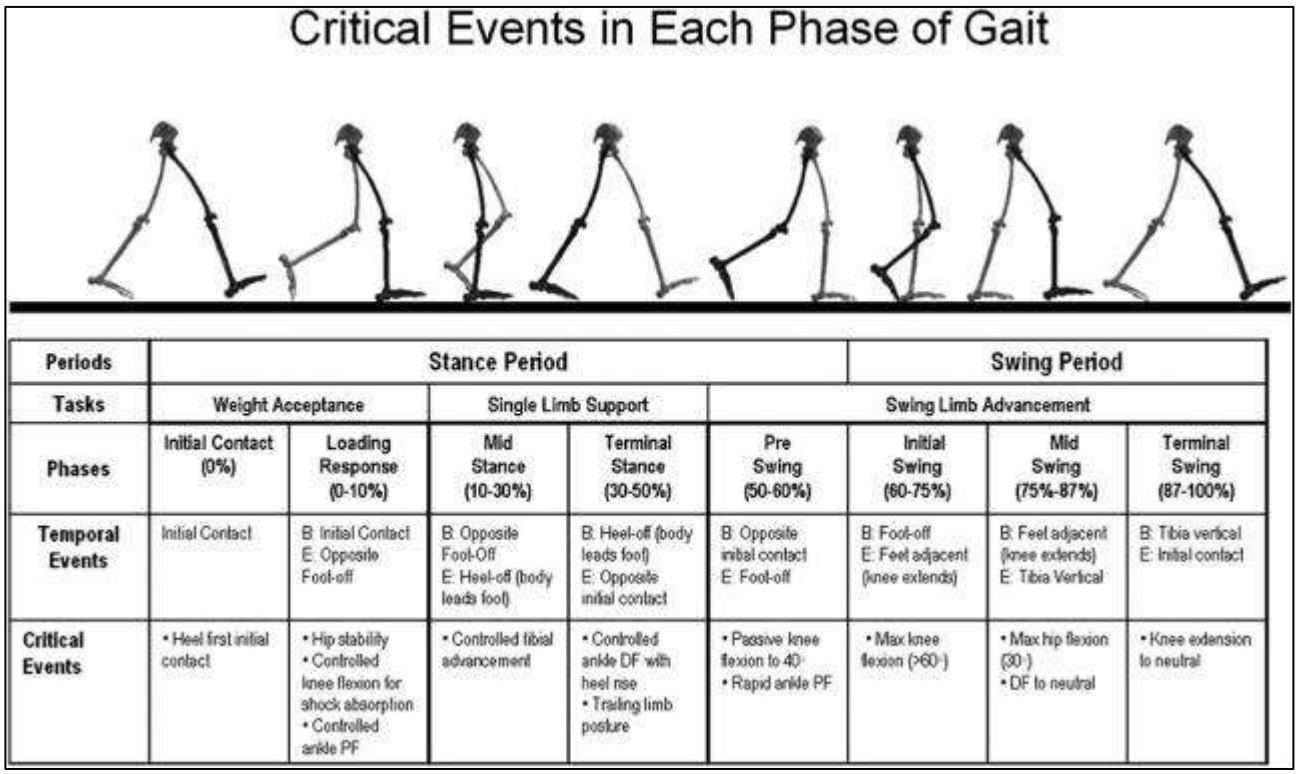
Knee replacement surgery is one of the main treatments for significant orthopaedic knee problems. Effective therapy to lessen pain and enhance functioning is the recommended course of treatment for knee complications. Treatment steps often involve treating meniscus injury, treating degenerative changes surgically, and treating patellar instability. In most of the rehabilitation process, CPM machines have been utilized for therapy [6]. Application of CPM machines is to avoid arthrofibrosis that involves joints to have limited mobility in knee and elbow joints [7]. Knee flexion therapy can be improved in weeks after arthroplasty by utilizing both physical therapy and CPM techniques [8]. Continuous passive motion (CPM), enables joints to move passively by a preset arc of motion [9]. Range of motion (ROM) is the critical parameter which the CPM machines focuses and in general for adequate knee flexion ranges from 90° to 120° for performing day to day activities like sit and stand, climbing stairs etc [10]. Three-dimensional computerized gait analysis or flexible electro goniometry have been used to measure knee kinematics during walking and stair climbing (5). In order to increase knee range of motion, CPM therapy is carried out as limited motion arc, ranging between 30° to 40° and increased by 10° to 20° each day [11]. It is challenging to carry out several types of tasks when knee stiffness is present, such as getting up from a seated posture. Following surgery or a joint injury, stiffness progresses via four stages: fibrosis, granulation tissue, edema, and hemorrhage [12]. One of the human body's most highly loaded moveable joints, the knees permit comparatively complicated motions that facilitate movement. [13]. Many individuals suffer from Osteoarthritis and other knee injuries and it is degenerative joint disease [13], [14].

Osteoarthritis (OA), is a chronic condition that leads to pain, fatigue, decreased mobility and structural changes in and around the knee joint [14]. The Knee injuries can be repaired by reconstructive surgery [15]. Injuries and its reconstructive surgery are (Anterior cruciate ligament (ACL), knee arthroplasties, arthrofibrosis are commonly knee joint problems [16]. Restoring the knee's normal range of motion requires physical treatment to minimise joint stiffness and oedema. Physical therapist uses manual pressure or mechanical devices for attaining the knee flexion or extension [16]. After surgery, intense physical therapy and rehabilitation are necessary to fully restore joint function and range of motion. The goal of post-operative physical therapy is to lessen joint stiffness and restore the knee's natural range of motion. Muscle activation is not necessary for passive motion, which is movement produced by an external source. Repetitive passive motion for rehabilitation can be done by either a physical therapist or a continuous passive motion (CPM) machine [17]. Worldwide, chronic illnesses, trauma, violence, and ageing all contribute to the more than 600 million individuals who live with various forms of disability (World Health Organisation, 2007). One of the more prevalent disabilities brought on by a brain injury or stroke is hemiplegia. The total loss of muscle function in one or more muscle groups is known as paralysis. It mostly happens as a result of abnormal muscle function, which typically causes sensory loss in the affected area of the body and damages the spinal cord, which impacts the body's central nervous system. There are many types of paralysis and one type of generalized paralysis is Hemiplegia. This type just affects the one side of the human body [4].

It results in muscle stiffness, weakness, and issues with muscle control. The site and severity of the damage can affect the degree of hemiplegia symptoms. Either the left or right side of your body might be affected by hemiplegia; symptoms on the affected side of the brain correspond to the opposite side of the body. The affected people have symptoms like muscle weakness, muscle spasticity, trouble during walking, poor balance, trouble grabbing object, seizures [5]. In order to address potential side effects of paralysis, enable the paralysed person to live as independently as possible, and enhance their quality of life, rehabilitation is frequently advised. Those who are paralysed may also benefit from the following rehabilitation techniques. Heat, massage, and exercise are common physical therapy treatments used to stimulate muscles and nerves. Occupational therapy, on the other hand, emphasizes performing daily activities. Examples of mobility aids include scooters and both manual and electric wheelchairs. Assistive technology like voice-activated computers, as well as supportive devices such as walkers, canes, and braces, also play a key role in therapy.

II.1 CONTINUOUS PASSIVE MOTION (CPM)

A tool called Continuous Passive Motion (CPM) is used in physiotherapy and rehabilitation to give the limbs and joints movement. It is mostly used to support postoperative therapy and improve knee joint mobility. CPM devices are generally utilised in the early stages of recovery after trauma or soft tissue surgery. Depending on the joint in question, these devices gradually improve the range of motion of the joint by continuous movement [18]. For a passive-assist strengthening exercise, the patient can be guided to provide a little amount of resistance against the moving attachment, or they can choose to remain relaxed and allow the device to move passively through its range of motion. To optimise patient benefits and improve physician outcomes, it is imperative to preserve range of motion following medical operations. Early in the rehabilitation process, it is beneficial to combine Active Assisted Range of Motion (AAROM) with Targeted Force and Continuous Passive Motion (CPM) to enhance muscle strength, control, coordination, and endurance. Range of motion (ROM) is the critical parameter which the CPM machines focuses and in general for adequate knee flexion ranges from 90° to 120° for performing day to day activities like sit and stand, climbing stairs etc [10]. From the literature review it is identified as the knee injuries is the main factor for reduced range of motion and commonly affected muscular skeletal degenerative joint disease. In the work an attempt is made to reduce the joint stiffness and restore the normal range of the knee flexion or extension through CPM machine.



III. DESIGN AND METHODOLOGY

From the literature finding, skeletal degenerative disease is more common against knee. In order to reduce the knee stiffness, joint function and improve the range of motion of knee flexion and knee extension, by incorporating gate analysis a modified CPM machine is to be designed. Designed CPM machine, incorporates the gate analysis of human leg and it is automated with the cam design. The designed CPM machines, considers the design calculations of gait, incorporating the gait analysis to design the cam profile.

This cam profile designed will cater the functionality of the CPM machine and it satisfies the range of motion needed for the therapy used for Hemiplegia treatment of the post-operative assistive techniques used for physical therapy. Further discussion will focus on gait cycle and calculation of gait cycle.

III.1 GAIT CYCLE

As seen in Figure 1, a gait cycle is the interval of time between consecutive, repeating walking activities. The same sequence of events occurs in both legs, but with a half-cycle phase shift. The stance phase, which makes up 60% of the gait cycle, and the swing phase, which makes up the remaining 40% [19], are the two primary stages of the cycle. Gait combines both closed-chain and open-chain operations.

Periods	Stance Period					Swing Period		
Tasks	Weight Acceptance		Single Limb Support		Swing Limb Advancement			
Phases	Initial Contact (0%)	Loading Response (0-10%)	Mid Stance (10-30%)	Terminal Stance (30-50%)	Pre Swing (50-60%)	Initial Swing (60-75%)	Mid Swing (75%-87%)	Terminal Swing (87-100%)
Temporal Events	Initial Contact	B: Initial Contact E: Opposite Foot-off	B: Opposite Foot-Off E: Heel-off (body leads foot)	B: Heel-off (body leads foot) E: Opposite initial contact	B: Opposite initial contact E: Foot-off	B: Foot-off E: Feet adjacent (knee extends)	B: Feet adjacent (knee extends) E: Tibia Vertical	B: Tibia vertical E: Initial contact
Critical Events	• Heel first initial contact	• Hip stability • Controlled knee flexion for shock absorption • Controlled ankle PF	• Controlled tibial advancement	• Controlled ankle DF with heel rise • Trailing limb posture	• Passive knee flexion to 40° • Rapid ankle PF	• Max knee flexion (>60°)	• Max hip flexion (30°) • DF to neutral	• Knee extension to neutral

Figure 1: Stages of Gait Cycle.
Source: Authors, (2026).

The two primary phases of the gait cycle are the stance phase and the swing phase. The stance phase, which accounts up 60% of the gait cycle, commences with the heel strike, in which the toes are still elevated above the ground at the time of the heel strike. The foot settles near the lateral border during the midstance phase. The stance phase ends and the swing phase (also referred to as the propulsive phase) begins with the toe-off phase [5]. In the swing phase, the toe-off and heel hitting phases are separated. The swing phase also includes the acceleration and deceleration subphases. From toe-off to mid-swing, the body is driven forward by the swift forward motion of the swing leg during the acceleration period. From mid-swing to heel strike, the following stage is the deceleration. Forward motion is controlled throughout this stage to ensure the foot lands softly [20], [21]. The mid-swing phase, which occurs between these two sub-phases, is when both feet are beneath the torso and the heels are in alignment.

III.2 CALCULATION OF GAIT CYCLE

Initial contact, loading reaction, mid-stance, terminal stance, pre-swing, initial swing, mid-swing, and late swing are the eight different phases that make up the gait cycle. Every stage involves movement of the whole body and leg. Forward leg movement is made easier by an anterior-posterior displacement in the pelvic region that alternates from left to right. This displacement is roughly 4-5° on each side [4]. The foot moves in a certain way in the frontal plane between heel strike and foot flat, and between heel-off and toe-off. Between heel-off and foot flat, a small valgus movement is also seen. During the gait cycle, which is a typical time frame for periodic human walking, the hip displays additional lateral motions. On level ground, the cycle is determined by the interval between consecutive heel strikes. When the foot strikes the ground, the leg moves into 5° of supination, increasing by 5° increments, marking the beginning of the gait cycle, or initial contact. During this phase, the knee flexes 15% to 20%. With lateral rotation, the hip flexes to 20° after extending to 10° during the swing phase. The ankle shifts from 20° of plantar flexion to dorsiflexion, while the knee flexes to 40°–60°. During the mid-swing phase, the adductors contract to cause the hip to flex to 30°, and the tibialis anterior muscle contracts to dorsiflex the ankle. With a locked extension of the knee, a neutral ankle position, and 25°–30° hip flexion, the late swing or terminal phase starts. Incorporating the gait cycle into the design of a Continuous Passive Motion (CPM) machine is crucial to the design process. To develop a modified CPM machine, components such as links, a slotted bar, and a cam are needed. The motion of the human leg, including the up-and-down movement triggered by the knee joint and the forward movement initiated by the hip joint, must be considered as a mechanism in the CPM machine. The positioning of the leg within the CPM machine is illustrated in Figure 2.

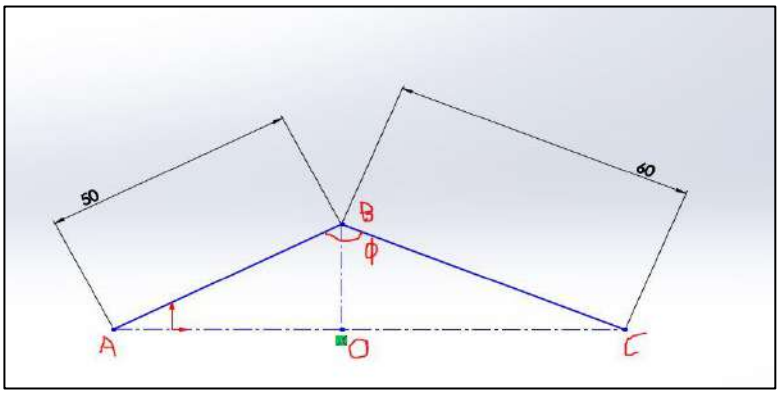


Figure 2: 2D drawing scematic of model leg in COM.
Source: Authors, (2026).

From the Figure 2, let us consider the following assumptions;

Consider AC as the base of the machine which is the travel length of the leg.
AB represents thigh portion.
BC represents below knee portion.
Ø represents the total angle between the thigh and the crus.
Line AOC represents ground (rest position of leg)
AB=50 cm and BC=60 cm.
Calculation:
BO –distance from the ground
Cos Ø =adjacent side/hypotenuse side
cos(Ø/2) = BO/BC
BO=BC cos(Ø/2)
BO=60 cos(Ø/2)
To find AC:
AC=AO+OC
AO= 50*sin(Ø/2)
OC = 60*sin(Ø/2)
So, AC=50*sin(Ø/2) + 60*sin(Ø/2)

Based on the above calculations, linear displacement as tabulated in Table 1 for each gait angle and the distance from the center of the cam are shown in the Table 1.

Table 1: Shows the calculation of Linear Displacement based on the schematic model leg.

Knee Angle (In Deg)	Distance of knee joint Angle (In Deg)	BO (Linear Displacement) (In Cm)	Distance from Centre Of Cam (In Cm)

III.3 DESIGN OF MODIFIED CPM MACHINE

After soft tissue surgery, Continuous Passive Motion (CPM) devices are used in the initial phase of rehabilitation. During the first phase of rehabilitation, the main objectives are to control pain following surgery, lower inflammation, enable passive movement in a certain plane, and safeguard the healing tissues. Several elements need to be taken into account when building a CPM machine, including:

- The length and intensity of post-operative physical therapy can be affected by the kind of operation, the extent of the injury, and the patient's degree of activity.
- Gender, size, and weight of the patient are all significant factors in selecting the proper range of motion and velocity for the CPM device.
- Adjusting important factors including knee flexion velocity, range of motion, and treatment time is necessary to maximise the benefits of physical therapy.
- To provide optimal therapy outcomes, it is imperative to examine the knee's biomechanics during passive motion in order to comprehend the interaction between user input settings and the CPM machine.

Table 2 contrasts the improved CPM machine, which incorporates gait analysis into its design, with the current CPM machine. The CPM machine's design considers all of the previously described elements, making sure that it satisfies every need for successful post-operative rehabilitation including knee flexion and extension. The redesigned device has motor-driven velocity control and is made to fit the needs of each user, male or female. Compared to the present CPM machines, this model is more suitable for a larger range of people due to its adjustability to users with different leg lengths.

Table 2 Comparison with existing CPM machine.

S.no	specification	Current CPM description	Designed CPM model
1	Maximum crus length	49cm	60cm
2	Maximum patient weight	160 kg	120 kg
3	Maximum Thigh length	41cm	50cm
4	weight	12kg	22kg
5	length	90cm	110cm

Source: Authors, (2026).

While most existing CPM devices offer just standard exercises, our created model incorporates the knee's unique gait cycle into the exercise mechanism. The gadget attempts to mimic the way the human leg moves naturally, which consists of two main movements: a forward motion started by the hip joint and an upward and downward motion led by the knee joint during a whole gait cycle. We chose to account for this variability by creating a cam profile in the CPM machine that matches gait cycle data because the angle variations that occur over a gait cycle are not uniform. Before deciding on the cam-follower mechanism, a number of mechanisms and their levels of complexity were assessed in order to determine its suitability and efficacy in correctly recreating the gait cycle.

III.4 DESIGN OF CPM WORKING MODEL

For designing the modified CPM machine, above mentioned factors are considered. The design has mechanical components like cam and follower, links to connect, shafts to hold the position of the leg and motor to drive the modified CPM machine. The designed CPM must perform the functionality of CPM machine by incorporating the Gait analysis in to the design. The working model of CPM machine is comprised of 6 components which is assembled together to get the unique modified CPM machine incorporating gait cycle. The components are base, cam follower, roller, links, centre shaft and midshaft. The components of the model are briefed further in the following sections.

III.5 DESIGN OF CAM

For implementing the displacement made by the knee in the design of the cam, cam profile is made into 20 divisions and each division represents the particular gait cycle angle and the displacement of each division is calculated and shown in the Table 1.

Figure 3: Components of Modified CPM machine.
Source: Authors, (2026).

The profile of the cam is generated with these calculated values and it is shown in Figure 3. The final profile of the cam after proceeding with the above steps will follow the gait cycle pattern because the profile of the cam is designed for each gait angle. The base has a sliding t-slot running through it all along which paves the way for the roller to slide through it. This slot prevents the roller from its up and down movement mainly because it helps the setup to be stable after the loads has been added to the links. Only one translational movement is provided and the rest two kinds of motion are arrested. It has two mounts near the end which helps the links to fix through it like a pin joint. There is a plate with four holes at the front side of the base. The other plate of the shaft stand can be screwed up with this for the ease of removal of the cam if needed. The cam has been designed with a hole shaft inside which supports the rotation of the cam with the rotating motor in it. The gait cycle is incorporated in the cam which moves the leg placed in the machine as accordingly. The major need of the roller is to convert the rotary motion of the cam to linear motion of the roller follower. The roller has a shaft in which the mounts for holding the below knee part is connected and they are affixed through nuts and bolts. There is a center roller which will be connected to the cam and provides the necessary translation motion for the movement of the leg. There are two blocks connected at each end of a shaft which slides through the T-slot.

There are actually four links in which the there are two similar thigh links and other two similar links for the below knee part. The links are connected at their ends with bolt and nut while the amidst part is connected with a midshaft. The thigh region is usually smaller when compared with the crus. So, the thigh link is smaller. The two links has slots through which the length of the leg according to the person can be adjusted. Thus, this results that the machine can be used by everyone irrespective of the leg length. In between the two links a soft cloth will be wrapped up as this prevents the direct contact of leg with any part of the machine and the legs will be kept hold in a netted cloth since a plate may be felt uncomfortable for some persons. The cloth takes the shape of the leg and it does not induce any pain while resting on it. The centre shaft is an assembly of two components centre shaft and the shaft stand. They together become the setup for holding the cam. The centre shaft has threads at the end of its step shaft. The threads are provided in order to mate with the shaft stand. The cam will be made concentric with the centre shaft and a very small gap is left between the cam shaft and the centre shaft to rotate the cam. The shaft stand has a cup shaped opening with threads cut inside them to fit into the centre shaft. The shaft stand has a plate at the bottom which fits with the similar plate made at the top of the base. The midshaft has threads at the end and the link has no threads in them because to adjust the length of the leg through the links easily threads are not provided in the links. A stud is kept in the main shaft as shown above to prevent the links from displacing since only the midshaft is locked with the nuts and the links are free to move through the axis when the roller rotates.

III.6 WORKING PRINCIPLE OF THE CPM MACHINE

The cam is mounted on the center shaft which has been supported through a stand attached to the base. The cam has only rotational motion on one axis only and a roller is attached to the cam. The base has a T-Slot running through it which makes the roller part slide against it. The two links connected with the roller forms the below knee part of the leg and the other two links are for the thigh region. They are connected with the base through the mounts. A midshaft is attached between the two links which makes them to move parallel always. When the motor is powered, the shaft attached with the cam rotates. So, the rotation of the cam brings out a translatory motion to the roller which slides through the slot. Hence the link attached with the roller moves up and down resulting in the movement of the leg. The final assembled view of the CPM machine is shown in Figure 4.

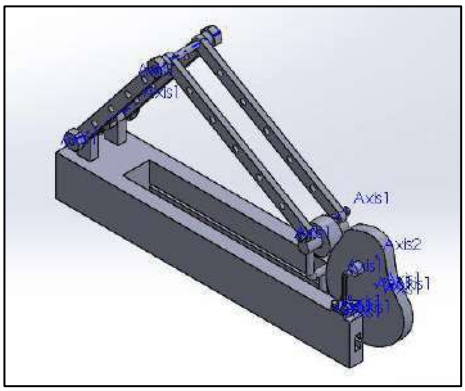

Figure 4: Assembled model.

IV. RESULTS AND DISCUSSION

Designed CPM machine incorporates the functionality of movement by utilizing gait cycle in to the mechanism. Designed CPM machine is of easy to use and it can be an effective system for post operative physio therapeutical procedures. From the designed CPM machine for effective utilization of the gait analysis was carried out and it is simulated to check the functionality of knee Osteoarthritis.

IV.1 ANALYSIS OF GAIT CYCLE

The analysis of the design is important because it helps to reduce the errors on a system by optimizing and running the iteration several times. The software used for analyzing the designed cam for the gait cycle incorporated is working model 2D. The working model 2D is a real time 2D motion analysis and mechanical system analysis software that can be used to plot graph and arrive at the math data that sequencingly corresponds to the output.

Force is exerted on the roller which is the force exerted when a leg placed on the links connected to the roller. Motor has been connected to the cam and it rotates about the axis. With the rotation of the cam and by tracing the path made by the roller the displacement of the roller according to the velocity of the cam can be calculated. Figure 5 shows the graphical analysis of gait cycle simulation. The graph shows the plot obtained by plotting the roller velocity against the cam. The first graph is obtained when the roller touches the cam at its outer surface. The second graph shows the plot obtained when the centre of mass on the roller rolls over the defined cam path. The graph obtained from the analysis figure is more likely similar to the one obtained in the gait cycle. It can be inferred that for any one cycle in the graph the curve is similar to the gait graph which affirms that it follows the gait cycle.

V. CONCLUSION

Focus of the paper is to design a CPM machine for Osteoarthritis (OA), is a chronic condition that leads to pain, fatigue, decreased mobility and structural changes in and around the knee joint. The modelled design can also be used by the osteoarthritis affected persons, leg fractures and knee injured persons. The designed CPM machine should be able to adapt to the human gait cycle pattern and incorporating gait cycle analysis in the CPM machine could be used at the therapy session to reduce joint stiffness and swelling in order to restore the normal range of motion of the knee. The designed CPM model is assembled in such a way that it not only acts as a physiotherapeutic device but also acts as a device for faster reclamation of the leg tissues with the incorporation of the gait cycle. The analysed model is safer to use by any person irrespective of gender, weight and height. The designed model works well for generalised paralysed person for whom the design has been developed.

ABSTRACT

The development of austenitic stainless steel-based matrix composites with powder metallurgy were attracting interest for many uses in the aerospace and defense sectors. The influence of sintering temperature (1100, 1200, and 1300 °C), compaction pressure (550, 650, and 750 MPa), Ti6Al4V content (5, 7, and 9wt%), and sintering duration (45, 90, and 135 minutes) on the density, hardness and compressive strength of SS316/Ti6Al4V composites was evaluated utilizing Taguchi, ANOVA, and response surface methodologies. The research employed L9 OA based on Taguchi method. The composite powder were compressed using single-action die subsequently sintered at muffle furnace. The Simultaneous Evaluation of Criteria and Alternatives (SECA) approach was employed to obtain the significance of criteria for performance assessment. According to SECA analysis, the density of 0.1592, the hardness of 0.1363, and the compressive strength of 0.1347 was obtained. The application of MARCOS for ranking evaluation indicates that composite reinforced with Ti6Al4V demonstrated the most advantageous physical and mechanical properties. The verification of ranking through several decision-making confirms the efficacy and reliability of suggested method. The S/N ratio-based Taguchi approach identified the optimal input parameters, whereas ANOVA evaluated the individual contribution percentage of all factors. The response surface methodology was employed to assess contour plots, surface plots and regression equations for response qualities. The ANOVA results indicated that compaction pressure significantly influenced the properties of the fabricated composites, followed by the percentage of Ti6Al4V, sintering time, and sintering temperature, in that order. The results of the SECA-MARCOS approach demonstrate that the formulation with 7 wt.% Ti6Al4V is the most advantageous for defense and aerospace applications. Consequently, the formulated models of response qualities for costly trial tests, thereby enhancing the diminishing production costs and efficiency of the optimization process.

I. INTRODUCTION

Matrix composites based on stainless steel are in high demand within the defense and aerospace sectors. This were due to their highly sought-after attributes, which encompass exceptional strength, lightweight composition, corrosion resistance, adequate wear resistance, stiffness and reduced cost relative to traditional stainless steel. A356 composites with nano-alumina were produced by powder metallurgy and forging techniques. Increased sintering temperature and finer alumina decreased porosity and enhanced hardness. Augmented diffusion increased density, whereas elevated temperature facilitated grain coarsening [1]. 316L stainless steel augmented with 1–5 vol% Ti and sintered at 1380 °C, exhibited enhanced densification and the production of β-Ti.

The optimal compromise was 3 vol% Ti at 1380 °C, resulting in a high density of 96.1%, an ultimate tensile strength of approximately 433 MPa, and commendable wear resistance. A low modulus of 58.9 GPa at 5 vol% Ti underscores its appropriateness for biomedical implant applications [2]. Ti-Mn alloys with minor Sn additions were fabricated by powder metallurgy to improve the strength-ductility equilibrium. Sn reduced the melting point and enhanced densification in Ti-2Mn alloys, resulting in refined α/β phases, increased ductility (15.9%), a strength of 784 MPa, and improved corrosion resistance. In Ti-4Mn alloys, Sn induced β-phase coarsening and impeded densification, hence diminishing performance enhancements [3]. The Ti-16Nb-4Sn alloy was synthesized using powder metallurgy, exhibiting a predominant β-phase structure alongside a minor α-phase. Elevating sintering temperature and duration diminished porosity and enhanced compressive strength. The elastic modulus approximated that of normal bone, rendering the alloy appropriate for biomedical implants without inducing stress shielding [4]. The TA15 alloy was produced by Spark Plasma Sintering (SPS) with the sintering temperature predominantly dictating the microstructure, while pressure exerted no effect. Increased temperature and duration enhanced densification, resulting in optimal mechanical performance at 900 °C, 50 MPa, and 5 minutes. The incorporation of 0.5% graphene further improved yield and compressive strength at both ambient and elevated temperatures [5]. Ti–Zr alloys were sintered using SPS utilizing

Ti and ZrH_2 powders, with homogeneous Zr dissolution attained at temperatures of 1000 °C or higher. Hardness augmented with temperature; nevertheless, excessive grain formation at 1200 °C diminished strength. The ideal sintering temperature was determined to be 1000 °C, achieving a balance between solid-solution strengthening and microstructural stability [6]. MgB_2/SS316L superconducting wire was produced by in-situ packing, sintering, and hot rolling processes. An elevated sintering temperature and extended holding duration enhanced superconducting transition and diminished porosity. Optimal performance was achieved at 800–820 °C with a sintering duration of 1–3 hours [7]. The WAAM-CMT process of SS308L was assessed utilizing the Taguchi L9 orthogonal array to investigate the impacts of current, welding speed, and gas flow on ultimate tensile strength, microhardness, residual stress and elongation. The Fuzzy AHP–MARCOS method determined the ideal parameters to be 140 A, 8 mm/s, and 16 L/min, with current as the predominant influence. XRD and EDX analyses verified that the optimally manufactured samples corresponded to the composition of industrial stainless steel [8]. Fe-based composites reinforced with nano-sized carbides and borides (B_4C, Fe_2B, Fe_7C_3, TiB_2) were fabricated using mechanical alloying and subsequently sintered at 1100 °C for 2 hours. Elevating B_4C concentrations diminished the particle sizes of TiC and TiB_2 while augmenting the TiB_2 content, resulting in a reduction of hardness owing to its comparatively softer characteristics.

Microstructural investigations revealed alterations in void concentration and stiffness corresponding to different reinforcement ratios [9]. A WC-6.4Fe-3.6Ni hard metal was produced using spark plasma sintering as a substitute for WC-Co. Elevated sintering temperatures (up to 1300 °C) enhanced densification and hardness (~1633 HV) but diminished toughness because to a smaller mean free path of the binder. The Fe-Ni binder improved wettability and diffusion, resulting in attributes that are competitive with traditional WC-Co grades [10]. Ti-15Nb-25Zr-(0–8) Fe alloys were sintered by SPS at temperatures ranging from 800 to 1200 °C to investigate phase evolution and mechanical properties. Elevated temperatures facilitated the development of the β-phase, resulting in increased strength (up to 1604 MPa) alongside favorable flexibility (~35%). Moderate iron addition (4%) enhanced diffusion and strengthening, but excessive iron (8%) resulted in intermetallic formation and grain coarsening, hence diminishing overall performance [11]. Fe-based composites reinforced with Ti, Ni_3Al, and Al_2O_3 were fabricated using mechanical alloying and subsequently sintered at 1000 °C for 1 hour. Nanocrystalline nickel-rich solid solutions with crystallite dimensions of several nanometers were synthesized. The incorporation of titanium enhanced microhardness, and phases including Fe_3Al, TiAl, NiAl, Al_3Ni_2, Al_2O_3, and Fe_3O were discovered [12]. The research investigates the melting of copper and its infiltration into iron-based matrices during sintering, enhancing interfacial diffusion. Liquid-phase copper improves adhesion at particle interfaces, fortifying typically vulnerable areas in powder compacts.

Enhanced diffusion at elevated temperatures and prolonged sintering durations results in substantial improvements in mechanical and physical characteristics [13] Ti-35421 alloys underwent hot pressing, and the influences of temperature, pressure, and duration were assessed. The sintering temperature was the primary factor influencing density, secondary α-phase dimensions, and mechanical characteristics. Optimal circumstances (900 °C, 45 MPa, 2 h) resulted in a yield strength of 1248 MPa and a strain of 23%; nevertheless, elevated temperatures led to grain development and diminished strength [14]. Zirconia coatings were deposited on TC4 titanium alloy via discharge plasma sintering to enhance tribological performance. Increased sintering temperatures improved coating density, adhesion, and hardness, with optimal wear performance achieved at 1500 °C for 20 minutes. Enhanced diffusion at increased temperatures decreased friction (0.33) and wear rate due to augmented interfacial bonding [15]. A pseudo quasi in-situ technique was employed to investigate pore evolution, grain growth, and phase fractions in MIM-sintered Ti-6Al-4V alloys. Elevated sintering temperatures expedited pore elimination and grain coarsening, dictated by an activation energy of 252.2 kJ/mol. The optimal mechanical parameters (922 MPa strength, 12.8% elongation) were achieved at 1200 °C for 4 hours with little porosity [16].

FeNiCoCr HEA components produced using binder jet 3D printing exhibited an increase in density (78–98%) during sintering at temperatures ranging from 1410 to 1440 °C, resulting in the formation of a singular FCC phase. Hot Isostatic Pressing (HIP) markedly enhanced strength and ductility solely when the original sintered density surpassed 91%. The 1440 °C + HIP sample attained around 99.4% density, exhibiting elevated mechanical characteristics and corrosion resistance surpassing that of 316L stainless steel [17]. Mullite/kaolinite hollow fiber membranes reinforced with 0–12 wt% SS316L exhibited a significant enhancement in bending strength, increasing from 32 to 80 MPa. A balanced structure was achieved at 10 wt% SS, exhibiting commendable strength (66.7 MPa), 29% porosity, and 96.9% oil–water rejection. The optimized fibers shown significant potential for water treatment owing to improved strength and permeability [18]. The research assesses Ti6Al4V composites augmented with dual-ceramic ZrO_2–Si_3N_4 particles by Spark Plasma Sintering at 900 °C. All samples exhibited significant densification (~96.65%) and enhanced nanomechanical characteristics. The minimal ceramic content (S1) yielded optimal hardness, elastic modulus, and nano-hardness, but increased ceramic proportions diminished density and performance [19]. Ti6Al4V/TiCp nanocomposites were synthesized using Spark Plasma Sintering (SPS) at temperatures ranging from 1050 to 1160 °C, incorporating various concentrations of TiC. FE-SEM and XRD revealed dense, poreless microstructures with uniformly distributed TiC particles.

Elevating TiC concentration resulted in the formation of new phases and significant alterations in microstructure and mechanical properties [20]. The research examines the impact of porosity on the mechanical and acoustic properties of Ti-6Al-4V, engineered to replicate human bone. Increased porosity reduced the elastic modulus, elastic constants, and surface acoustic wave velocities as a result of structural phase transitions. The porous alloys exhibited enhanced mechanical-acoustic performance relative to cortical and cancellous bone [21]. Ti6Al4V–ZrO_2–Si_3N_4 composites were synthesized by Spark Plasma Sintering (SPS) at temperatures ranging from 950 to 1200 °C to investigate the influence of temperature on densification and nanomechanical properties. Properties its raised from 950 °C to 1100 °C, but decreased at 1200 °C, indicating a non-linear development. The optimal performance was observed at 1100 °C, attaining maximum hardness, and elastic modulus, with all samples sustaining over 95% relative density [22]. The novelty of this study lies in formulating a unified experimental–computational framework for optimizing SS316/Ti6Al4V powder metallurgy composites through an integrated Taguchi–SECA–MARCOS approach.

Unlike previous studies that examine individual PM parameters or rely on single-objective optimization, this work simultaneously evaluates the influence of four critical factors—Ti6Al4V content, compaction pressure, sintering temperature, and sintering duration—on density, hardness, and compressive strength. A comparative multi-criteria evaluation was performed using MARCOS and benchmarked against established MCDM methods such as ARAS, WASPAS, MOORA, and COPRAS to validate ranking stability and methodological consistency. The inclusion of SECA further provides objective weighting of the performance criteria, enabling a more rigorous assessment of parameter significance. This combined optimization and comparative analysis technique successfully identifies the optimal reinforcement level and processing parameters for achieving low-density, high-strength SS316/Ti6Al4V composites, offering a robust pathway for advanced material design in aerospace and defense applications.

II. MATERIALS AND METHODS

SS316 stainless steel powder (45 µm, 99.5% purity) served as the matrix material and was obtained from Matrics Enterprises, Nagercoil, Tamilnadu, India. Ti6Al4V alloy powder (<45 µm) was chosen as the reinforcement owing to its elevated specific strength and compatibility with Fe-based matrices, purchased from same Matrics Enterprises. The characteristics of both powders were presented in Table 1. Table 2 displays the chemical composition of SS316. The SS316 and Ti6Al4V powders were amalgamated at a 10:1 ball-to-powder ratio, 200 rpm speed, and a milling duration of 2 hours to ensure homogenous mixing. The necessary powder amounts were measured using a digital balance. The composite powders were compressed into cylindrical pellets of 10.5 mm in height and 13 mm in diameter utilizing a single-action die and a hydraulic press (EIE Instruments, 1000 kN). Three compaction pressures were established: 550, 650, and 750 Mpa. The green compacts were sintered in an argon-controlled high-temperature furnace at 1100 °C, 1200 °C, and 1300 °C for durations of 45, 90, and 135 minutes, chosen to facilitate solid-state diffusion and densification of the SS316/Ti6Al4V system.

Table 1: Characteristics of SS316 and Ti6Al4V.

Material	Type	Melting point, (℃)	Hardness (HB500)	Compressive strength, (Mpa)	Elastic modulus, (Gpa)	Density, (g/cc)

Density was assessed by Archimedes' principle, hardness was determined using Rockwell B tester (Samarth Engineering, 1/16" indenter, 100 kgf load), and compressive strength was quantified utilizing Universal Testing Machine. Nanoindentation demonstrated a substantial enhancement in hardness in all reinforced samples [22]. Microstructural analysis was conducted on the sintered SS316–Ti6Al4V samples to examine particle dispersion and porosity. The specimens were abraded with 400–2000 grit SiC sheets, polished with 1 µm diamond paste, and etched using a modified glyceregia solution [23]. The etched samples were analyzed with an optical microscope (Metzer-M, India) at different magnifications to evaluate reinforcement distribution and adhesion quality within the matrix. A Taguchi L9 orthogonal array was utilized to examine the effects of Ti6Al4V weight percentages (5, 7, 9%), compaction pressure (650–750 MPa), sintering temperature (1100–1300 °C), and duration (45–135 min). The conclusive factor amounts employed in the trials are delineated in Table 2. Figure 1 shows the methodology used in this research Archimedes' principle (Equation 1) were employed to determine the samples density [24].

$$\rho=(W/(W-W\_1\ ))*\rho\_1 \quad (1)$$

where,
q1: Water density
W1: Sample mass at distilled water
W: Sample mass in the air
q: Sample density

II.1 OPTIMIZATION USING SECA – MARCOS TECHNIQUE

II.1.1 Seca

The SCEA approach [25] evaluates multi-objective non-linear technique to concurrently ascertain overall efficiency scores of criteria weights and alternatives for specific decision-making challenge. It were predicated at two reference points. The initial reference point were established using within-criterion variation data, represented by the SD of all criterion, while the subsequent reference point is determined by the correlation measure.

Step 1: Creation of preliminary decision matrix

A decision matrix were constructed based on performance data of m alternatives.

$$X = \begin{bmatrix} x_{11} & x_{12} & \dots & x_{1n} \\ x_{21} & x_{22} & \dots & x_{2n} \\ \dots & \dots & \dots & \dots \\ x_{m1} & x_{m2} & \dots & x_{mn} \end{bmatrix} \quad (2)$$

where x_{ij} signifies the value of the ith alternative on the jth criterion, and $x_{ij} > 0$.

Step 2: Standardization of decision matrix

The components of initial decision matrix were standardized to create the equivalent normalized matrix. Relying on the criterion type, two equations can be utilized. [26].

$$n_{ij} = \frac{x_{ij}}{\max_i x_{ij}} \text{ if } j \in \text{ beneficial} \quad (3)$$

$$n_{ij} = \frac{\min_i x_{ij}}{x_{ij}} \text{ if } j \in \text{ non - beneficial} \quad (4)$$

n_{ij}, denotes the normalized value within the decision matrix.

Step 3: Computation of the SD and level of discord

The vector for all criterion, $V_j = [n_{ij}]_{m\times 1}$, has now been established. Utilizing the components of between-criteria variation, normalized decision matrix, and within-criterion metrics are assessed as correlation (r_{jl}) and SD (σ_j) for all pair of criterion vectors.

$$\pi_j = \sum_{l=1}^{n} (1 - r_{jl}) \quad (5)$$

For each criterion in the SECA method, the contrast intensity was determined using the standard deviation, which denotes data dispersion and is represented by σ_b. Conversely, the correlation index, (r_{jl}) signifies the intensity of the linear link among two criteria.

Step 4: Establishment of criteria weights

The reference points for between-criteria and within-criterion mass were derived as values of π_j and σ_j.

$$\sigma_j^N = \frac{\sigma_j}{\sum_{l=1}^{n} \sigma_l} \quad (6)$$

$$\pi_j^N = \frac{\pi_j}{\sum_{l=1}^{n} \pi_l} \quad (7)$$

where σ_j^N and π_j^N are the normalized values of σ_j and π_j.

Step 5: Formulation of the multi-objective linear programming model

A multi-objective linear programming model has been formulated, encompassing the following objective functions: minimization of the deviation of criteria and maximization of overall performance (S_i), along with the necessary constraints.

$$\max S_i = \sum_{j=1}^{n} w_j n_{ij}, \forall i \in 1,2,\dots,m \quad (8)$$

$$\min \phi_b = \sum_{j=1}^{n} \left(w_j - \sigma_j^N\right)^2, \quad (9)$$

$$\min \phi_c = \sum_{j=1}^{n} \left(w_j - \pi_j^N\right)^2, \quad (10)$$

$$\sum_{j=1}^{n} w_j = 1, w_j \le 1, \forall j \in 1,2,\dots,n \text{ and } w_j \ge \varepsilon, \forall j \in 1,2,\dots,n \quad (11)$$

Where φ_b and φ_c represent the changes of criteria weights from the reference points of between-criteria and within-criterion $\varepsilon \le w_j \le 1$ delineates the range of w_j and w_j denotes the weight of the j-th criterion, between ε and 1, with ε being the lowest positive value of criterion weight.

Step 6: Enhancement of multi-objective nonlinear programming framework

The previously created optimization model may be transform into a single-objective problem in optimization:

$$\max Z = \phi_a - \beta(\phi_b + \phi_c) \quad \text{subject to } \phi_a \le S_i, \forall i \in 1,2,\dots,m \quad (12)$$

II.1.2 Marcos

The MARCOS method were employed to address many decision-making difficulties due to its straightforward computation. The subsequent steps of the MARCOS technique are as follows [27].

Step 1: Establish a decision-making matrix utilizing Equation 13 The decision matrix $\left([Z_{ij}]_{p\times q}\right)$ is expanded by adding the Anti ideal value (AIV) and Ideal value (IV)

The AIV and IV were calculated by the equations (13) and (14).

$$AIV = \max(Z_{ij}) \nearrow \text{ if } j \in N_{nb}, \text{ and } AIV = \min(Z_{ij}) \nearrow \text{ if } j \in N_b \tag{13}$$

$$IV = \max(Z_{ij}) \nearrow \text{ if } j \in N_b, \text{ and } IV = \min(Z_{ij}) \nearrow \text{ if } j \in N_{nb} \tag{14}$$

Step 2: The revised decision matrix is within range 0 to 1 utilizing the following equation (15).

$$z_{ij} = \frac{z_{ij}}{z_{VV}} \nearrow \text{ if } j \in N_b \tag{15}$$

$$z_{ij} = \frac{z_{VV}}{z_{ij}} \nearrow^{\text{if}} j \in N_{nb} \tag{16}$$

Step 3**:** The weighted decision matrix were formed using equation (17).

$$\varpi_{ij} = \omega_j \times z_{ij} \tag{17}$$

Step 4 Computing the average of the weighted matrix using the equation (18).

$$k_i = \sum_{i=1}^{p} \varpi_{ij} \tag{18}$$

Step 5 The degrees for IV and AIV were determined by the following formula.

$$k_i^+ = \frac{k_i}{k_{IV}}, \text{ and } k_i^- = \frac{k_i}{k_{AIV}} \tag{19}$$

Step 6: Regarding AIV and IV, the functions were computed by the following equations.

$$f(k_i^+) = \frac{k_i^-}{k_i^+ + k_i^-}, \text{ and } f(k_i^-) = \frac{k_i^+}{k_i^+ + k_i^-} \tag{20}$$

Step 7: Regarding AIV the and IV, the utility functions were computed [28].

$$f(k_i^+) = \frac{k_i^-}{k_i^+ + k_i^-}, \text{ and } f(k_i^-) = \frac{k_i^+}{k_i^+ + k_i^-} \tag{21}$$

Step 8: The final utility function is determined by

$$f(k_i) = \frac{k_i^+ + k_i^-}{1 + \frac{1-f(k_i^+)}{f(k_i^+)} + \frac{1-f(k_i^-)}{f(k_i^-)}} \tag{22}$$

Step 9: Evaluating the options. The alternatives are graded in descending order of their $f(k_i)$ from best to worst. principles.

III. RESULTS AND DISCUSSION

III.1 TAGUCHI METHOD

This study categorizes physical properties density, under "smaller-the-better" principle of Taguchi technique with the objective of minimizing the weight of the SS316/Ti6Al4V composite. Conversely, hardness and compressive strength fall within the "larger is better" paradigm, aimed at enhancing the strength and hardness of composites.

Consequently, the signal-to-noise ratio was calculated utilizing Equations 3 and 4. Table 5 displays the statistical and experimental outcomes for the hardness, density and compressive strength of SS316/Ti6Al4V composites. ANOVA and Taguchi analysis results was derived with Minitab software [29].

Table 5: Results of statistical analysis for SS316/Ti6Al4V composites' hardness, compressive strength and density.

S.No	Density		Compressive strength		Hardness	
	Result	S/N Ratio	Result	S/N Ratio	Result	S/N Ratio
1	3.032	-9.635	332.34	50.43	39.05	31.83

III.2 COMPOSITES RANKING

III.2.1 Weight Calculation

The powder metallurgy composite has nine possibilities and three criteria, organized in decision matrix presented at table 5, by utilizing Equation (2). Initially, the n_ij.values were utilized to construct normalized decision matrix according to Eq. (3) & (4). Table 6 displays normalized outcomes.

Table 6: Normalization of decision matrices for SECA analysis.

S.No	Density	Compressive Strength	Hardness
1	1.0000	0.8603	0.8967
2	0.9915	0.8946	0.9150
3	0.9793	0.9678	0.9830

The normalized inside criterion, (σ_j^N), and between criteria, (π_j^N), reference points were used to ascertain the optimal criteria weights through multi-objective linear model. The resultant weights and their deviations from reference points are displayed in Table 5, while overall performance scores (Si) are also presented. Criteria with elevated normalized reference points were assigned greater weights, hence improving the performance of leading alternatives. The model adeptly balanced the performance enhancement with deviation reduction, ensuring robustness and consistency.

Table 7: Optimized criteria weights and deviation from the reference points.

Criteria	Sigma	Pi	Sigma_N	Pi_N	SECA_Weight
Density	0.0090	3.5477	0.1067	0.4839	0.299
Compressive Strength	0.0411	1.8808	0.4852	0.2566	0.368
Hardness	0.0346	1.9024	0.4081	0.2595	0.333

Source: Authors, (2026).

The criterion weights were calculated as: Density = 0.299, Compressive strength = 0.368, and Hardness = 0.333.

III.2.2 Alternatives evaluation

The choice matrix were constructed after establishing the AIV and IV using Eq. (13) & (14). The decision matrix employed at MARCOS for specified criteria and alternatives were presented in Table 7. According to the MARCOS technique outlined, each value were normalized using Equations (15) & (16). The normalized matrix for MARCOS evaluation were presented at Table 8. Table 8 shows the weighted choice matrix and normalized decision matrix for MARCOS analysis.

Table 8: Weighted and normalized decision matrix for MARCOS analysis.

	Normalization			Weighted Normalizaton		
S.No	Density	Compressive Strength	Hardness	Density	Compressive Strength	Hardness
1	1.0000	0.8603	0.8967	0.2994	0.3166	0.2983

Subsequently, Equations (18)-(20) of the MARCOS technique were used to derive the utility functions (f(k_i^+),f(k_i^-)) and degree k_i^+,k_i^-. The utility function, (f(k_i)) for all choice were determined by Equation (21). The results of MARCOS were encapsulated at Table 9.

Table 9: MARCOS Results.

Ultimately, the alternatives were ranked on the (ki).. values. Table 9 indicates best processing parameters are 7 wt.% Ti6Al4V reinforcement, a sintering temperature of 1100°C, a sintering duration of 90 minutes and compaction pressure of 750 MPa, GNPs-reinforced Cu/Ti6Al4V composites (0.3 wt% GNPs) were fabricated by vacuum hot pressing, and the influence of sintering settings was examined through orthogonal testing, in contrast to another study. The sintering temperature predominantly affected density, microhardness, and compressive strength, whereas pressure and sintering duration showed negligible contributions. The ideal parameters—1150 °C, 35 MPa, 40 min—produced elevated density (99.34%), microhardness (585.4 HV0.1), and compressive strength (2382 MPa), together with distinct α/β-Ti phases and preserved graphene in the microstructure. [30].

The powder metallurgy composite alternatives organized in descending way as A6, A3, A9, A8, A7, A4, A5, A2, A1. The composite A6, containing 7 wt.% Ti6Al4V, is determined to be the optimal selection for defense and aerospace applications under the specified conditions, based on the nine criteria.

III.3 ASSESSMENT OF THE BEST POSSIBLE MIX OF INPUT PROCESS VARIABLES AND THEIR MAGNITUDES

To determine the optimal levels of factors for density, hardness, and compressive strength, the average utility function value f(k_i) for all level of the factors was assessed using main effect plot of the Taguchi method, with the highest value selected for all factor. The utility function f(k_i) evaluates corresponding values for three tiers of input factors, and principals related to the utility function f(k_i). Table 10 displays the emphasized bold values for utility function f(k_i) representing the maximum values for the three tiers [31].

Table 10: Impact table for utility function $\boldsymbol{f(k_i)}$.

	Means				S/N ratio			
Level	**A (wt.%)**	**B (MPa)**	**C (°C)**	**D (min)**	**A (wt.%)**	**B (MPa)**	**C (°C)**	**D (min)**
1	0.6576	0.6629	0.6700	0.6630	-3.644	-3.574	-3.483	-3.573
2	0.6786	0.6659	0.6679	0.6734	-3.369	-3.533	-3.508	-3.437
3	0.6780	0.6853	0.6763	0.6777	-3.376	-3.282	-3.398	-3.379

The ideal parameter combination for the coded level A2B3C3D3 was determined to be 7 wt.% Ti6Al4V (A), 750 MPa compaction pressure (B), 1300°C sintering temperature (C), and 135 minutes sintering time (D), which jointly produced enhanced response characteristics as depicted in Figure 2. A previous study involved the fabrication of graphene-modified TC11 high-temperature titanium alloy utilizing spark plasma sintering under diverse sintering circumstances. Optimal characteristics were attained at 900 °C, 5 minutes and 50 MPa resulting in enhanced compressive strength at both ambient and high temperatures [32].

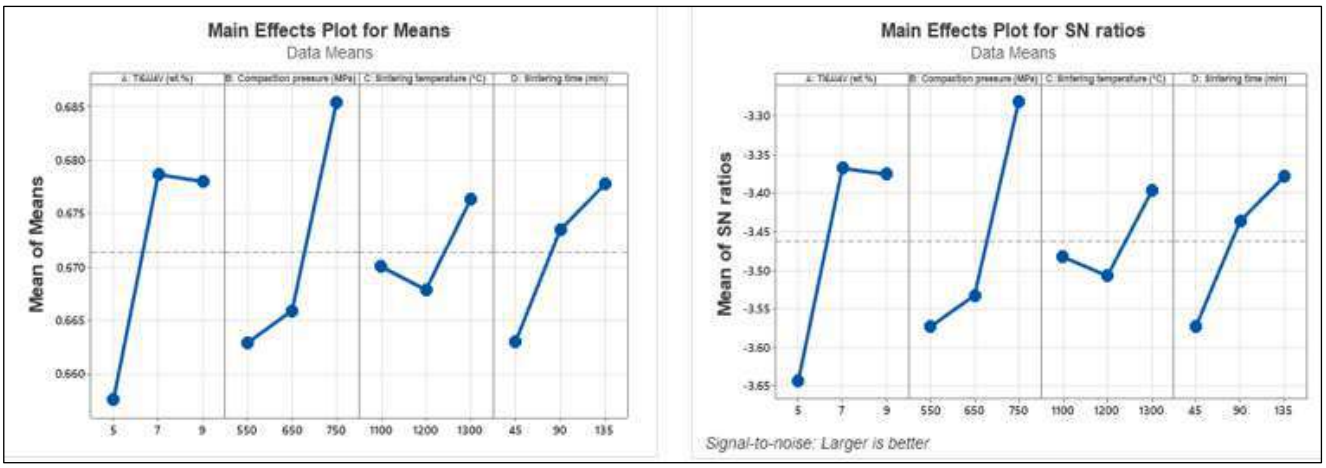

Figure 2: Graph showing a) main effect plot for Mean and b) S/N ratio of utility function f(k_i).
Source: Authors, (2026).

Figure 3 illustrates the microstructural characteristics of SS316/Ti6Al4V composites containing 5wt%, 7wt%, and 9wt% reinforcement, clearly showing how the increasing Ti6Al4V content influences particle dispersion and densification behavior. Figure 3 (a) and (b) 5wt% and 7% Ti6Al4V, the reinforcement particles appear uniformly distributed within the stainless-steel matrix, indicating that the powder blending, compaction, and sintering conditions were effective in promoting homogeneous mixing and strong metallurgical bonding. Figure 3(b) the 7wt% composite, in particular, shows the most refined and continuous microstructure, with smooth matrix regions, clean particle interfaces, and minimal porosity, suggesting enhanced diffusion during sintering and excellent compatibility between the SS316 and Ti6Al4V powders.

Figure 3(c) the reinforcement level increases to 9wt%, the microstructure becomes noticeably less uniform, with evident agglomeration of Ti6Al4V particles and the formation of larger pore pockets. This occurs because the higher volume of hard Ti6Al4V particles reduces the compressibility of the powder mixture, limiting particle rearrangement and densification during compaction and sintering. As a result, localized clusters form and trap pores within the matrix, leading to incomplete bonding and reduced structural integrity. Figure 3 (b) microstructural observations confirm that 7wt% Ti6Al4V provides the most balanced distribution and densification, while higher reinforcement levels introduce manufacturing challenges that negatively affect the final mechanical properties.

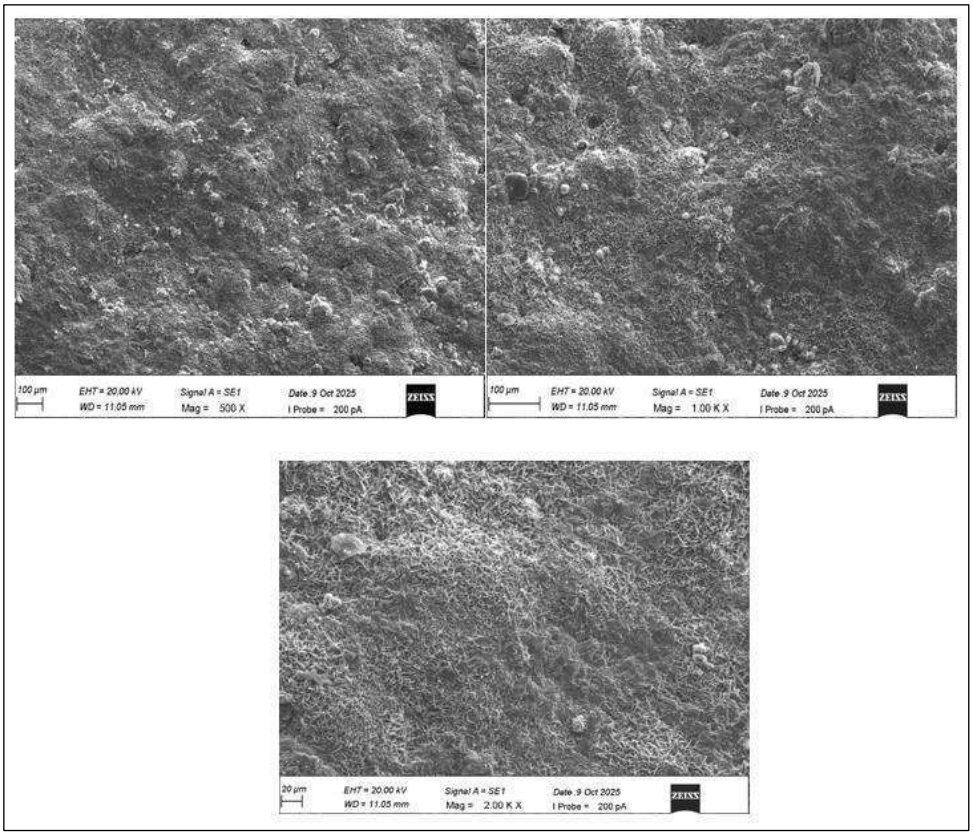

Figure 3: Microstructure of (a) SS316 /5% Ti6Al4V, (b) SS316/7% Ti6Al4V, and (C) SS316/9%Ti6Al4V composites.

III.4 UTILIZING ANOVA TO EXAMINE HOW INPUT PROCESS VARIABLES IMPACT PERFORMANCE METRICS

ANOVA was conducted to assess the contribution and importance of all process element to utility function (ki) value. Table 11 presents the ANOVA analysis, illustrating the F-ratio contribution of all process element to the density, compressive strength and hardness. ANOVA table reveals that, the process factors Ti6Al4V (wt.%) and compaction pressure (MPa) contribute 38.85% and 40.28%, respectively, making them the most significant factors. They are followed by sintering time (min) with a contribution of 15.66% and sintering temperature (°C) with 5.21% contribution to the process.
Regression Eq (25) for the established mathematical model were presented below. [33].

$$\text{Utility Function (f(ki))} = 0.6714 - 0.01379\ \text{A (wt.\%)}\_5 + 0.007226\ \text{A (wt. \%)}\_7 + 0.006568\ \text{A (wt.\%)}\_9 - 0.008473\ \text{B (MPa)}\_550 - 0.005471\ \text{B (MPa)}\_650 + 0.01394\ \text{B (MPa)}\_750 - 0.001361\ \text{C (°C)}\_1100 - 0.003533\ \text{C (°C)}\_1200 + 0.004894\ \text{C (°C)}\_1300 - 0.008405\ \text{D (min)}\_45 + 0.002065\ \text{D (min)}\_90 + 0.006341\ \text{D (min)}\_135 \quad (25)$$

III.5 COMPARISON OF DECISION MAKING TECHNIQUE

Comparisons were conducted utilizing ARAS, WASPAS, MOORA, and COPRAS methodologies. The selected approaches utilize the identical weights derived from SECA method, as applied at MARCOS ranking, to guarantee just and impartial comparison. Table 11 displays the alternative composites produced through various methods.

Table 11: Composite ranking employing several techniques for decision-making.

S.No		MARCOS		ARAS		WASPAS		MOORA		COPRAS
	f(ki)	Rank	Ki	Rank	Qi	Rank	Yi	Rank	Ui	Rank
A1	0.6394	9	0.9131	9	0.9133	9	0.1342	9	92.084	9
A2	0.6507	8	0.9296	8	0.9300	8	0.1408	8	93.751	8
A3	0.6828	2	0.9762	2	0.9763	2	0.1592	2	98.456	2
A4	0.6729	6	0.9617	6	0.9621	6	0.1535	6	96.990	6
A5	0.6696	7	0.9569	7	0.9573	7	0.1516	7	96.507	7
A6	0.6933	1	0.9915	1	0.9913	1	0.1653	1	100.000	1
A7	0.6764	5	0.9670	5	0.9672	5	0.1556	5	97.523	5
A8	0.6775	4	0.9685	4	0.9687	4	0.1562	4	97.671	4
A9	0.6800	3	0.9720	3	0.9722	3	0.1576	3	98.033	3

Source: Authors, (2026).

Alternative A6 were consistently regarded as first option, while alternative A3 were uniformly positioned as secondary choice across decision-making processes employed. Table 11 demonstrated that a ranking analogous to MARCOS was achieved for WASPAS, ARAS, MOORA, and COPRAS. Furthermore, the statistical method referred as Spearman's correlation analysis were employed to assess link among rankings obtained by SECA-MARCOS. The rank correlation among two datasets were calculated by Equation (26).

$$\mathrm{RC} = \frac{(p^3-p)-6\sum_{i=1}^{p}\delta_i^2}{p^3-p}, \nearrow -1 \leq RC \leq +1 \tag{26}$$

The correlation coefficient of 1 were attained among ranking of MARCOS method and COPRAS, WASPAS, MOORA, and ARAS methodologies. The strong correlation among ranks illustrates the stability and robustness of the integrated SECA-MARCOS methodology. The proposed method can facilitate informed and logical decision-making at selection and assessment of powder metallurgy composite materials.

IV. CONCLUSIONS

Stainless steel SS316/Ti6Al4V composites were effectively produced by the powder metallurgy (PM) method. MARCOS utilized Taguchi-based optimization and ANOVA to evaluate the effect of four powder metallurgy factors: SiC (wt.%), compaction pressure (MPa), sintering temperature (°C), and sintering time (min). The physical and mechanical properties, including density, hardness, and compressive strength, were utilized as assessment criteria. The SECA method were employed to assign mass to the selected criteria, while MARCOS approach were utilized to determine the composites rank. The subsequent conclusions were derived from the statistical analysis:The ideal processing parameters were determined to be 7 wt.% Ti6Al4V reinforcement, a sintering temperature of 1100°C, a sintering duration of 90 minutes and compaction pressure of 750 MPa. The results SECA-MARCOS approach demonstrate that the composite with 7 wt.% Ti6Al4V is the most advantageous for defense and aerospace applications.

The utility functions $f(ki)$ – Taguchi analysis identified the optimal combination of process variables to attain favorable material properties, yielding minimum density and maximum compressive strength and hardness at 7 wt.% Ti6Al4V (A), 750 MPa compaction pressure (B), 1300°C sintering temperature (C), and 135 minutes sintering duration (D).The combined effects of density, hardness and compressive strength demonstrated that Ti6Al4V (wt.%) accounted for 38.85%, compaction pressure (MPa) for 40.28%, sintering temperature (°C) for 15.66%, and sintering time (min) for 5.21% of the total variability, signifying that these variables exerted a substantial influence on the mechanical and physical characteristics of the composites. Moreover, congruent rankings was attained for specified alternatives and criteria employing the ARAS, WASPAS, MOORA, and COPRAS techniques. The Spearman's correlation among suggested technique and other MCDM methodology illustrate consistency of the ranking findings. The study presented a thorough SECA-MARCOS method to tackle the issue of material selection.

ABSTRACT

This paper examines the integration of advanced AI technologies with traditional navigation systems, revolutionizing flight path planning for drones. It covers key navigation technologies such as Global Navigation Satellite Systems (GNSS), Inertial Measurement Units (IMUs), and Lidar, demonstrating how these systems provide the foundation for precise geolocation, stability control, and obstacle detection through 3D spatial mapping. The paper delves into sophisticated AI techniques, including Simultaneous Localization and Mapping (SLAM) and Convolutional Neural Networks (CNNs), which enable drones to navigate autonomously in complex environments without human intervention. Emphasis is placed on dynamic AI algorithms that optimize flight paths in real time, addressing challenges such as air traffic, unpredictable weather, and environmental constraints. Path planning algorithms, such as A* and Rapidly-Exploring Random Trees (RRT), are discussed alongside machine learning and reinforcement learning models that allow drones to continuously learn and adapt for enhanced safety and efficiency. Additionally, the paper explores the integration of multi-agent communication systems, demonstrating how fleets of drones can operate collaboratively to optimize airspace usage and task execution. Case studies across industries, including commercial delivery and environmental monitoring, are presented to highlight practical applications. The role of real-time data exchange technologies like 5G and RF in improving communication and control is also examined. The paper concludes by addressing the future of AI in drone path planning, discussing ethical considerations and the need for regulatory frameworks to ensure safe, responsible AI utilization. Through a comprehensive review of current technologies and forward-looking trends, this paper provides valuable insights into the evolution of drone navigation systems in the AI era.

I. INTRODUCTION TO AI-POWERED ROUTE PLANNING FOR FLIGHT

Artificial intelligence and machine learning models being incorporated in drone technologies are transforming the way unmanned aerial vehicles (UAVs) function. This integration helps the drones to evaluate real-time environmental data to adjust and change their trajectory while optimizing the route and energy consumption. ML algorithms and sensor fusion techniques combined have achieved amazing environmental awareness.

AI-powered drones are able to perform complex tasks like delivering packages in congested areas and conducting prolonged surveillance operations with lesser human intervention. These drones have influenced spectrum of applications from conducting life-saving search, rescue operations, examining infrastructure to optimizing logistics and keeping an eye on ecological systems. All of this is possible by an AI-powered drone because of its instant intelligent decision making, great performance and adherence to safety standards that shift the paradigms of what's possible in aerial domain.

I.1. ROLE OF AI IN REVOLUTIONIZING THE DRONE'S FLIGHT PATH PLANNING

Fusion of artificial intelligence into the drone technology makes it more feasible for adaptive flight path planning. Since the overall traditional navigation methods, which worked quite well for well-defined controlled environments, face enormous difficulties during unpredictable practical scenarios, AI deals with that deficiency by equipping the drones with adaptive decision-making capabilities to navigate dynamic environments with high precision. What lies at the heart of this transition is the ability to calculate large data sets in real time. Current AI-contrived drones can monitor flight patterns and make on-the-spot changes to avoid unexpected hazards or calculate the most energy-efficient route. It has opened an era of autonomous aerial vehicles beyond the traditional realm of operation.

This is much beyond the simple avoidance of collisions. Such systems apply an all-encompassing approach that covers synthesis of various variables such as meteorological conditions, national aviation rules, mission parameters, and power management. These AI-powered drones can execute the complex missions autonomously, from sustained surveillance operations to urban deliveries. It affects many industries through technological advancement. Business sectors are stormed by AI-enhanced navigation as it opens up far more efficient and cost-effective networks for deliveries. Now, far more accurate and comprehensive data sets are collected by environmental scientists, but the very same technology is used by search and rescue teams to scan vast areas efficiently so that they may significantly improve their living-saving abilities.

I.2 SCOPE AND OBJECTIVES OF THE PAPER

This paper attempts to give an all-round view of AI-based flight path planning and its influence on drone autonomy and navigation. First, we examine an overview in the evolution of drone navigation technologies: first, the traditional ones, followed by infusion with AI-based systems. Further sections have sketched out some historical perspective so that we may better comprehend the innovativeness of such AI-driven solutions for today. The study applies AI techniques in dynamic planning of the flight path and autonomous navigation. It integrates into a complex decision-making system, models of machine learning, and algorithms that essentially form an intelligence-based navigation system for drones. It claims to provide an inside look at how an AI system reads sensory inputs, predicts optimal routes, and adjusts conditions on the fly. A significant amount of the paper is dedicated to the actual real-world applications of AI in the activity of planning flight paths. We provide quite numerous case studies and actual examples demonstrating how this technology can be applied in reality, as of today, in such various industries as, for instance, urban air mobility and precision agriculture. These data, besides quite clearly producing vistas of what today's AI-powered drones can accomplish, sketch enormous potential for future improvements. This paper also deals with key issues in the domain of communication in drone fleets and multi-agent systems.

Coordination of multiple drones by AI-driven systems sets new possibilities for complex cooperative missions. Section 5 looks at distributed decision-making and swarm intelligence in more detail to outline further developments in the scope of what is possible in air operations. Another important area we look at is the integration of edge computing with AI in drones. The improvement of edge computing processing capabilities will reduce the need for constant cloud communication; complex on-board processing and real-time decision-making are possible. It is impossible to have a complete discussion about AI in drone technology without referring to the ethical, legal, and regulatory issues surrounding it. We take an in-depth look into its potential and problems in this rapidly developing environment while discussing how laws change to keep abreast with technological advancements. As for this conclusion, we look into the future with new designs and prospects of flight route planning afforded by AI technology. This visionary perspective will inspire the reader and show him or her thousands of dimensions of revolutionary technology. By the end of this paper, readers would learn how AI is going to transform drone autonomy and navigation through complex flight path planning. To any enthusiast into drones, for an industry professional, or as a researcher, it is all here, interestingly informative information found within the pages of this paper and brings into play one of the most exciting new developments in modern technology.

II.CLASSIC NAVIGATION TECHNOLOGIES IN DRONES

As you progress to further exploration in this exciting area, it is very essential to understand foundational AI principles when it comes to flight path planning. Classic navigation technologies have played a big role in aiding drone autonomy, with many of which now being essentially an element of AI-enhanced systems. This section reviews the major technologies that had a key influence on drone navigation before the development of AI-driven solutions. Each part of Figure 1 represents the various sensors and technologies that constitute the totality of a conventional navigation system within a drone.

II.1 CORE COMPONENTS OF DRONE NAVIGATION

II.1.1 Position and Orientation Sensing

The ability to determine position and orientation in three dimensions is important to drone navigation. Inertial Measurement Units (IMUs) and Global Navigation Satellite Systems (GNSS) are the main tools used to do this. Global positioning systems (GNSS), such as GPS, GLONASS, and Galileo, triangulate satellite signals to deliver position data. Although GNSS works quite well in open spaces, it may not work as well in confined spaces in urban canyons where signals may be blocked. IMUs provide a high-rate, short measurement of the drone's motion and attitude. Such information is a valuable adjunct to data provided by GNSS. With the accelerometers and gyroscopes-an IMU measures both linear acceleration and angular velocity, the drone can determine its position and orientation even when the GNSS signal is temporarily unavailable.

Magnetometers are used along with IMU to compute the heading of a drone as a digital compasses. Drones rely on three sensors in order to continuously collect information regarding location and orientation-in this case, GNSS, IMUs, and magnetometers.

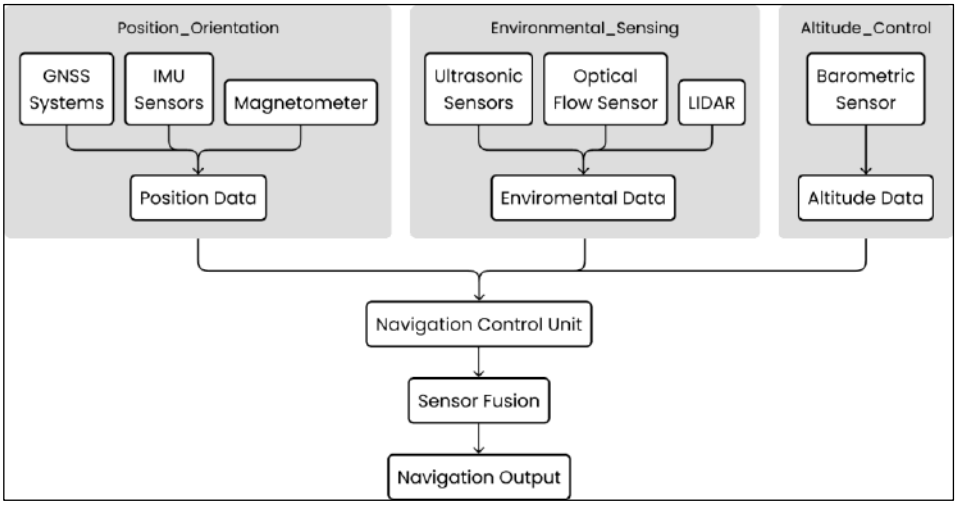

Figure 1: Classic Navigation System.
Source: Aurhors, (2026).

II.1.2 Environmental Sensing and Mapping

Basically, sensors help drones feel and grasp the world around them for navigation purposes in difficult environments. Type of sensors used are Lidar, optical flow sensors, and ultrasonic sensors. The UAV have LiDAR mounted at the bottom which provides an accurate 3D map of their surroundings in real time. The Lidar systems can well map the terrain and detect obstructions by sending out laser pulses and calculating the time to their return. It has great utility for such tasks as gathering accurate data of the environment and being able to navigate places without GPS.

For example, optical flow sensors, utilizing camera technology to monitor the movement of the drone with respect to the ground or other obstructions, help in the accurate low altitude navigation and stability of hover. Calculating the apparent motion of objects within their scope of vision, these sensors help. Supplement used within such systems is the ultrasonic sensors, which provide accurate short range distance measurements. Extremely helpful when precision matters during takeoff, landing, and low altitude flying.

II.1.3 Altitude and Pressure Sensing

Precise altitude measurement is absolutely essential for the safe, efficient operation of drones. GNSS information does provide altitude, but pressure sensors are most commonly utilized because they give better accuracy, particularly in lower-altitude operations. A barometer measures atmospheric pressure to determine the altitude above sea level for a drone. Drones can able to maintain precise altitude level above ground while adjusting to the changes in terrain when coupled with data coming from LiDAR and ultrasonic sensor.

II.2 SENSOR FUSION

Sensor fusion is a technique of combining data for multiple different sensors resulting in less uncertainty that reveals the incredible potential of modern drone navigation. Drones can maintain accurate placement and orientation in almost any environment by providing rich data of environmental awareness through complex sensor fusion algorithms [1] that combine many different data streams into one. How do the systems adapt to adverse conditions? The drone smoothly transitions to inertial measurements and optical flow data for real-time navigation needs in degraded satellite signals.

Even though GPS and barometer measurements have a higher order position accuracy, Lidar scanning is stronger in very dense environments about detecting obstacles. Dynamic sensor interaction entails superior performance through a variety of scenarios. However, this complicated interdependence declares the limitations of an individual sensing technique that are inherent. The inertial measurement devices may drift away from the real position or interfere and block the satellite communication arising along with malfunctioning of environmental sensors due to the presence of adverse weather conditions or shiny surfaces. It is therefore necessary to consider such constraints in designing a robust navigation solutions.

II.2.1 Limitations and The Path to AI Integration

Traditional navigation system responds to operator commands or follows the preset routes pretty well, it fall short in unpredictable circumstances. This is where it opens up a vector of AI incorporated navigation systems. Looking into a real world problem, let's consider a drone running into an unforeseen situation, the potential barriers it can face though they have sensor data are optimal rerouting, power consumption, time efficiency and mission priorities. All these barriers can be overcome by AI-powered navigation system. AI-powered navigation system achieve this with higher order flexibility like human reasoning. We'll go through how these intelligent systems make the AI-powered navigation system stand out.

III. AI TECHNIQUES FOR AUTONOMOUS DRONE NAVIGATION

Artificial intelligence techniques employed in UAVs for automation have made drone self-reliant and requires less human supervision. These advancements are made possible by several machine learning techniques such as, convolutional neural networks (CNNs), reinforcement learning (RL) and simultaneous localization and mapping (SLAM) techniques. CNN is used to process images/videos captured by cameras (mounted on drones) and make it interpret its surrounding more efficiently. Reinforcement learning is designed to take adaptive decision while navigating. One of the main technique involved in the navigation is SLAM, it creates a detailed mapping of the given environment while tracking its precise location. All these techniques get governed by fail-safe management systems which ensures safe operations in challenging scenarios and overall it makes the system more robust and advanced for UAVs.

III.1 SIMULTANEOUS LOCALIZATION AND MAPPING (SLAM)

Simultaneous localization and mapping is a computing technique to construct or update a map of given unknown environment while simultaneously keeping track of its agent position [2]. In drones this technique is used when there is no availability of GPS signals. Usually SLAM is used in indoor environment where the GSP signal is either weak or dead. As shown in Figure 2, SLAM takes input from various sensors and the data undergoes preprocessing where it extracts the feature and do pose estimation which helps to determine the position and locality of where the drone is. Parallelly it construct and updates the global and local map respectively with loop closure in between. Loop closure helps in reducing the errors while updating the map.

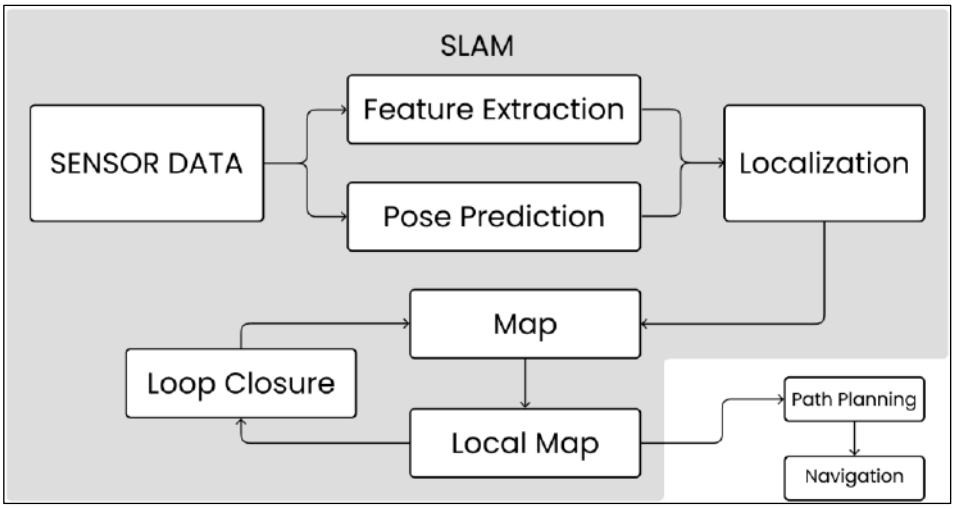

Figure 2: Simultaneous Localization and Mapping (SLAM).
Source: Aurhors, (2026).

Modern SLAM uses various methods to enhance localization and mapping. One of those methods is visual-inertial odometry (VIO) [3],[4]. It fuse the data coming from cameras and inertial measurement unit (IMU). IMUs are known for producing high-frequency data such as, acceleration, orientation, and angular rate which helps in drone stability and control while cameras are excellent at capturing detailed pictures of environment. Nevertheless, these sensor face issues when they are exposed to high low-light or rapid motion scenarios. Researchers are developing more sophisticated systems like ORB-SLAM3 [5] and VINS-Fusion [6] which are built using optimization-based techniques and loop closure and uses bundle adjustment processes to preserve accurate positioning and map consistency While integrating SLAM into UAVs, there are some technical difficulties which needs be considered [7]. SLAM requires lot of computing power as it has to process the real-time data which itself is a compute intensive task.

It requires the system to have lot of onboard compute resources to perform task accurately. Many studies have been done to scale down the need of resources while maintaining the performance, one such approach is stereo-visual system [8]. Apart from this, many research has been done to optimize the performance of SLAM while maintaining low cost computing resources. One of the most sophisticated framework developed for upgrading SLAM technique is ORB-SLAM3's Atlas framework, it allows the drone to operate smoothly in diverse settings. While new collaborative SLAM algorithms allow many UAVs to collaboratively create and share environmental maps, the integration of deep learning techniques has transformed feature identification and environmental interpretation. These developments are broadening the scope of autonomous aerial navigation and opening the door for more sophisticated uses in urban air mobility, infrastructure inspection, and search and rescue missions.

III.2 CONVOLUTIONAL NEURAL NETWORKS (CNNS) FOR VISUAL PROCESSING

Convolutional Neural Networks (CNNs) have transformed drone navigation systems' visual processing capabilities by providing strong instruments for GPS-free autonomous flight. The CNN architecture feeds vital navigational data to the drone's visual odometry and flight control algorithms by processing raw camera video through a series of convolution, pooling, and flattening steps, as shown in Figure 3. The human visual system is mirrored in this hierarchical processing, with deeper layers interpreting intricate patterns necessary for navigation while earlier layers identify basic characteristics.

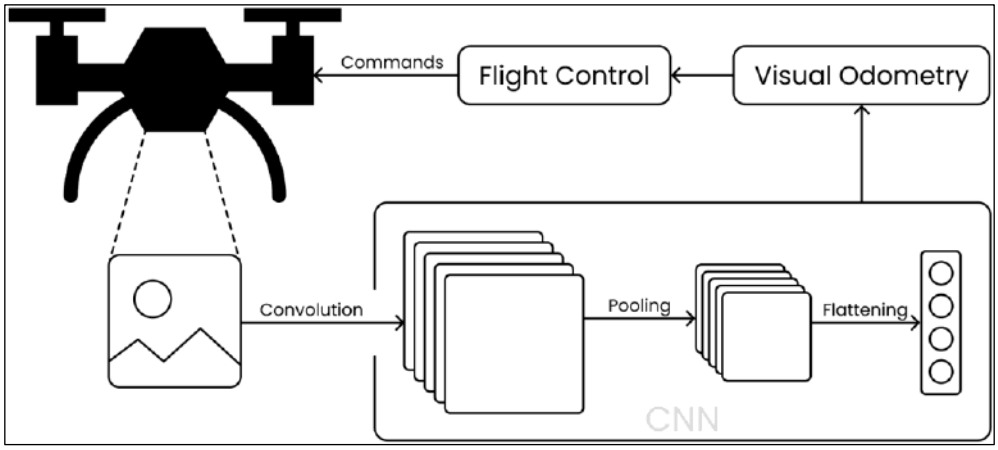

Figure 3: CNN Architecture for Vision-based Drone Navigation.
Source: Aurhors, (2026).

CNNs are particularly good at a number of crucial tasks in drone navigation, including recognizing unique features for localization, seeing possible collision hazards, differentiating between accessible and restricted locations, and deciphering visual indicators for motion and posture estimates. CNNs covers several input ranging from, depth maps, thermal data to conventional RGB images, guaranteeing reliable performance in different environmental circumstances. The best CNN architecture to process the visual data is Xception [9]. This architecture has more processing power balanced with computational efficiency. While training CNN model one should ensure that the dataset contains various situations and conditions such as low light, flashy light, resolution of images etc. it makes the model predictability more accurate.

Given that these CNN model gets deployed onto the drones where they have to handle real-time processing, their visual processing should me more efficient. CNNs are evolved to get considered as best for autonomous drone navigation. It has the ability to convert visual input into control commands for the flight control. CNNs are known for their sematic segmentation of input images which in turn helps drones to achieve pixel-level understanding of environments. Some of the advance CNN architecture do multitasking by simultaneously performing motion prediction, depth estimation, and object detection in a single pipeline. The more interesting thing in machine learning is the concept of transfer learning, which helps in rapid adaptation to new tasks. It makes the CNN more considerable for visual processing in drone technology.

III.3 REINFORCEMENT LEARNING FOR ADAPTIVE DECISION MAKING

Reinforcement learning (RL) [10] is an interdisciplinary area of machine learning which is concerned with how a system should interact with the dynamic environment in order maximize the reward signal. These reward signals are associated with different factors such as, avoiding collisions, reaching pre-determined waypoints, decreasing flight time and energy consumption. Drones flashed with RL algorithms are useful in dynamic or unknown environment, because they are designed to optimize their behavior while exploring the given environment. For instance, consider a scenario of rescue mission. A RL-powered drone can dynamically modify its search task by evaluating terrain, windspeed, landscape etc. This adaptive nature of RL algorithm makes the drone balance between optimizing the existing factors and exploring new locations and looking into intriguing leads.

Several studies have been made on to improve reinforcement learning algorithm in drone navigation. One such improved version is Deep Q-Networks (DQN) [11]. This algorithm have demonstrated the efficiency in acquiring state-action value functions and control policies using policy gradient techniques. It is a hybrid method where DQN is utilizing both value function estimates and policy learning methods to enhance learning capability and helps to perform better in wide range of tasks. However, transfer learning in RL become an obstacle. As RL equipped drones are expected to perform well in unexplored environments, transfer learning may lead to overfitting to the source domain which causes the drone to perform poorly in uncharted areas. To overcome this, incremental learning where the drone first masters the basic tasks and eventually exposed to complex one. This method allows for drone to gradually adapt and enhance its performance.

III.4 FAIL-SAFE NAVIGATION WITH AI ALGORITHMS

The development of navigation system using artificial intelligence requires fail-safe measures which can anticipate and fix the possible upcoming issues. This fail-safe measures are important in the critical task of military operations and commercial delivery systems. Under fail-safe management, uncertainty quantification is implemented. Implementation includes machine learning models that augments their prediction with confidence measures. It ensures that the drone is navigating safely in unclear situation, as a result reducing risks in unforeseen circumstances.

The integration of fail-safe management system monitors the sensor reading and report the advance anomaly detection which can lead to system failure. As the drones are equipped with sensor fusion techniques where multiple stream of data should be handled, this system handles the conflicting sensor data. Drones are programmed with RL algorithms that enables adaptive decision-making. These drones are complemented by fallback systems which has pre-programmed decisions that drones should take to at least navigate safely by compromising performance. The implementation of this fail-safe systems needs good processing capabilities, specialized hardware with edge computing integration.

IV. DYNAMIC FLIGHT PATH PLANNING WITH AI

As drones are expected to navigate autonomously in complex and unpredictable situations, the drones should be equipped with dynamic path planning algorithms. In recent days dynamic path planning algorithms allows drones to modify their flight paths while ensuring safety and optimizing energy consumption using machine learning models. The use of sophisticated algorithms like A* and rapidly-exploring random trees (RRT) are at the forefront of pathfinding algorithms. These algorithms are designed in such a way that they guarantee mission specific requirements and adhere to regulatory compliance.

IV.1 REAL-TIME PATH PLANNING ALGORITHMS

The fundamental competency of autonomous unmanned aerial vehicle navigation is real-time path planning in dynamic and complicates situations. Algorithms like A* and RRT have proved its well-known solutions when compared with other algorithms in this domain. Both A* and RRT have offers their own unique benefits for autonomous UAVs. The basic workflow of A* pathfinding algorithm [12] is depicted in Figure.4. It starts by initializing required data structures list and then select and expand nodes until the goal is reached.

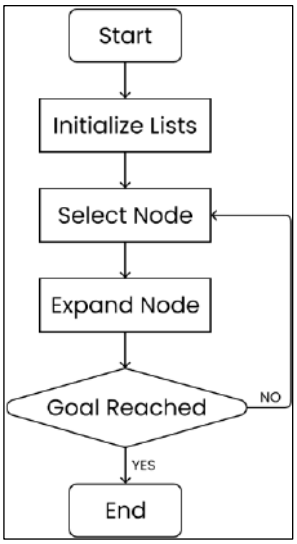

Figure 4: Workflow of the A* Pathfinding Algorithm.
Source: Aurhors, (2026).

In 3D environments A* uses heuristic technique which performs efficiently in pathfinding and graph traversal. Functionality of A* algorithm is defined by two main parts, a closed list that tracks the nodes which have been visited and an open list that has nodes that are waiting to get explored. A* employs a cost function $f(n) = g(n) + h(n)$, where $g(n)$ represents the actual cost from the start node to the current node n, and $h(n)$ is a heuristic estimate of the cost from n to the goal node. This cost function directs the algorithm's decision-making process. A* chooses nodes with lowest $f(n)$ values and expands them to produce the further ones. After doing that, it updates the open list. It does this until it reaches its destination or runs out of options. Theta* and Lazy Theta* [13] outperforms the traditional A* in path length and vertex expansions. Theta* enables any-angle path planning, permitting off-grid movements resulting in more feasible trajectories. Likewise, Lazy Theta* reduces line-of-sight tests preserving path quality to enhance efficiency. The creation smooth paths in 3D is handled by variants of A* such as D*, Field D*, and Anytime Repairing A* (ARA*) [14]. It is observed from the reviews that A* preforms well simple straightforward settings rather than complicated ones.

Theta* and Lazy Theta*'s performance is hindered by its higher computing demands, though it produces better path-way in 3D environment. Weighted heuristics can speed up search processes at the expense of path optimality. In large 3D environment, as memory management plays a crucial role, it is handled by one of memory-bound algorithm known as Simplified Memory-Bounded A* (SMA*) [15]. Sampling-based techniques like Rapidly-Exploring Random Tree (RRT) or probabilistic roadmaps frequently work better in very big or complicated contexts. The Rapidly-Exploring Random Tree (RRT) [16] algorithm is a particularly advanced method for negotiating challenging situations. Basically, the area is investigated by RRT's refined tree building procedure. The basic workflow of RRT algorithm is depicted in Figure 5. The workflow start by configuring and initializing the tree, and then iteratively samples random locations in the space, and gradually expands toward uncharted areas by joining new points to the closest preexisting nodes. Because of its systematic approach, RRT is especially well-suited for UAV applications, since it automatically takes into account Kino dynamic constraints (such as acceleration and velocity bounds) as well as nonholonomic constraints (such as turning radius limitations).

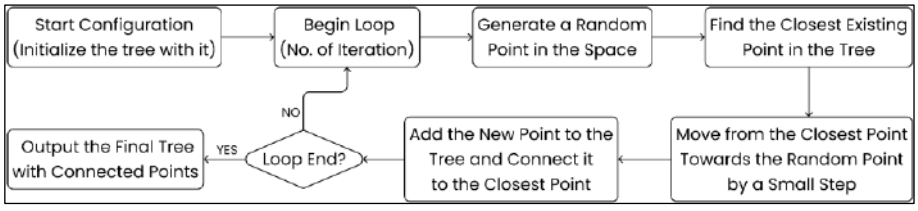

Figure 5: Workflow of Rapidly-Exploring Random Tree.
Source: Aurhors, (2026).

RRT* is an improved variant of RRT which introduces a concept of asymptotic optimality to the path finding process. RRT* has the capability of optimizing the tree structure by reconfiguring the tree in order to improve the path quality, while traditional RRT is excellent in finding feasible paths quickly. This advancement of RRT* helps finding optimal path in long-range missions and in time-sensitive deliveries, where energy consumption and flight time are crucial factors. Although RRT* is more efficient than traditional RRT, it comes at an expense of high computational power. To address the computational challenges exposed by RRT*, researchers created Hierarchical Probabilistic Optimal Rapidly-exploring Random Tree (HPO-RRT*) [17]. HPO-RRT* has implemented potential biases in field-based sampling and lazy collision checking to improve the fundamental tree-building process. This approach builds hierarchical framework that smoothly combines the optimizer, path planner, and sensory system of the UAV. HPO-RRT* algorithm has the ability to grow the tree toward regions of interest and delaying resource-intensive collision tests which is very helpful to operate in dynamic situations. Another advancement is the development of PF-RRT (Potential-Field-RRT) [18], which uses a novel potential field technique to speed up pathfinding. PF-RRT creates repulsive pressures around obstacles and attractive forces toward goals.

This improvement has shown remarkable results, boosting path quality and cutting pathfinding time by up to 70% when compared to traditional RRT implementations. These developments are especially beneficial for the UAVs flying around compact areas and complex 3-D domains. The purposes of the algorithmic derivatives are one and the same: allowing UAVs to find paths well and safely but under some environmental constraints. Current algorithms based on RRT in their implementations can give to UAVs better capabilities that are needed in solving a real-world problem. Quite a few selection criteria are necessary to carefully determine the most suitable path-planning algorithms intended for UAVs. RRT-based techniques will allow better speed and scalability for complex scenarios, and A* guarantees the optimization in more traditional approaches. Pragmatically, it has been used that those algorithms often collaborate with sensor systems at high levels in several applications. They tend to blend multiple strategies for both leverage of their respective strength, such as, exploration from RRT could be first used to discover a rough path and then be refined via A*. The field is still maturing with the goal of designing algorithms that can safely manage a dynamic, ever-growing complicated environment in such a manner that it conserves the real-time performance along with the operational safety. Innovations in hybridizing the algorithm and complex sensing, followed by integration, are many a times part of this very process.

IV.2 AI-DRIVEN ENERGY EFFICIENCY IN FLIGHT PLANNING

Artificial intelligence has totally revolutionized the energy management of drone operation [19], [20], particularly concerning one of the major problems that the industry faces: short battery life. Advanced machine learning algorithms can now accurately predict patterns of energy use by combining a multitude of factors, such as flight paths and ambient conditions by exploiting historical flight data. One of the great developments in the field of energy management has been how to develop high-performance systems that can predict battery performance accurately. Such systems rely on deep neural network architectures like recurrent neural network (RNN) and long short-term memory (LSTM) for making incredibly accurate predictions relating to battery life.

These solutions reduce the risks of power depletion during mid-flight while achieving unparalleled precision in the mission planning through variables related to battery degradation, ambient conditions, and past usage data. Almost entirely, this varied combination of AI components, like predictive analytics or adaptive flight control, has made it possible to work together with the outcomes of evolving and bettering flight plans to realize the improved mission capabilities of drones while staying within their energy consumption range. Here, energy management is a widely accepted idea that signifies important progress made in resolving a persistent flaw in drone systems, particularly the short battery life that readily interferes with their ability to function.

IV.3 MACHINE LEARNING FOR ENVIRONMENTAL ADAPTATION

The ability of autonomous drone systems to adjust to changing settings is essential to their development, and machine learning is the foundation of this flexibility. Proximal Policy Optimization (PPO) and Deep Q-Networks (DQN) [11] are advanced reinforcement learning algorithms that are used in real-world applications to produce excellent effects. Such advanced technologies evaluate the intricate sensor data presented by the drones and make judiciously informed judgments in real-time while balancing safety parameters, operational efficiency, and mission-specific objectives through an optimization process. With the advent of neural networks, autonomous drones have been capable of taking decisions much better than ever before. Complex landscapes can now be crossed with unprecedented accuracy due to the robust object detection and categorization capabilities of Convolutional Neural Networks' (CNNs). In addition to that, RNNs are quite good at processing temporal data sequences that help drones predict and respond to dynamic obstacles with amazing accuracy.

These neural architectures together provide an all-around system which adapts to unanticipated challenges but still maintains the operational efficiency. A recent research project [21] that focuses on wind turbine inspection processes provides a powerful example of these concepts in action. To navigate the intricate world of wind turbines, this work used a DQN-based control system that was supplemented with the YOLOv5 object detection capabilities. With substantial training in a high-end simulation environment using Unreal Engine and AirSim, the system was found to be very flexible with respect to the varying flight characteristics with regard to the dynamic movement of the blades of the turbine. The creative incentive system used on this application increased the operating efficiency significantly, as it brought about the ideal balance between the need for safety in navigation and the requirements for inspection.. After extensive training in over 7500 time-steps, the system was able to reliably maximize its performance utilizing updated flight trajectories and reliable reward measures. This is a good example of how machine learning can highly revolutionize the operations of drones in demanding and changing situations, especially in applications that require accuracy as in the case of an infrastructure inspection.

IV.4 HANDLING USER-DEFINED CONSTRAINTS IN AI-DRIVEN DRONES

The necessity for advanced constraint management systems has increased due to the widespread usage of drone technology in various industrial sectors [22], especially when it comes to incorporating user-defined operational parameters into autonomous control frameworks.

And constraints need to be implemented that balance mission requirements with safety protocols and regulatory standards as the operations become ever more complex with the growing propensity of drones. Modern artificial intelligence systems align the various constraints in a way that they are simply integrated into drone operations through such key features such as robust systems for defining and updating operational limits, adaptive geofencing in view of changes in the environment, sophisticated algorithms for optimizing routes while respecting already established boundaries, and real-time monitoring that would immediately alert operators to potential violations of safety.

IV.4.1 Inputting Operational Limits and Regions of Interest

For an autonomous drone system to obtain operational superiority and regulatory conformity, a user's specified limits need to be set. In modern AI architecture, a number of advanced techniques are available that deal with limitations effectively. Critical operational factors, such as defined areas of interest, no-fly zones, and restricted airspace [23], are dynamically stored in sophisticated geospatial databases. Natural language processing (NLP) frameworks make definition of constraints straightforward through translation of human input to parameters which the machine understands. Through the interaction of navigation systems and the constraint satisfaction algorithm, full compliance will be ensured throughout the operations of flight.

IV.4.2 Geofencing and Virtual Boundaries

AI-driven geofencing has completely replaced traditional autonomous drone system boundary management. Dynamic frameworks of geofencing are well driven by advanced machine learning algorithms that allow real-time border adjustments according to varying operational conditions. Fuzzy logic can be implemented, it can offer sophisticated decision-making capabilities especially when dealing with strict confined environment. The adaptive design can be supported by cloud-based infrastructure, which guarantees that boundary data will always be in sync during mission.

IV.4.3 Optimizing Path Planning Within Defined Boundaries

The defined boundaries systems utilizes refined algorithms such as RRT and A* to map constraint spaces effectively. These algorithms comply with operational requirements such as, maintaining safe distances from no-fly zones while minimizing flight length.

IV.4.4 Real-Time Boundary Violation Alerts and Adjustments

Modern autonomous flight systems employs complex algorithms that continuously analyze flight trajectories, monitor velocities, and predict potential violations to enable preventative actions by utilizing advance predictive capabilities. These are further augmented by reinforcement learning components which ensures optimal adaptive responses. CNN models offers feature which can provide real-time marker identification and restricted zone recognition. It ensures enhanced operational awareness and boundary compliance. Collectively all these models contribute in proactive violation prevention, continuous monitoring, mission compliance assurance, and dynamic response capabilities, leading to a comprehensive safety ecosystem for autonomous flight operations.

V. MULTI-AGENT DRONE SYSTEMS AND COMMUNICATION

The shift from single drone operations to multi-agent drone system is significant. It represents advancement of autonomous system development where multiple drones are communicating with each other and collectively performing certain tasks. This cooperative system is developed using distributed intelligence framework and refined communication protocols for coordination. Using mesh networking technology, real-time data sharing, and complex airspace management algorithms, they can effect unprecedented levels of operational coordination without compromising stringent safety regulations. The integrated task allocation mechanisms with adaptive fleet management tactics have really transformed the way complex missions are executed under various operational scenarios.

V.1 COLLABORATION IN DRONE FLEETS

Contemporary multi-agent drone systems are the best representation of the collective intelligence. Fundamentally, these systems make use of the power of cooperation, with individual drones cooperating to complete tasks that would be impossible for one unit to complete alone (as seen in Figure 6). This cooperative method, which implements decentralized control mechanisms where autonomous decisions arise from straightforward, local interactions rather than centralized orders, is inspired by the behaviors of natural swarms. The complexity of these systems lies in the emergent behaviors that arise from interactions, not in their inherent complexity. Drone fleets show phenomenal adaptability, easily adapting to changing mission needs and environmental changes, just like natural swarms.

Algorithms that draw inspiration from biological systems, including Particle Swarm Optimization (PSO) and Ant Colony Optimization (ACO) [23], improve this adaptability by facilitating anything from dynamic formation management to effective area searches. These systems' task distribution is an intriguing example of how artificial intelligence and operational effectiveness can coexist. Modern AI-driven methods consider the capabilities of individual drones, energy limitations, spatial distribution, and mission priority. The integration of MADRL has been highly successful in allowing drones to create complex cooperative tactics that are a result of finding the tradeoff between the limits of an individual and group goals.

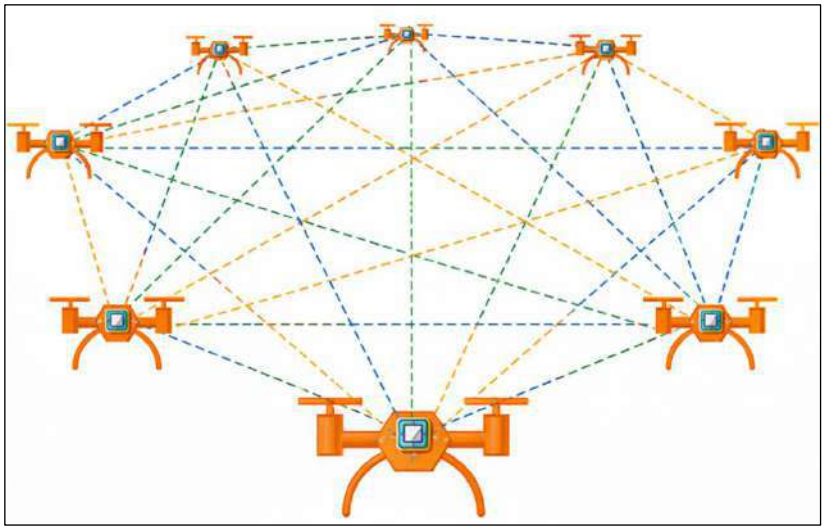

Figure 6: Multi-Agent Drone Fleet System.
Source: Aurhors, (2026).

These systems are even more strongly collaborative in nature, particularly in mapping and sensing applications. Drone fleets create complete models of their environment, providing capabilities far beyond those possible with a single unit due to distributed Simultaneous Localization and Mapping (SLAM) and advanced sensor fusion. To optimize these cooperative mapping efforts for effective resource utilization and full environmental surveillance, smart coverage path planning further optimizes them. The most important characteristic of these collaborative drone fleets is the inherent redundancy that makes them very resilient. The architecture is distributed, meaning that a system can very rapidly detect anomalies and redistribute responsibility among remaining units, such that even if some units fail, the system remains operational. Systems of this type are, therefore very well suited for critical applications like search and rescue and disaster relief.

V.2 5G AND RF TECHNOLOGIES IN DRONE COMMUNICATION

Convergence of advanced RF systems with 5G is opening an array of multi-agent airborne operations, which is revolutionizing drone communications. As illustrated in Figure 7, present-day cities integrate several layers of communication to support a broad area of drone application, ranging from package delivery and surveillance to others. The result is unprecedented operational capacity, efficiency, and dependability.5G will revolutionize the way drones operate [24]. Ultra-low latency, potentially below a millisecond allows for control and data to be transmitted practically instantaneously to manage synchronized flying maneuvers with split-second decision-making.

High-definition video feeds and rich sensor data can be transmitted with relative ease, given the large bandwidth capacity of the network, allowing for greater situational awareness for difficult cooperative activity. Network slicing and edge computing integration enables the operators to develop specialized virtual segments of the network and provide guaranteed bandwidth allocation for critical mission processes. The integration of edge computing is going to enable near distributed data processing near the units of drones.

Figure 7: Urban Drone Communication Infrastructure with 5G Integration.
Source: Aurhors, (2026).

Exceptionally outstanding performance figures are shown by 5G, which maintains user-experienced speeds of 50 Mbps and 100 Mbps while attaining peak data rates of 10 Gbps uplink and 20 Gbps downlink. At a stunning 99.999% dependability rate, the network's latency is consistently less than one millisecond. Various drone demand different communication characteristics.

Specifications for aerial photography, package delivery, and surveillance missions vary, requiring throughput needs of 200 kbps to 30 Mbps, covering heights of up to 100 meters, and end-to-end latencies of 500 to 3000 milliseconds. Apart from the above, many leading-edge RF technologies enhance drone communication systems over and above 5G. Drones can have dynamic, ad hoc networking using mesh networking, increasing their operational range for relay inter-unit capabilities. Cognitive radio systems minimize interference by maximizing spectrum utilization through switching dynamically between frequency bands. In the dense swarm of drones, directional antennas and beam-forming technology accurately focus radio frequency energy to enhance signal quality and minimize interference. Software-defined radio (SDR) platforms have flexible communication protocols.

This is the most versatile communications platforms ever developed using a variety of frequencies and standards.Some of the issues arise when putting these platforms into actual use. Such issues include proper interference handling with multi-base stations, cell-to-cell handovers, maintaining a connection at a high altitude, and for long-duration missions, command, control, and navigation is still dependent on dependable coverage. In networked drone systems, the security issue and resilience became central issues. This includes stringent authentication procedures, encrypted control signals and data transfers, and sophisticated jamming detection and mitigation techniques. In case a link breaks down, preservation of operational continuity requires robust redundant communication channels.

V.3 AIRSPACE OPTIMIZATION FOR MULTI-AGENT SYSTEMS

Increasing drone operations have created the need for efficient management of airspace. Advanced artificial intelligence, with algorithms sophisticated enough to optimize the allocation of airspace dynamically based on input such as traffic patterns, operational priorities, and environmental conditions, has been one possible response. The temporary flight corridors and ideal aircraft spacings in real-time will be made available by using machine learning algorithms that can learn lessons from large historical datasets and simulated scenarios. Collision avoidance using sophisticated methods: Advanced collision avoidance systems will allow drones to predict collisions and respond collectively as a group by fusing collaborative avoidance techniques with predictive detection capabilities. Deep reinforcement learning ensures the optimization of decision-making processes by the systems for seamless interaction between unmanned aircraft and manned aviation via advanced airspace transition protocols and conflict prediction mechanisms. A recent study [25] made a significant contribution to this topic by developing a new two-phase optimization method for coordinating multiple drones. It shows an impressive efficacy in challenging operational circumstances, combines simulated annealing for work distribution with a hybrid technique that incorporates variable neighborhood descent and dynamic programming for route optimization.

Airspace management has undergone a trend to be more distributed in nature using decentralized AI systems and edge computing. Although keeping the performance operative and energy utilization at an optimum level with the safety constraint in place, it is always amenable to quick change in route and coordinated behavior of swarm. Digital twin technology was extremely useful for this aspect, as the validation of complete management strategy could take place before the application to the practical scenarios. Multi-agent drone systems represent a milestone in the development of aerial technology. These technologies are revolutionizing a number of industries, including supply chain management and emergency services, by fusing the concepts of swarm intelligence with cutting-edge communication infrastructure and intelligent airspace control. The combination of cooperative drone fleets, cutting-edge radio frequency technologies, and AI-driven optimization produces a strong foundation for scalable drone operations. This forward step in this science will imply ever more advanced uses, which altogether and radically will change how we shall use aerial space within the realms of the commercial, industrial, and public service industries.

VI. EDGE COMPUTING AND AI INTEGRATION IN DRONES

Edge AI technology is transforming drone technology as it is revolutionizing and making it possible to introduce unprecedented levels of autonomy as well as real-time decision-making. This integration provides a capability to process data on-board the UAV, eliminating latency and dependence on a network outside. As UAVs evolve into intelligent, autonomous platforms, they're ever more capable of tackling intricate tasks in difficult environments. This section delves deeper into how edge AI upgrades drone operations-from split-second navigation decisions to collaborative swarm intelligence.

VI.1 ROLE OF EDGE COMPUTING IN REAL-TIME DECISION MAKING

Edge computing has emerged as a revolutionizing technology in drone operations; it is changing the way unmanned aircraft interpret and react to data in real-time, making it radically different [26]. Edge computing surpasses the intrinsic drawbacks inherent in conventional cloud-based systems, especially the difficulties due to network latency and bandwidth limitations, by moving closer processing resources to the point of data origin. This is particularly important in operations where split-second decisions may mean the difference between life and death, such as emergency response operations or disaster relief missions, where every second counts.The inclusion of edge computing capabilities has allowed drone systems to interpret complex data on-device, significantly enhancing the capability of the system to carry out independent operations under challenging conditions.

These advanced drones are mobile computing platforms that interpret sensor data and make critical decisions in real time, independent of network availability, not using remote cloud servers [25]. Architectural strategy This has especially been helpful in those settings that are high-risk or remote where internet connectivity would be hard to ensure - for example, with surveillance of autonomous farms or search-and-rescue missions. Among the most important developments in autonomous aerial operations, edge-enabled drones can react in real-time to environmental changes, navigate intricate obstacles, and execute mission-critical decisions with a speed and reliability that had previously been unheard of by doing away with the need for continuous data transmission to centralized servers.

VI.2 CLOUD VS. ONBOARD PROCESSING IN AI-DRIVEN DRONES

A key design issue in AI-based drone systems is processing architecture. Whether or not the processing architectures are to be onboard or cloud-based significantly influences a great amount of the performance of the system. As infrastructure for cloud computing offers levels of processing capacity that had never been heard of, AI models can be more complex with large datasets and must handle and analyze. However, this benefit comes with drawbacks in the form of higher latency and network dependence that can sometimes negatively affect system responsiveness in time-sensitive applications.

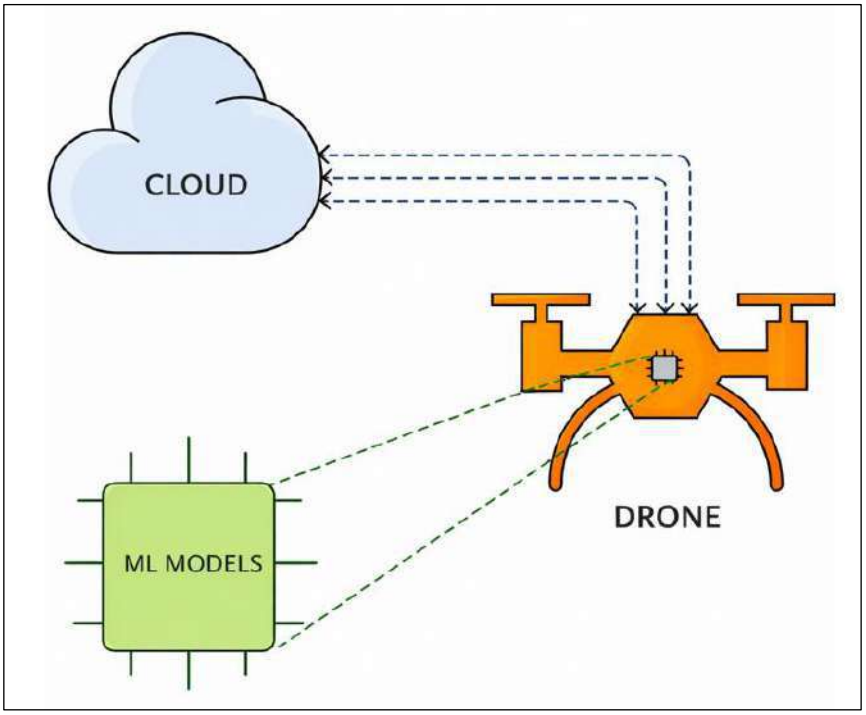

Figure 8: Drone Computing Architecture.
Source: Aurhors, (2026).

Onboard processing, therefore, gives a whole different approach to surmount most of the drawbacks cloud-based systems hold. The data could be processed almost instantaneously in a drone, thus giving room for better navigation through unpredictable surroundings [27]. Edge computing rules out the phenomenon of bottlenecks associated with communications through clouds, as sensor data is processed directly on a drone. This method saves a lot of energy and network resources and is highly beneficial in scenarios of bandwidth limitation and improper network access. There are disadvantages to edge computing. While onboard equipment limits the physical sophistication of deployable AI models compared to cloud-based competitors, it also potentially hampers the drone's analytical capability.

Most contemporary drone systems use a hybrid approach that balances these competing demands. Figure 8 shows this approach, dividing workloads judiciously between cloud and onboard processing. Real-time processing is done on the edge while computationally-intensive tasks like model training and full data analysis are offloaded to cloud infrastructure when possible. With this architectural flexibility, drones can exploit their computing resources and maintain peak performance under a wide range of operating conditions.

VI.3 DISTRIBUTED AI FOR REAL-TIME CONTROL

Distributed AI integration enhances the capabilities of the drone system, especially for real-time control and fleet coordination. The technique allows individual drones to decide while ensuring that the overall network collaboration is smooth since the advantages of a centralized system combine with those of edge computing. Such features are quite important in complex scenarios, where several drones have to collaborate in their actions, like surveying disaster areas or continuously observing metropolitan environments. Decentralized decision-making principles have the potential to transform drone fleet operations [27], according to a recent study. In a distributed artificial intelligence architecture, individual drones process local environmental data while also sharing vital information with other drones in the network. This integrated strategy, through synchronized movement patterns and real-time information exchange, maximizes fleet performance and allows dynamic task allocation relative to changing environmental conditions.

A survey [25] reports several important advantages of multi-drone systems. Distributed AI- drone ensemble's, showing the characteristic properties of swarm intelligence, combine observations and build detailed maps of their surroundings and detect any hazards. Advanced load balancing is possible and achieved through the division of computing workloads based on the energy and resource capacities of individual drones. Most importantly, it makes adaptive mission planning feasible, meaning that drones can change their goals and trajectories based on varying mission constraints or new circumstances. With distributed AI's collaborative capabilities combined with edge computing's low latency, drone systems become highly resilient, efficient, and adaptive. These are the qualities needed in many applications such as autonomous delivery services, disaster response programs, and search and rescue missions where split-second coordination makes all the difference between success and failure.

VII. CASE STUDIES: AI FOR PATH PLANNING OF DRONES

AI has revolutionized the navigation and path planning of drones.. These advancements encompasses applications such as environmental monitoring, commercial operations, defense operations etc. Environmental monitoring can be achieved through accurate terrain surveillance with advanced capabilities in handling difficult landscapes. In commercial operations, the optimization of delivery routes, analysis of real-time traffic with response to emergency conditions can be achieved through AI-powered drones. Defense applications comprises of executing complex task with minimal human intervention, adaptive decision-making, ensuring safety.

VII.1 DRONES IN COMMERCIAL DELIVERY SYSTEMS

Drones in commercial delivery systems has upgraded last-mile logistics sector. Industry titans which includes Amazon, Google, and DHL are early adopters who are utilizing this intelligent delivery drone system. Commercial delivery systems considers multiple factors like delivery time, energy constraints, weather conditions, and airspace limitations. These multiple factors are input for complex algorithms in order to generate optimal flight path. These systems are equipped with adaptive learning capability for improvement by monitoring delivery successes and failures. The ability of the systems to change dynamically is arguably the most astounding. According to recent research [28], drones can adjust their flight paths in midair as winds change or power levels drop. Delivery dependability has advanced significantly as a result of this real-time response to changing conditions. In the pursuit of increased energy efficiency, drone operations have seen impressive advancements. One of the biggest challenges facing battery-powered UAVs has been successfully overcome by researchers by extending the operational range of delivery drones by utilizing detailed power consumption models and even taking use of advantageous wind patterns.

Beyond single-drone operations, a novel study [29] has investigated synergistic strategies that integrate ground-based and aerial delivery techniques. These hybrid systems have recently demonstrated the ability to traverse intricate urban environments while circumventing the inherent range constraints of drone-only solutions. In drone delivery operations, safety and dependability are still crucial. Gaining regulatory approval and public trust now requires improved collision avoidance mechanisms, accurate landing systems, and complex obstacle navigation capabilities, all of which are driven by cutting-edge algorithms. As researchers investigate ever-more-advanced methods, the field keeps pushing the envelope. These developments, which range from federated learning for improved privacy to computer vision for navigation and reinforcement learning for decision-making, have the potential to completely transform delivery logistics in the future. As these technologies advance, they provide a sneak peek toward a more effective and eco-friendly substitute for conventional distribution technique.

VII.2 ENVIRONMENTAL MONITORING AND DISASTER RESPONSE

Drone technology and artificial intelligence have come together to provide a potent instrument for crisis management and environmental stewardship, especially in situations when prompt evaluation and action can make the difference between containment and disaster [30]. One striking example of this synergy is a creative partnership between forestry officials and computer vision experts, who together developed a cutting-edge drone system for wildfire monitoring. Fundamentally, this advanced platform combines a number of technologies: high-resolution cameras record visual data, thermal sensors look for heat signatures, and clever algorithms process the data in real time.

This device is unique in that it can automatically modify its flying patterns in response to changing threats and environmental circumstances, guaranteeing the best possible coverage and data gathering. This AI-enhanced strategy has had a tremendous impact. With the system spotting possible fires 75% earlier than with conventional techniques, detection rates have skyrocketed, giving emergency response teams vital extra time. As accuracy plays a major role in terms of resources, public safety and time consumption, this AI-powered systems enhances accuracy has led to significant 60% reduction in false alarms resulting it better resources management and false investigations. In spite of this, by making real-time mapping of fire progression the system can plan the evacuation which can potentially saving countless lives by enabling better decision-making.

VII.3 SURVEILLANCE AND DEFENSE APPLICATIONS

As defense of the country needs rigorous developments in the technology for the safety of public, these AI-powered drones suffice the needs [31]. This reflects in efficient military activities such as, tactical operations, intelligence gathering etc. It also exponentially enhances its surveillance capabilities through proficient monitoring systems and improved reconnaissance abilities. A straightforward implementation of this technology can be seen in border monitoring system, which utilizes swarm drone created by defense contractors. It demonstrates the power of collective airborne intelligence. This promises future advancements and increased efficiencies in defense sector. To bring down the powerful impact on defense operations, multiple drones come together with distributed decision-making to function as a single unit while maintaining individual autonomy.

This collective behavior needs inter-drone communication protocols that enables real-time information sharing, object tracking, pattern optimization, and continuous strategy adjustment. These features facilitate the smooth integration of past experience with current operational conditionsThis intelligent swarm system devises revolutionary effect. The software has made it possible for small teams to efficiently monitor large areas of border territory by tripling the coverage area as compared to traditional approaches. A quantum leap in the efficacy of border protection is represented by the system's improved detection capabilities, which achieved an 85% improvement in recognizing illicit crossings. The fact that these significant enhancements were made while operating expenses were cut by 40% is perhaps the most astounding example of the financial benefits of AI-driven automation in security systems. These case studies highlight the critical role artificial intelligence plays in enhancing drone capabilities in a number of areas, including adaptive behavioral responses, real-time decision-making, and intelligent navigation.

We are on the verge of far more advanced drone applications that have the potential to transform not only defense and surveillance but also commercial delivery services and environmental monitoring, as AI technology continues its rapid progress. The combination of AI and drone technology is a radical rethinking of what is feasible in aerial operations, rather than only a small enhancement.

VIII. ETHICAL, LEGAL AND REGULATORY ISSUES

AI autonomous drones arrive as something like a landmark in aviation technology and open entirely new horizons of moral dilemmas and legal issues far, far above the established aviation frameworks. This ever-increasing sophistication of intelligent machines increasingly renders impossible distinguishing man-made versus machine-based decision-making; hence it forces us to face some basic questions on control, autonomy, and accountability. The future will be delicate balancing of the need to push innovation while ensuring these aerial systems operate within careful and thoughtful legal and ethical boundaries that take precedence in favor of public safety and responsibility.

VIII.1 ETHICAL CONSIDERATIONS IN AUTONOMOUS DRONE OPERATIONS

The rapid advancement of artificial intelligence in drones throws up a number of complex moral questions worthy of careful reflection. Right at the heart of the concerns is the conflict between privacy rights and technological advancement. Modern AI-enabling drones, armed with high-quality sensors and imaging acquisition tools, can gather personal data without permission in public areas and residential neighborhoods like never before [32]. Such complexity in drone operations raises further questions of safety and responsibility. Because of the myriad relationships that exist between the maker, operator, and autonomous systems, it is almost impossible to determine who may bear the burden of incidents in case of accidents. There is also the algorithmic bias, where an AI system inadvertently perpetuates existing social injustices and could easily be applied to sensitive services such as law enforcement and commercial delivery services. One major issue is that AI decision-making mechanisms are opaque.

These systems intrinsic complexity frequently produces a "black box" effect, hiding the logic underlying autonomous behavior and giving rise to legitimate worries about accountability [33]. This lack of openness may make people less confident in autonomous drone operations. Another crucial ethical aspect of drone technology is its dual-use nature. According to research [32], inventions meant for civilian use can be modified for military use, hence development boundaries and ethical innovation methods must be carefully considered. Furthermore, as these systems have the potential to drastically alter wildlife patterns and ecosystem stability, the environmental effects of widespread drone deployment cannot be disregarded. In order to tackle these complex issues, cooperation is necessary. We cannot create complete ethical frameworks that direct the appropriate development and deployment of autonomous drone systems unless ethicists, policy experts, technological developers, and the general public engage in ongoing discourse.

VIII.2 REGULATORY CHALLENGES FOR AI-DRIVEN DRONES

The ever-growing artificial intelligence capabilities of unmanned aircraft systems pose a serious challenge that affects the regulatory framework far beyond conventional aviation frameworks [34]. There are a number of rather serious issues raised by the mismatch between regulatory supervision and technology advancement that require rapid attention. Perhaps the biggest issue, though is the unprecedented pace of technology advancement that has made it hard for the regulatory bodies to continue providing effective oversight [32]. In addition to posing a danger to safety, this type of regulatory gap also risks strangling responsible innovation in the industry. Defining a consistent nomenclature for different tiers of drone autonomy is a fundamental challenge to the business and a prerequisite step before developing logical regulatory frameworks.

The region of certification carries its unique intricacies. For the assessment of AI-controlled autonomous systems, conventional testing methods are not appropriately usable; so, new techniques for performance verification and safety validation are in demand. This problem becomes very pressing when international operations involve drones that may traverse multiple nations with divergent regulatory standards. Another significant aspect is data governance. Regulations have to be altered to suit widely recognized data protection norms like the CCPA and GDPR [32] as autonomous drones collect and process increasingly vast amounts of data. This also applies to cybersecurity measures due to the interconnectivity of modern drone systems, which demands robust security measures against cyber threats and unauthorized access.

Airspace infrastructures are challenged for air traffic control in new dimensions by the integration of self-governing drones, but this requires firm regulatory frameworks that can handle the management both of human and unmanned aircraft besides other technical solutions for safe and efficient operation [33]. Another relevant area is about the creation of insurance and liability frameworks. Traditional paradigms of accountability and risk assessment must be re-examined to accommodate autonomous decision-making systems where artificial intelligence influences the outcome of operations to a considerable extent. Paradigm change in the form of a shift in strategy will be required to overcome the regulatory hurdles. Such frameworks will need to strike a balance between innovation, public safety, and social interests through effective cooperation of corporate players, academic institutions, and regulatory agencies while creating flexible and progressive structures.

VIII.3 RESPONSIBLE AND SAFE AI USE

The integration of AI in drones needs a holistic framework that mainly prioritize the public trust while developing more advanced systems. Throughout the system's lifecycle, the framework should ensure the safety, ethics and transparency. Ethical consideration includes algorithm fairness, privacy protection and operational transparency. While designing the framework the core design philosophy should be safety-first approach. It should have built-in safety guards with human oversight while doubling down on proactive implementation rather than reactive solutions. The developed framework should go through proper validation procedures.

Validation process tests the framework in simulated environments as well as in wide range of real-world scenarios while covering all edge cases and failure modes.

After validation, the deployed framework should be continuously monitored for the detection and correction of newly arising challenges. These kind of monitoring ensures the framework's optimal performance.Framework's transparency plays a key role as it directly has the impact on public. Thus it's crucial to gain the public trust by making the underlying algorithm transparent. This process makes the public final decision makers ensuring responsible deployment of autonomous systems. This can only happen if these technologies are successfully implemented through inclusive stakeholder engagement. Ethics experts, lawmakers, business and public service leaders can work together to help firms develop more comprehensive and digestible governance frameworks. Robust education and training initiatives that enhance understanding of AI's potential and constraints for all stakeholder groups should underlie such a collaborative approach.

International coordination is crucial to establish cross-border norms for the responsible deployment of AI in drone systems. Once self-navigating drones are deployed around the world, this international coordination becomes highly essential [32]. Regular audits of system operations support such efforts by pinpointing potential biases or flaws in the performance of the autonomous decision-making processes as well as ensuring that continued compliance with safety and ethical standards is maintained. By following these steps systematically, the drone industry can tap into the promising disruptive nature of AI in a way that maintains safety and high ethical standards over its operations. This is what will be critical for winning public acceptance and ensuring long-term sustainability for autonomous drone technology in modern society.

IX. FUTURE TRENDS IN AI-POWERED DRONE NAVIGATION

Certainly the use of artificial intelligence for navigation in the application of autonomous systems is exciting. One of the more recent inventions that radically alter how an unmanned aerial vehicle interacts and then adjusts to its environment signals a new era of intelligent flight systems. This change is more than just improved capabilities in the individual capabilities of a single drone-it sets up the stage for complex swarm behaviors, as well as fully independent aerial operations.

IX.1 NEW AI TECHNOLOGIES IN DRONE NAVIGATION

Some of the more exciting AI breakthroughs are changing drone navigation forever. Right at the top of this change is deep reinforcement learning. It applies iterative learning techniques to show drones complex navigational tactics. By trial and error, these systems learn intricate movements and instantly adjust to new situations. Simultaneous developments in computer vision are significantly improving drones' perception. Unprecedented object detection precision is made possible by modern algorithms, which further enhance environmental mapping and obstacle avoidance. The development of genuinely autonomous flight operations is significantly advanced by this improved spatial awareness.

Most specifically, the integration of natural language processing provides that fundamental bridge between the drones systems and humans. Any level of user can now engage more intuitively and readily operate drones using voice controls to navigate and plan for their missions [35]. Increasingly, there exists the need to develop explainable AI as autonomous abilities become more prevalent. It interpretable models provide insight into how decision-making occurs within AI navigation systems, which is important for building confidence and ensuring responsible deployment in a variety of applications.

IX.2 NEXT-GENERATION APPLICATIONS AND INDUSTRY TRANSFORMATIONS

Revolutionary changes are occurring in many sectors with the advent of AI-powered drone navigation. It is changing urban mobility with autonomous air taxis and self-flying delivery. It is answering long-standing questions on the perennial problems of traffic jams and the efficiencies of transit within crowded places. Changes will particularly be realized in the agricultural field [36]. With more sophisticated navigation, drones can now conduct targeted application programs and crop monitoring at unprecedented accuracy. Precise measurements enable a data-informed decision-making process and optimal resource allocation, maximizing productivity within sustainable farming mechanisms. A parallel transformation is taking place in infrastructure maintenance. AI-powered drones are transforming the way critical structures such as power lines, bridges, and extensive pipeline networks are inspected. Such robotic tools represent a considerable leap forward in procedures related to managing infrastructure because they remove operating costs, while the exposure of humans to harmful inspection environments remains limited.

Disaster response scenarios are increasingly demanding the deployment of next-generation navigation systems. Advanced drones, beyond improving the capability to perform searches and rescues and skills in damage assessment by maneuvering difficult post-disaster terrain in remarkable ways, have proven to be critical to reach areas that would otherwise be inaccessible, which facilitate rapid rehabilitation operations, most importantly saving lives. These technological advances also help in environmental conservation efforts. Improved navigation systems, along with advanced data gathering capabilities, are making possible more accurate ecological monitoring and wildlife tracking. These materials provide conservation biologists unparalleled insights into wildlife behavior and environmental trends, bolstering evidence-based approaches to biodiversity conservation and resource management.

IX.3. FUTURE OF DRONE AUTONOMY

It stands at the nexus of innovation and deployment, holding great promise and difficult challenges with the future of drone technology. The development of such complicated regulatory frameworks would have to balance technical growth with considerations of privacy and public safety. These regulations have to be unprecedented in flexibility; they have to keep changing step with quick technology advance. Special care will have to be given to the ethical effect when drones are used autonomously. Matters regarding accountable algorithms, data protection, and safeguarding personal integrity will be much more significant with these more complex systems. Industry players, legislators, and ethicists, each hitherto focused on different parts of this system, will have to start acting in ways unprecedented for that industry. The cohesiveness is even more important in complex processes where human judgment is still indispensable. Optimizing the AI-to-human interface is a key element in future growth [37].

The challenge is to enhance human judgment with high-end AI support in specific delicate or high-stakes situations rather than replacing it. High development priority should be given in R&D activities by a sound navigation system to handle high uncertain circumstances and developing and developing the scope in order to give high functionality, similar to handling edge cases, or other unforeseen difficulty that forms an important demand toward a more general appreciation of Autonomous drone technology [38]. This promises to open up entirely new possibilities in the combination of AI and leading-edge technologies, including those considered further advancements within materials science, 5G networks, and IoT infrastructure.

This cross-pollination of technical advance can bring far more than is already being utilized in the applications we use today, and it has a capacity to alter whole industries completely, something we are only just now beginning to realize. This is not a development simply of technology; it represents a paradigm shift in how the public and commercial sectors will think about aerial operations. We stand at the cusp of a revolution that will reshape the contours of what unmanned aerial systems can achieve, as we push further along the road to increased AI capability.

X. CONCLUSION

The advent of artificial intelligence has significantly altered the skills in drone navigation. This is a paradigm shift in UAV technology, where complex algorithms, particularly A* and RRT, have brought about previously unheard-of improvements in real-time navigation. Machine learning applications have also significantly increased flying efficiency, broadening the range of applications for drone technologies. One of the most revolutionary developments in cooperative airborne operations is the emergence of the drone swarm system, prompted by sophisticated AI and 5G communication networks. These achieve great gains in autonomous decision-making through edge computing architecture, especially important in circumstances where time is of the essence. This technological convergence led to innovations across all fields, from improvements in environmental monitoring and defense applications to innovations in logistics and changing delivery systems. But with very fast advancement in technology, such important questions of ethics and governance have come forth. As the autonomous capabilities of industry entities grow, it has its challenges in creating a total regulatory framework to look into safety procedures, privacy-related issues, and moral dilemmas that could come in AI-driven decision-making systems. The future of drone technology looks bright with recent advancements in deep reinforcement learning and computer vision, soon to significantly enhance capabilities to navigate.

Innovations that can transform what could have a significant impact on a wide array of businesses-range from urban air travel to agricultural technologies, emergency response, and maintenance of infrastructure. Several technical and non-technical barriers still stand in the way to complete autonomy of drones, including the design of flexible legal frameworks and dependability in challenging real-world operation. It will combine AI with state-of-the-art technology, including advanced materials science, 5G, and Internet of Things sure to make previously unthinkable tasks achievable by aerial systems. In the future, there is likely to be optimization in the collaboration of AI systems and human operators. An all-inclusive approach is therefore required to monitor and address ethical concerns in the optimization of autonomous aerial systems. AI-based flight planning represents a fundamental shift in the way we regard aerial operations and our engagement with unmanned systems, being not just advancement in technology but also in orientation.Future of AI and Drones involved innovative Applications without Boundaries Further innovations in AI and drones can push the boundaries for many more industries and further advance autonomous airborne functionalities. It will transform our aerial operations in territories we never even thought about and solve all the issues we face today. Research people, industry people, politicians, and ethicists must continue to collaborate on ensuring that AI-driven drone systems evolve according to society's needs and values, contributing toward a more inventive and sustainable future.

ABSTRACT

Correct and fast fault localization of high voltage overhead transmission lines is a primary need toward ensuring the stability and sustainability of present day power systems. The traditional methods of fault location such as impedance-based and travelling-wave methods are known to be limited by the following factors: sensitivity to fault impedance variations, reliance on synchronized multi-terminal measurements and expensive communication infrastructure. This paper proposes a new single-terminal fault location architecture that resolves these limitations by taking advantage of a special and deterministic post fault system state with neither long-range data nor inter-substation communication. The algorithm proposed is based on a model of distributed parameter transmission lines, which is able to faithfully model the electromagnetic behavior of long transmission lines. Clark transformation is used to transform the coupled three-phase system to decoupled modal networks, which allow each of the sequence components to be analyzed separately. The native genius here is that the momentary operation window is strategically used wherein, the remote-end circuit breaker has cleared the fault, yet the local-end breaker is not activated. One effect of this short time interval is that the current at the receiving-end is zero, and so the fault location equation is completely deterministic and does not require the remote source impedance parameters. The nonlinear objective function obtained is then solved with the help of a hybrid metaheuristic algorithm that combines Particle Swarm Optimization with a Genetic Algorithm. The combination takes advantage of the fact that PSO is very good at local exploitation and GA is very good at search exploration, which has the effective effect of avoiding premature convergence and guiding to the global optimum with high accuracy. The validity of the proposed approach is supported by thorough MATLAB/Simulink simulations that have been made on a real 400 kV, 239 km transmission corridor between Iraq and Iran. Evaluation of faults of various types, such as single line-to-ground, line-to-line, double line-to-ground, and three-phase faults, indicates that the hybrid PSO-GA technique can always provide significantly higher localization accuracy than the standalone PSO and non-iterative benchmark techniques without increasing the computation time (less than 0.5 seconds).

I. INTRODUCTION

High-voltage overhead transmission lines are the vital element of electricity networks of modern electric power systems, which carries bulk electrical power over regional and national borders. They are by nature vulnerable to a broad range of fault causing occurrences such as lightning hits, heavy wind loading on conductors that causes galloping, ice formation, wild fires and encroachment of vegetation [1],[2]. Not only do the incidences of such faults destroy the delivery of power to the consumers, but they also cause cascading instabilities that may jeopardize the integrity of the rest of the interconnected grid [3]. As a result, the quick and accurate determination of fault positions is still one of the most operationally critical issues the engineers of power system protection have to deal with in modern times. The cost of transmission line faults is enormous.

Unscheduled disconnections lead to immediate losses in the utilities, penalties by the regulations, and indirect expenses incurred by industrial and commercial consumers whose operations rely on the continuous availability of power [4]. The process of fault localization by making use of manual inspection is not only time-consuming but also hazardous to carry out in long-distance transmission corridors especially those that cover tough terrain, thus increasing the economic cost of any given fault event [5]. Automated algorithmic fault location systems are thus essential tools in the operations of modern grids, as they allow maintenance crews to be guided to the fault location as precisely as possible and restore service in the short time possible. Among the algorithmic fault localization techniques, impedance based single terminus method has received a lasting interest, as it is operationally simple and does not depend on inter-substation communication links [6]. These techniques estimate the fault location by calculating the apparent reactance that is observed at the local terminal using measurements at fundamental frequency of voltage and current taken at the local terminal. Nonetheless, they are highly inaccurate due to the existence of fault resistance, remote-end load infeed and uncertainty in source impedance parameters all these cause systematic estimation errors, which deteriorate the localization performance [7], [8].

Different correction methods have been suggested to overcome these limitations such as additions of pre-fault load current compensation and iterative process of refinement, but still, residual errors exist in highly resistive fault conditions [9]. Two-terminal measurements, that take advantage of simultaneous voltage and current measurements at each end of the fault line, are significantly more accurate, removing the remote infeed ambiguity of single-terminal models [10] . Such methods require a credible phasor measurement unit infrastructure and communication channels with high availability between substations that are reliable to deploy practically [11]. However, fault conditions do not always guarantee the integrity of the communication links and the synchronization requirements add extra costs on infrastructure which might not be justifiable on all transmission corridors [12]. These are factors that drive the further investigation of high-accuracy single-terminal methods, which are independent of any communication infrastructure. The travelling-wave fault location paradigm is another measurement philosophy that approximates fault distance by the propagation time of transient electromagnetic waves that are produced at the fault point [13]. The most recent developments in high-speed signal processing hardware and time-domain reflectometry have rendered these techniques more practicable [14]. However, in a networked environment, it is still difficult to identify the wavefront accurately due to interference by reflections at impedance discontinuities, parallel line coupling and transient waveforms produced by switching [15].

Further deployment costs are imposed by the high sampling rates and accuracy time devices needed to implement fault location, which restricts the widespread use. Over the last few years, the use of artificial intelligence and machine learning in fault location increased tremendously [16, 17]. Convolutional neural networks and long short-term memory networks are deep learning models that have shown encouraging outcomes in learning intricate fault signature design designs on huge past datasets [18], [19]. Nevertheless, the reliance of data-driven approaches on large datasets with labeled data, data sensitivity to changes in operating conditions not modeled in the training data, and physical interpretation remain issues that restrict their use in unconditionally in safety-important protection systems [20].The use of metaheuristic optimization methods offers a physically based alternative to the data dependency of machine learning methods in order to solve the inherently nonlinear fault location problem [21]. Hybrid algorithms which are a synthesis of particle swarm optimization and genetic algorithm operators have been especially effective in trade-offs between exploration of the global solution space and local optimization, both resulting in better convergence properties relative to both algorithms used alone [22], [23]. Combined with precise distributed parameter line models and modal decomposition using the Clarke transformation, these hybrid optimizers provide a strict and computationally inexpensive framework of fault localization at single terminals [24]. This paper constructs and confirms a framework of this kind on one of the real 400 kV, 239 km transmission system, and shows uniform benefits of accuracy over the current benchmark procedures over all types of major faults

II. THE HYBRID PSO-GA

The rationale of the integration of Particle Swarm Optimization and a Genetic Algorithm is due to the complementary nature of the behavioral traits of each method separately. PSO exhibits a great potential of enhancing the search in the already-identified promising regions of the solution space by refining the candidate solutions with higher fitness values. In contrast, GA works with a more liberal philosophy of exploration, as it repeatedly works on unexplored spaces by selection, crossover and mutating operators. Putting these two opposite types of behavior into one unified framework results in an optimization process that is more balanced and more resistant to premature convergence to suboptimal solutions simultaneously [22]. In the suggested model, optimization will start fully under the control of PSO. A random distribution of an initial population of candidate solutions, each of an encoding of a possible fault distance, fault resistance pair is distributed across the search space. Successive iterations enable each particle to update its position, by concurrently taking into account both its best historically identified position and the best position ever identified by any of the swarm member, which enables the population to self-organize towards successively better solutions.

The switch to the hybrid operation is controlled by a probabilistic switching. A uniform sampling of the interval [0, 1] is done to get a random number at every iteration. Once this value has reached this threshold of 0.8, at an approximate rate in the statistics of twenty percent, the existing PSO population gets transferred directly to the GA module as its initial population, which then undergoes genetic operators to further optimize it [21]. This selective and uncommon activation performs two fundamental functions, viz.: To recover population diversity lost in PSO convergence, and to avoid stagnation, as well as to escape local optima that PSO would otherwise falsely recognize as the global optimum. The polished population is then fed back to PSO and the cycle repeated in much the same way until convergence is reached. Each particle is associated with a potential solution vector in an N-dimensional domain in accordance with the conventional PSO update rules. Formally, the ith particle's location is defined as:

$$X_i = (x_{i1}, x_{i2}, \dots, x_{in}) \tag{1}$$

Additionally, every particle keeps a record of its historically ideal location, which is stored in a specific memory vector.

$$P_i = (p_{i1}, p_{i2}, \dots, p_{in}) \tag{2}$$

According to the following formulation, every particle in the swarm moves around the search space with a distinct velocity vector:

$$V_i = (v_{i1}, v_{i2}, \dots, v_{in}) \tag{3}$$

The Particle Swarm Optimization (PSO) model consists of particles, each of which is a potential solution, but maintains a record of the present coordinates as well as an optimal historical location (the p_{best}). Also, the global best position (g_{best}), the optimal value of p_{best} reached by any population member, is shared by the swarm population. This strategy follows a social learning process, whereby a particle reacts by modifying the behavior based on its personal experience as well as the behavior of other particles. A major characteristic of PSO is that not every particle in the swarm is going to search alone - the advancements of other particles within the swarm have an active influence on the behavior of movement and convergence of all other particles within the swarm. To be more exact, the new location of each particle is computed by its velocity which in turn relies on two randomly selected elements that jointly determine the trade-off between the exploration of new areas and exploitation of known good solutions:

1. Cognitive Component:
This is the term that means the impact of the own history of a particle on its movement. It is the deviation of the current position of the particle with respect to the best position which has been personally visited by the particle (p_{best}). This is literally a part of an individual memory, in other words, it draws the particle back to the best answer it has ever found, and it is also indicative of its aptitude to teach itself.
2. Social Component:
This term is used to measure how the swarm behavior affects an individual particle. It is the distance between the current position of a particle and the optimal solution of any particle in the whole population (g_{best}). With the addition of this term, every particle is attracted to the area of the highest potential known to date found by the group effectively simulating the way people in a swarm can use the knowledge available to them and collaborative actions.

The combination of these two elements forms a dynamic equilibrium between the cognitive and the social parts which pushes each particle to believe in its own experience on one hand and to believe in the wisdom of the swarm on the other.
This updating formalism is implemented mathematically by use of a velocity equation. More specifically, the velocity of every particle will be altered in line with the subsequent formulation of Inertia Weight Approach (IWA):

$$v_i = w.v_i + c_1.r_1(P_i - X_i) + c_2.r_2(P_g - X_i) \tag{4}$$

Where:
v_i denotes the velocity vector of the ith particle.
X_i represents the current position vector of the particle.
w is the inertia weight, a parameter governing the momentum of the particle by scaling the influence of its previous velocity.
c_1 and c_2 are positive acceleration coefficients that scale the cognitive and social guidance components, respectively.
P_i and P_g signify the particle's personal best position (p_{best}) and the swarm's global best position (g_{best}), respectively.
r_1 *and* r_2 are stochastic elements, uniformly distributed random numbers within the interval [0, 1], introduced to preserve population diversity and facilitate stochastic exploration.

As a result, each particle's future position is decided by a weighted stochastic mixture of its unique past experience (p_{best}) and the swarm's collective knowledge (g_{best}). Particles can traverse a continuous solution space in the basic PSO formulation since the search domain is usually unbounded.

The inertia weight in Eq. (4) was kept constant at 1.0 during the optimization process for the purposes of this investigation. The algorithm's behavior was made simpler and the computational burden of adjusting adaptive inertia weight strategies such as defining minimum and maximum bounds as mentioned in Eq. (5) was eliminated by choosing this configuration, which guarantees a constant and uniform convergence rate. It is mentioned that there are other approaches; for example, the method proposed in Ref.[25] dynamically adjusts the inertia weight during each iteration.

$$w = w_{max} - \frac{w_{max} - w_{min}}{iter_{max}} \times iter \tag{5}$$

In this formulation,w_{max} and w_{min} denote the initial and final inertia weights, respectively, while $iter_{max}$ and $iter$ represent the maximum permitted iterations and the current iteration count. This equation implements a linear decrement of the inertia weight, thereby systematically reducing the exploration (diversification) tendency of the swarm over time. As a result, the resulting computed velocity moves search agents increasingly towards the areas of p_{best} and g_{best} resulting in more exploitation (strengthening). Nevertheless, there is one significant shortcoming of the adaptive inertia weight strategy, which has been mentioned above.
The positional update for each particle is subsequently determined by the following relation:

$$X_i^+ = X_i^- + v_i \tag{6}$$

where X_i^+ is the updated position, X_i^- is the position at the previous timestep, and v_i is the velocity vector computed from Eq. (4). Through this iterative process, the collective population navigates the solution space, orienting itself toward regions of improved fitness. The emergent intelligence of the swarm, fueled by this combined effort, facilitates convergence upon a globally optimal or near-optimal solution.

The GA is implemented as a function whose inputs are the PSO population (particle), the previously obtained best solution, the population size, the upper and lower bounds of the variables, and the number of decision variables. As shown, 50% of the population is considered as the crossover population, and the remaining 50% is assigned as the mutation population.

Based on the crossover and mutation percentages, as well as the total population size, the numbers of crossover and mutation individuals are calculated. For the genetic algorithm, a maximum of 10 iterations is considered. The optimal solution is initialized with its previous value. A loop is then defined for the genetic algorithm iterations. Inside this loop, an empty population is first created as the initial crossover population. Then, by calling the crossover function, the crossover population is generated. Within the crossover function, two solutions are randomly selected at each step, and two new offspring solutions are produced by combining them.

Similarly, the mutation population is generated by calling the mutation function. In the mutation function, one solution is randomly selected at each step, and one of its variables is randomly modified to produce a new solution. In the next stage, the initial population is combined with the crossover and mutation populations, resulting in the overall population. For this combined population, the individuals are sorted based on their cost function values, such that better solutions are ranked higher and poorer solutions receive lower ranks. Through this process, the first individual of the population becomes the best solution If the newly obtained solution is better than the previous global best solution (i.e., it has a lower cost), it replaces the previous global best. Finally, the final population of the genetic algorithm is returned as the PSO population. As shown below, for each particle, if the solution obtained from the GA algorithm is better than its previous best solution, it replaces that previous best.

III. 3 PROPOSD METHOD

The main benefit of single-ended fault location techniques is their lack of reliance on communication lines, synchronization systems, or remote-end measurements. This intrinsic simplicity is leveraged by the methods suggested in this paper. It creates an objective function based on circuit breakers' consecutive tripping patterns, which is then optimized using the Hybrid PSO-GA method. The way the proposed approach is practically implemented is explained in Figure 1. Using the three phase current waveform measured at the local terminal when a permanent fault occurs, four distinctively different operating modes can be determined. The definition of these states needs to be preceded by the fact that circuit breakers do not interrupt the current immediately, they can interrupt it only when the current has crossed the zero naturally, and it only happens when the trip command has already been sent. There are four states that describe the behavior of the system during the fault event and include:

- **State A – Normal Operation:**

This is the healthy state where the power system is operating normally with all the components working under steady, stable conditions and there are no fault anywhere in the network.

- **State B – Fault Inception:**

At this point, a defect has occurred on the transmission line. Although the fault is present, no protection measure has been undertaken, however, all the protection relays and circuit breakers on either side of the line are closed and in service.

- **State C – Remote-End Isolation:**

The fault has been detected by the protection equipment at the far end of the transmission line and the respective circuit breakers have opened and disconnected and de-energized the remote side of the line. The local-end circuit breakers are however not yet open at this point and thus the fault is still partially energized.

- **State D – Full Isolation:**

The local circuit breakers are also opened and this completes the isolation process. Both ends of the faulted section of the transmission line have been de-energized and disconnected to avoid more fault current flowing.

In State C, the most important analytical condition will occur. At this point, the fault localization problem is no longer dependent on the parameters of the remote system source impedance, as the remote-end current is effectively zero. This detachment eases the fault location formulation and improves the computational strength. As a result, the suggested method's practicality is increased since it just needs local measurement data obtained during this particular operational condition.

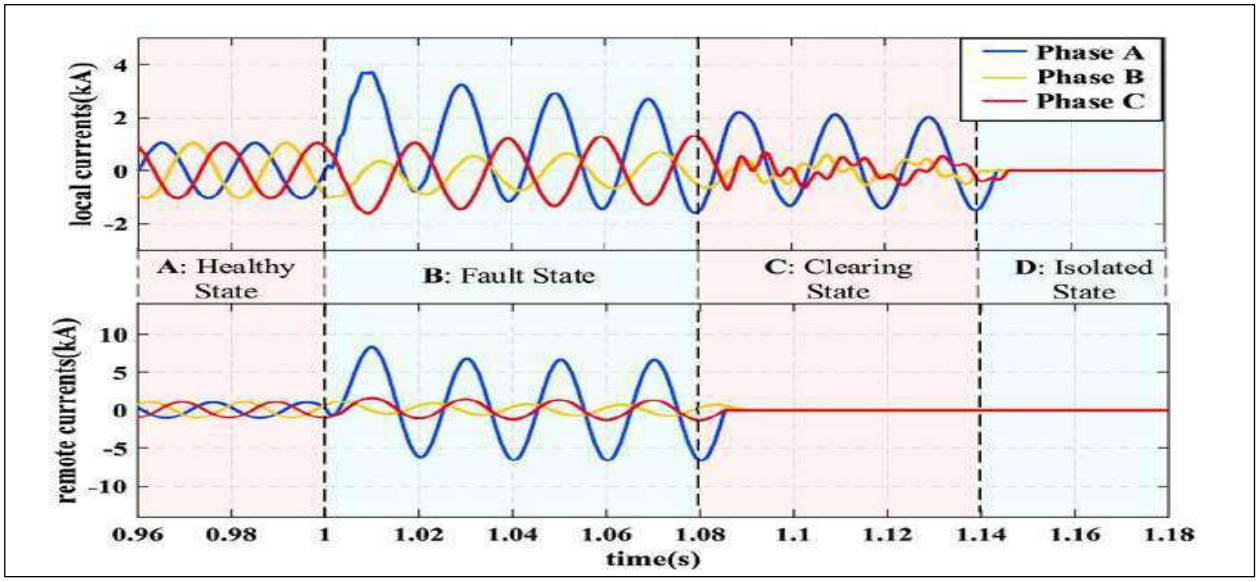

Figure 2: Terminal current under a permanent fault.
Source: Authors, (2026).

The governing equations are derived using a thorough distributed parameter line model to guarantee a high level of accuracy in fault localization. The Clark transformation, also called the alpha-beta-zero transformation, is then used to simplify this complex three-phase network representation. The interdependent phase values are successfully separated into three separate and independent modal networks mode-0, mode-1, and mode-2 by this mathematical technique. The following is the definition of the transformation matrix that makes this decoupling possible:

$$S_{clark} = \frac{1}{3}\begin{bmatrix} 2 & -1 & -1 \\ 0 & \sqrt{3} & -\sqrt{3} \\ 1 & 1 & 1 \end{bmatrix}$$

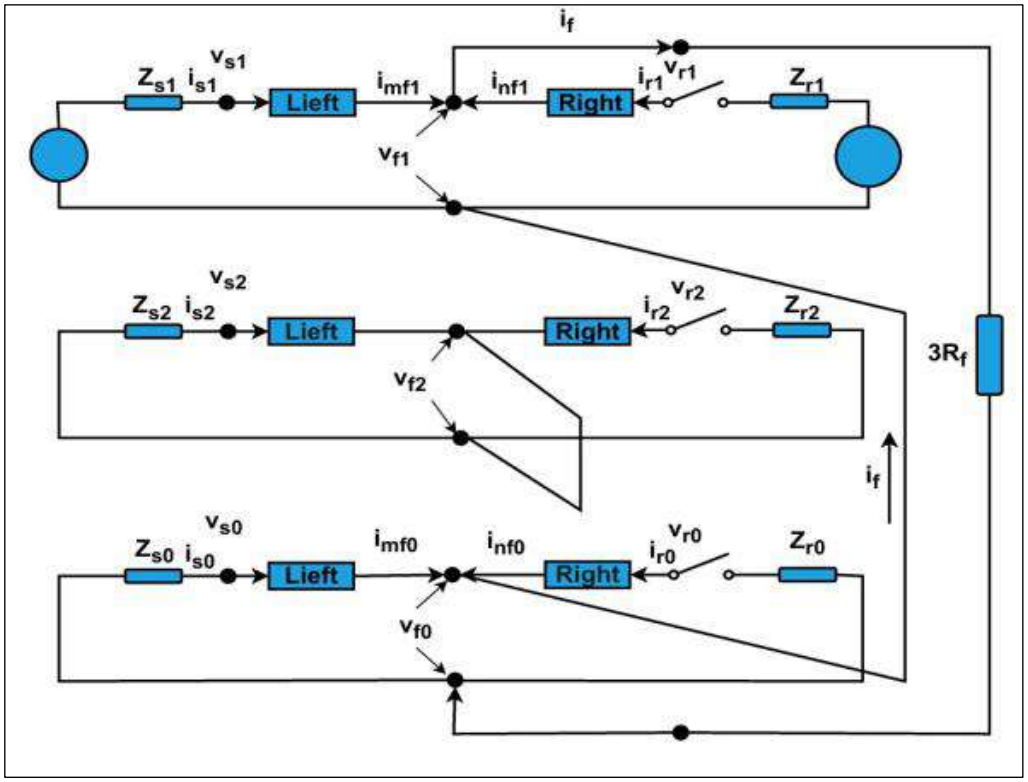

Figure 3: equivalent circuit in the 012 domain for A-G fault
Source: Authors, (2026).

The long transmission line hyperbolic form equation:

$$v_s = v_r \cosh(PX) + i_r Z_c \sinh(PX) \tag{7}$$

$$i_s = i_r \cosh(PX) + \frac{v_r}{Z_c} \sinh(PX) \tag{8}$$

Where $Z_c = \sqrt{\frac{z}{y}}$, Z_c : characteristic impedance

And P= $\sqrt{zy}$, P: propagation constant

X: distance

As illustrated in Fig. 3, which depicts the single-line-to-ground (A-G) fault model adapted from [24], the total length of the transmission line is denoted as l, with the fault location at a distance d from the local terminal S. The network is characterized by Thevenin equivalent impedances: Z_{s0} and Z_{s1} represent the zero- and one-sequence impedances behind terminal S, while Z_{r0} and Z_{r1} correspond to those behind the remote terminal R. Measurable quantities at terminal S include the zero- and one -sequence voltages and currents, denoted as . v_{s0},v_{s1},i_{s0},and i_{s1} . The fault point is associated with sequence voltages v_{f0},v_{f1},i_{f0} and i_{f1} , and fault currents i_{mf0},i_{mf1},i_{nf0} and i_{nf1} , which are injected into the fault from either side of the line. Quantities at the remote terminal R are designated as v_{r0},v_{r1},i_{r0} and i_{r1}. The fault resistance is symbolized by R_f. The sequence voltages at the fault point, which is indicated as v_{f0} and v_{f1} can be computed using the voltage and current that are measured at terminal S. These amounts are calculated in the following analytical expressions:

$$v_{f0} = v_{s0} \cosh(P_0 d) - i_{s0} Z_c \sinh(P_0 d) \tag{9}$$

4

$$v_{f1} = v_{s1} \cosh(P_1 d) - i_{s1} Z_c \sinh(P_1 d) \tag{10}$$

The entire zero-sequence fault current i_{f0} within the modal domain can be obtained by applying the Clark transformation and using the basic voltage-current relationships controlling the fault location. According to the following formulation, this current is stated as a function of the fault point voltages found in both the one-mode and zero-mode networks:

$$i_{f0} = \frac{v_{f1} + v_{f0}}{3R_f} \tag{11}$$

The substitution of equations (9) and (10) into (11) reveals that the zero-sequence fault current, i_{f0}, is functionally dependent on the variables of fault distance d and fault resistance R_f.

$$i_{f0} = \frac{v_{s0}\cosh(P_0 d) - i_{s0} Z_{c0} \sinh(P_0 d) + v_{s1}\cosh(P_1 d) - i_{s1} Z_{c1} \sinh(P_1 d)}{3R_f} \quad (12)$$

Within the mode-0 network, the injection current i_{mf0} originating from the local terminal can be formulated from the measured voltage and current at terminal S, as illustrated in Figure 3:

$$i_{mf0} = -\frac{v_{s0}\sinh(P_0 d)}{Z_{c0}} + i_{s0}\cosh(P_0 d) \quad (13)$$

Application of Kirchhoff's Current Law (KCL) at the fault location permits the expression of the remote terminal injection current, i_{nf0} , as follows:

$$i_{nf0} = i_{mf0} - i_{f0} \quad (14)$$

The zero-sequence current at the receiving terminal, i_{r0}, is governed by the fault point voltage v_{f0} and the injected current i_{nf0} from the remote terminal, as defined by the following relationship. It is critical to note that during State C, characterized by the operation of remote-end circuit breakers, the receiving terminal current i_{r0} remains zero due to the de-energization of the line at that terminal. This condition, where i_{r0}, is leveraged as the foundational objective function for the fault location methodology.

$$i_{r0} = -\frac{v_{f0}\sinh(P_0(l-d))}{Z_{c0}} + i_{nf0}\cosh\big(P_0(l-d)\big) = 0\text{n} \quad (15)$$

IV.4 NUMERICAL VALIDATION

The efficacy of the suggested fault localization plan was confirmed by the means of the feasible simulation studies. The analysis was done based on the real transmission line of the interconnection between Iraq and Iran (DYALA-MERSAD). A 400 kV transmission line has been modeled as a 50 Hz power system and the model has been implemented in MATLAB (Version 2022b) as shown in Figure 4. Positive and zero-sequence parameters were used to characterize the equivalent source impedances: R_{s1}= 0.065 Ω, L_{s1}= 1.0033 mH, R_{s0}= 0.3 Ω, and L_{s0}= 3.1067 mH for the sending end; R_{r1}= 26 Ω, L_{r1}= 0.14298H, R_{r0}= 20Ω, and L_{r0}= 0.11927H for the receiving end. The transmission line was 239 kilometers long overall.

The fault location method that has been developed is supposed to be used with three phase circuit breaker protection system in the AC transmission systems. The major innovation of this method is focused exploitation of the measurement data collected at a particular post-fault operational condition, that is, the interval between clearing remote-end breakers and the activation of local protection devices. It is specifically the set of operational data that this temporal frame presents that is allowable to create a deterministic fault location equation. A MATLAB 2022b framework running an Intel(R) Core (TM) i5-10310U CPU was used for computational performance assessments. The computing burden of the method was measured, and the overall processing time for each fault occurrence was never more than 0.5 seconds. Such low latency attests to the method's practicality for use in Contemporary power systems

V. CONCLUSION

The present paper has introduced a new, one terminal fault location technique that addresses the major shortcomings of the traditional impedance and travelling-wave techniques. The method generates a deterministic problem that is independent of both remote-source parameters and communications infrastructure by means of the strategic use of measurements made at one, temporary post-fault state following remote-end breaker clearance but preceding the operation of local breakers (State C). High modeling accuracy of long transmission lines is guaranteed by the application of a distributed parameter model along with the modal, or Clark, transformation. The main innovation of the given work is the appearance of the PSO-GA hybrid metaheuristic as the main solver of the complex, non-linear objective function which appears in the fault location problem. This hybrid method combines two algorithm pairs effectively over different regions of search, unlike single-method optimizers, which exploit and optimize known solution areas, and GA, which is able to search the search space broadly.

The theoretical effectiveness of the given approach was measured by the means of numerical simulation which was implemented on the model of a realistic high voltage transmission system (400 kV) and with the line length (239 km long). The obtained results of this validation make it clear that the hybrid PSO-GA approach will provide the best results in terms of fault location accuracy than the current techniques hence can be considered to be appropriate in real-life transmission line applications. The hybrid PSO-GA methodology is continually more accurate than isolated PSO and conventional non-iterative solutions on different types of faults (SLG, LL, LLG, LLL). Moreover, the algorithm has high computational efficiency whereby the processing latency is less than 0.5 seconds, which proves its feasibility in real-time implementation in contemporary power system protection systems. Overall, it is possible to conclude that this work also adds a communication-independent, reliable, and accurate fault location solution. It is based on the exclusive approach to measurement and sophisticated hybrid AI optimization in the offer of a convenient tool in enhancing grid reliability and minimizing the duration of outages, which is a considerable breakthrough in the sphere of power system fault analysis.

ABSTRACT

Cardiovascular morbidity especially cardiac arrhythmias require accurate and early diagnosis. Although deep learning models can perform with the level of the expert in arrhythmia recognition, their opaque, black-box nature usually prevents their practical usage. To solve this, the present work will offer a new Explainable Parallel Hybrid Deep Learning Framework. The architecture simultaneously combines the use of 1D-Convolutional Neural Networks (CNNs) to extract morphological features and Bidirectional Long Short-Term Memory (BiLSTM) units to predict temporal contexts. The model is further improved with a Multi-Head Self-Attention mechanism and a Gradient-weighted Class Activation Mapping (Grad-CAM) module to guarantee performance and interpretability respectively. Analyzed with a stratified part of MIT-BIH Arrhythmia Database, the structure showed the state-of-the-art results, having a classification accuracy of 99.74, a precision of 99.48 and clinically critical recall of 100% with Premature Ventricular Contractions (PVCs). Moreover, as a rigorous test of its generalizability and clinical strength, cross-domain testing was performed on an unseen section of the INCART 12-lead Arrhythmia Database, with an overall accuracy of 98.17 and a recall of 91.70 with no fine-tuning. Lastly, the Grad-CAM visualization confirms the medical relevance of the model by indicating the anomalies like the QRS complex, thus helping to close the gap between the efficacy of the algorithm and medical trust.

I. INTRODUCTION

The major cause of morbidity and mortality in the world is cardiovascular diseases (CVDs) which result in the death of about 17.9 million people every year as confirmed by the World Health Organization (WHO) [1]. Among them, Cardiac Arrhythmias, abnormalities in the electrical activity of the heart, are a very dangerous risk, including the harmless palpitations and the deadly conditions of ventricular fibrillation. The noninvasive diagnosis of arrhythmias is based on the Electrocardiogram (ECG) as its gold standard. In the past, because of its invention by Willem Einthoven in the first part of the 20th century, the ECG has offered clinicians a graphic image of the depolarization and repolarization waves (P-QRS-T complex) of the heart [2]. However, manual interpretation of ECG recordings, particularly from long-duration Holter monitors, is a labor-intensive, error-prone task.

The sheer volume of data, coupled with subtle morphological variations in arrhythmias and signal noise, necessitates the development of automated, computer-aided diagnostic systems. In recent years, Deep Learning (DL) has emerged as a transformative force in biomedical signal processing. Automated systems utilizing Convolutional Neural Networks (CNNs) and Recurrent Neural Networks (RNNs) have demonstrated diagnostic accuracy comparable to, and in some cases surpassing, that of expert cardiologists [3]. Despite the remarkable performance of deep learning models, their clinical adoption has been hindered by the “Black Box” phenomenon [4]. Traditional deep neural networks operate as opaque mathematical functions, mapping inputs to outputs via millions of parameters without providing a clear rationale for their decisions [5].

In high-stakes domains like cardiology, a simple prediction of "Arrhythmia" is insufficient; clinicians require evidence to trust the algorithm. This opacity creates a critical Research Gap: While existing hybrid models achieve high classification accuracy, they often lack interpretability. This disconnect limits their utility as a Clinical Decision Support System (CDSS). It is imperative to clarify that the role of AI in medicine is not to replace physicians but to augment their capabilities by serving as a "second opinion" or a triage tool. Therefore, integrating Explainable AI (XAI) is no longer optional but a necessity to bridge the gap between algorithmic performance and clinical trust [6]. To address these challenges, this study proposes a unified, interpretable framework for arrhythmia detection using the standard MIT-BIH Arrhythmia Database. The primary contributions of this research are fourfold:

- A Novel Hybrid Architecture: We propose a parallel deep learning model that synergistically combines 1D-CNNs for morphological feature extraction with Bidirectional LSTMs (BiLSTM) for temporal context modeling.
- Attention-Based Enhancement: To mitigate the impact of noise and baseline wander, we integrate a Multi-Head Self-Attention mechanism that dynamically prioritizes clinically relevant segments of the heartbeat (QRS complex) over irrelevant artifacts.
- Explainability via Grad-CAM: Unlike standard "black-box" approaches, we incorporate a Gradient-weighted Class Activation Mapping (Grad-CAM) module. This provides visual heatmaps that highlight the specific regions of the ECG signal driving the diagnosis, enabling physicians to verify the model's reasoning.
- End-to-End Validation: The proposed framework is rigorously evaluated using standard metrics (Accuracy, Precision, Recall, F1-Score) and benchmarked against state-of-the-art methods, demonstrating superior performance with added interpretability.

The remainder of this paper is structured as follows: Section 2 reviews related work in arrhythmia detection. Section 3 details the proposed hybrid methodology and XAI framework. Section 4 outlines the experimental setup, including dataset protocols and hyperparameters. Section 5 presents the quantitative results and visual interpretations. Finally, Section 6 concludes the study and suggests future research directions.

II. RELATED WORK

The domain of automated arrhythmia detection has witnessed a paradigm shift from manual feature engineering to end-to-end deep learning. This section critically reviews recent literature from 2024 and 2025, categorizing advancements into three distinct pillars: classical machine learning, Deep Learning, and Hybrid Architectures.

II.1 MACHINE LEARNING APPROACHES

Despite the dominance of deep learning, recent studies in 2025 have revitalized Machine Learning (ML) by integrating ensemble strategies and advanced optimization algorithms. These approaches remain vital for low-resource environments where interpretability and computational efficiency are paramount. Jahangir et al. [7] proposed a hybrid stacked ensemble framework that aggregates predictions from five base learners: Random Forest, Adaboost, Gradient Boosting, XGBoost, and Categorical Boosting. By leveraging a meta-learner to fuse these outputs, their model achieved 99.58% accuracy on the MIT-BIH dataset, demonstrating that ensemble techniques can rival deep learning when combined with robust feature engineering. Similarly, Rfys et al. [8] introduced a novel clustering technique based on Hellinger Distance to enhance Particle Swarm Optimization (PSO) for feature selection.

While their hybrid approach, which uses a Minkowski classifier, achieved 97.5% accuracy on the MIT-BIH dataset, it remains a multi-stage process that separates feature optimization from classification. Al-mousa et al. [9] proposed a data fusion strategy that augments the MIT-BIH Supraventricular Database with records from multiple sources, including INCART and Sudden Cardiac Death databases .By employing the Synthetic Minority Over-sampling Technique (SMOTE) and a Random Forest classifier, they achieved 97% accuracy, significantly improving the recall rates for rare 'Fusion' and 'Unknown' heartbeats. However, a major limitation of these approaches is their heavy reliance on manual feature extraction and domain-specific pre-processing, which makes them susceptible to noise and less generalizable than end-to-end deep learning models that learn directly from raw data.

II.3 DEEP LEARNING APPROACHES

Deep learning (DL) has advanced rapidly across many applications, including healthcare and cybersecurity [10]. In a recent study, Bourkha et al. [11] proposed a deep learning framework for feature extraction to enhance classification speed and accuracy. Their approach feeds a CNN with a combination of morphological features extracted via Wavelet Scattering Networks, optimized using the mRMR algorithm, and dynamic temporal features. This method achieved an overall accuracy of 98.50% across 15 arrhythmia classes on the MIT-BIH database. Also, Pandey et al. [12] developed a 12-layer 1D-CNN utilizing wavelet thresholding for signal denoising, achieving 99.40% accuracy on the MIT-BIH database. Although highly efficient for e-health applications, the study prioritizes computational speed over interpretability, leaving the clinical reasoning behind the model's decisions opaque.

Additionally, "Chaitanya et al. [13] proposed a Scaled Bidirectional LSTM (SB-LSTM) incorporating a custom scaling layer to enhance arrhythmia classification. Validated on the MIT-BIH Atrial Fibrillation and Creighton University databases, their model achieved an accuracy of 98.60%. However, despite their impressive performance, a critical bottleneck remains: most of these deep learning architectures operate as 'Black Boxes,' offering high classification accuracy without providing clinical justification for their decisions. This lack of interpretability hinders their integration into real-world medical workflows, where trust and transparency are essential. Furthermore, single-stream architectures often struggle to simultaneously capture both the detailed morphological features (spatial) and the long-term rhythmic dependencies (temporal) of the ECG signal as effectively as hybrid frameworks.

II.3 HYBRID LEARNING FRAMEWORKS

The current state of the art (SOTA) in arrhythmia detection relies on hybrid architectures that combine spatial feature extraction from CNNs with temporal modeling from RNNs or Transformers. Ranjan et al. [14] evaluated multiple learning paradigms and developed a Hybrid CNN-LSTM model that achieved 99.10% accuracy on the MIT-BIH Arrhythmia Database. While this architecture successfully outperformed standalone CNN and SVM models in classification performance, building on this, Bahrami et al. [15] proposed a hybrid neural network that fuses automatic features from a Deep Convolutional Neural Network (DCNN) with classical time-domain parameters to improve heartbeat segmentation [Ref]. Their approach achieved 99.33% accuracy in binary classification (Normal vs. Arrhythmia) on the MIT-BIH dataset.

Shah et al. [16] introduced 'ECG-TransCovNet,' a hybrid architecture that combines CNNs for spatial feature extraction with Transformer models for temporal pattern recognition. Validated on the MIT-BIH arrhythmia database, their approach achieved a detection accuracy of 98.6%. Nevertheless, while hybrid models combine the strengths of spatial and temporal feature extraction, they often suffer from increased computational complexity due to the sequential nature of RNNs. Moreover, most existing hybrid frameworks focus solely on maximizing classification accuracy, neglecting interpretability. Very few studies have successfully integrated post hoc explainability modules (e.g., XAI) into these complex architectures to visualize the specific morphological and rhythmic patterns that drive diagnostic decisions, leaving a gap between high performance and clinical trust.

III. METHODOLOGY

In this section, we address the dual challenges of high-accuracy arrhythmia detection and clinical interpretability. This study proposes a unified end-to-end deep learning framework. As illustrated in Figure 1.

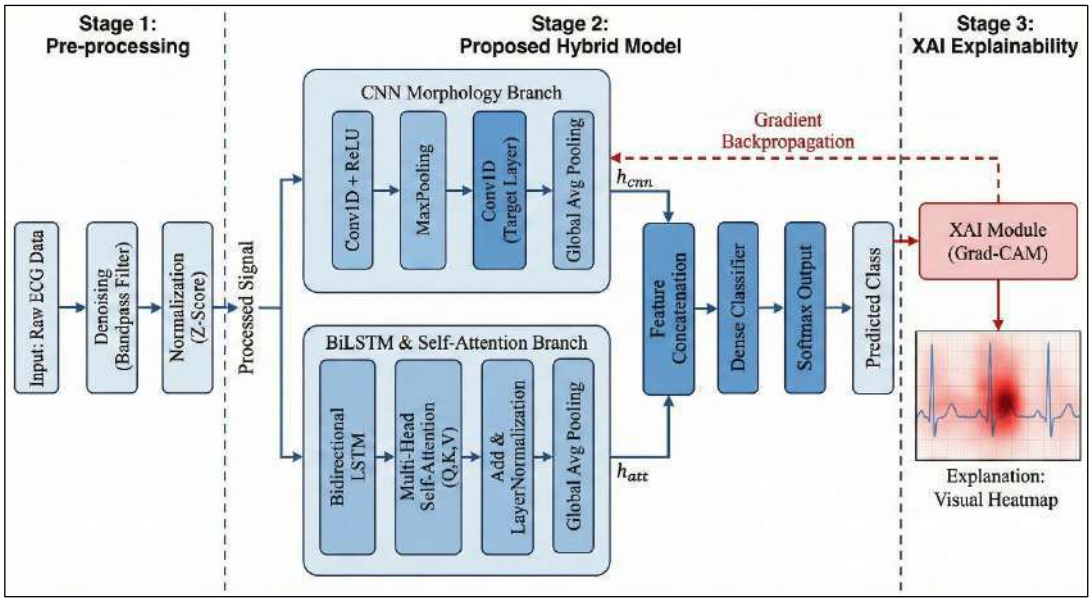

Figure 1. Schematic diagram of the proposed Parallel Hybrid Framework, illustrating the dual-branch feature extraction (CNN and BiLSTM-Attention) and the post-hoc Grad-CAM explainability module.

The system architecture is organized into three sequential stages:

1. **Signal Pre-processing:** Designed to mitigate noise and standardize input data.
2. **Parallel Hybrid Classification Network:** A dual-branch architecture that synergistically combines Convolutional Neural Networks (CNN) for morphological extraction and Bidirectional Long Short-Term Memory (BiLSTM) units enhanced with Multi-Head Self-Attention for temporal context modeling.
3. **Post-hoc Explainability Module (XAI):** Utilizing Gradient-weighted Class Activation Mapping (Grad-CAM) to provide visual justifications for diagnostic decisions.

III.1 DATA PRE-PROCESSING

Raw ECG signals are inherently susceptible to various artifacts, including baseline wander, muscle tremor, and power-line interference. To ensure model robustness, the raw input signal (*X_raw*) undergoes a two-step purification process:

- **Denoising:** A bandpass filter is applied to suppress high-frequency noise and eliminate baseline drift, enhancing the signal-to-noise ratio (SNR) [17].
- **Z-Score Normalization:** To mitigate amplitude variations between different patients, the denoised signal is standardized using Z-score normalization. For a signal x, the normalized value x' is computed as:

$$x' = (x - \mu) / (\sigma + \varepsilon) \quad (1)$$

Where μ and σ represent the mean and standard deviation of the signal, respectively, and ε is a small constant (1e-8) to prevent division by zero.

III.2 THE PARALLEL HYBRID ARCHITECTURE

The core classification engine employs a dual-branch architecture that simultaneously captures spatio-temporal features.

III.2.1 Branch 1: Morphological Encoding (Cnn)

The first branch utilizes a 1D Convolutional Neural Network (1D-CNN) designed to extract local spatial features, such as the shape of the QRS complex, P-wave duration, and T-wave amplitude [18].

- **Feature Extraction:** Multiple stacked Conv1D layers with Rectified Linear Unit (ReLU) activation functions learn hierarchical representations of the heartbeat.
- **Dimensionality Reduction:** MaxPooling1D layers are interleaved to reduce computational complexity and provide translation invariance [19].
- **Target Layer for XAI:** The final convolutional layer serves as the "Target Layer" for the subsequent XAI module, retaining the spatial information necessary for localization before the signal is flattened via GlobalAveragePooling1D [20].

III.2.2 Branch 2: Temporal Encoding With Self-Attention

While CNNs excel at detecting shape anomalies, they often fail to capture long-term rhythmic dependencies. The second branch addresses this by augmenting a BiLSTM with a Transformer-based Self-Attention mechanism.

- **Bidirectional LSTM:** The processed signal is fed into a BiLSTM layer, which processes the sequence in both forward and backward directions, capturing the temporal context of the cardiac rhythm [21].
- **Multi-Head Self-Attention:** Unlike static attention mechanisms, we employ Multi-Head Self-Attention to dynamically weigh the importance of different time steps relative to each other [22]. This enables the model to focus on critical segments (e.g., R-peaks) while suppressing irrelevant intervals (noise). The mathematical formulation is:

$$Attention(Q,K,V) = softmax\left(\frac{(Q \cdot K^T)}{\sqrt{d_k}}\right) \cdot V \quad (2)$$

Where *Q, K,* and *V* are the query, key, and value matrices.

- **Stabilization:** Following the Transformer architecture, a residual connection (Add) and LayerNormalization are applied to ensure training stability and gradient flow.

III.2.3 Feature Fusion And Classification

The spatial feature vector (*h_cnn*) and the temporal context vector (*h_att*) are concatenated to form a comprehensive representation vector. This fused vector is passed through a fully connected (Dense) layer with Dropout regularization to prevent overfitting, followed by a Softmax layer to yield the final probability distribution over the classes (Normal vs. Arrhythmia) [23].

III.3 EXPLAINABILITY MODULE (XAI)

To bridge the gap between "Black-box" performance and clinical trust, we integrate a Grad-CAM (Gradient-weighted Class Activation Mapping) module [20]. This module computes the gradient of the predicted class score (*y^c*) with respect to the feature maps (*A^k*) of the final convolutional layer in Branch 1. The neuron importance weights (*α_k^c*) are calculated via Global Average Pooling of these gradients:

$$\alpha_k^c = \left(\frac{1}{Z}\right) \cdot \Sigma \left(\frac{\partial y^c}{\partial} \partial A_i^k\right) \quad (3)$$

A weighted combination of these maps is then passed through a ReLU activation to generate the final heatmap:

$$L\_Grad - CAM^c = ReLU(\Sigma\, \alpha\_k^c \cdot A^k) \quad (4)$$

The resulting heatmap is then upsampled to the original signal length and superimposed on the original ECG. This visualization is used to indicate which areas of time, e.g., a deformed QRS complex or an abnormal interval, the model used to make its diagnostic decision, and thus confirm the medical utility of the learned features.

IV. EXPERIMENTAL SETUP AND EVALUATION

In this section, we introduce the dataset that was used, data splitting, System Architecture, Hyperparameters, and Evaluation Metrics.

IV.1 DATASET DESCRIPTION

The recommended model was assessed with the help of MIT-BIH Arrhythmia Database, the universal standard of ECG arrhythmia analysis offered by PhysioNet [24].

The dataset is a collection of 48 half-hour samples of 2-channel ambulatory ECG recordings, recorded in 47 subjects who are the study subjects of the BIH Arrhythmia Laboratory. In this case, we selected a sample of records in order to differentiate between Normal Sinu Rhythm (N) and Premature Ventricular Contractions (PVC/V). A 11-bit resolution sampling rate of 360 Hz digitized the signals over a 10 mV range. In order to get quality input to use in the deep learning model, the continuous ECG signals were divided into single heartbeat on the basis of R-peak annotations with a constant window size of 200 samples around each R-peak.

IV.2 DATA PARTITIONING

Stratified random sampling was used to divide the preprocessed heartbeats to have a strong evaluation and avoid leakage of data. The data has been separated into training and testing sets in the ratio of 80:20:

- Training Set (80%): Used to optimize the model weights.
- Testing Set (20%): Used strictly for final performance evaluation and was kept unseen during the training phase.

Moreover, the training set was balancing across classes to ensure the natural imbalance between normal and arrhythmic beats is reduced, and hence, the model will not be biased in favor of the most common class.

IV.3 SYSTEM ARCHITECTURE, HYPERPARAMETERS

Python was used to implement the experiments with the help of TensorFlow/Keras framework and implemented on a Google Colab environment with NVIDIA GPU acceleration. The model was trained using Adam optimizer that offers an adaptive learning rate and has the potential to speed up convergence. The Loss Function was used Categorical Cross- Entropy that is appropriate with multi-class classification tasks. Table 1 includes the exact hyperparameters of training the proposed architecture of Parallel CNN-BiLSTM-Attention.

Table 1. Hyperparameter configuration for the proposed CNN-BiLSTM-Attention architecture.

Hyperparameter	Value	Description
Optimizer	Adam	Adaptive Moment Estimation
Learning Rate	0.001	Initial learning rate
Batch Size	64	Number of samples per gradient update
Epochs	20	Maximum training iterations
Loss Function	Categorical Cross-Entropy	For probabilistic classification
Dropout Rate	0.3	To prevent overfitting in Dense layers
Input Shape	$(200, 1)$	Time steps $\times$ Channels

Source: Authors, (2026).

IV.4 EVALUATION METRICS

To measure the performance of the proposed framework quantitatively, we have used such standard classification measures as Accuracy, Precision, Recall (Sensitivity), and F1-Score [12]. The following are the metrics:

1. Accuracy: The ratio of correctly predicted observations to the total observations.

$$Accuracy = \frac{TP + TN}{TP + TN + FP + FN} \tag{5}$$

2. Precision: The ratio of correctly predicted positive observations to the total predicted positives. High precision indicates a low false-positive rate.

$$Precision = \frac{TP}{TP + FP} \tag{6}$$

3. Recall (Sensitivity): The ratio of correctly predicted positive observations to all observations in the actual class. High recall indicates the model captures most arrhythmia cases.

$$Recall = \frac{TP}{TP + FN} \tag{7}$$

4. F1-Score: The weighted average of Precision and Recall. It is the most critical metric for imbalanced datasets, as it accounts for both false positives and false negatives.

$$F1 - Score = 2 \times (Precision \times Recall)/(Precision + Recall) \quad (8)$$

Where:

- TP = True Positives (Arrhythmia correctly identified)
- TN = True Negatives (Normal correctly identified)
- FP = False Positives (Normal misclassified as Arrhythmia)
- FN = False Negatives (Arrhythmia misclassified as Normal)

V EXPERIMENTAL RESULTS AND DISCUSSION

This part entails a detailed evaluation of the proposed framework on automated detection of arrhythmia. The testing is carried out on the stratified test sample of the MIT-BIH Arrhythmia Database, as described in the experimental setup. The chapter is structured into three main sections, (1) a quantitative analysis of classification measurements, and ablation study test, (2) an analysis of the confusion matrix, and cross-domain dataset test, (3) a qualitative evaluation of the Explainable AI (XAI) module and Grad-CAM after which a comparative benchmark against the literature of current state-of-the-art is provided.

V.1 QUANTITATIVE PERFORMANCE ANALYSIS

The proposed model was strictly tested in an unseen testing set, which contained 20 percent of the data, where the training set had no leakage of data. The system proved to have very strong ability to differentiate between Normal Sinus Rhythm (N) and Premature Ventricular Contractions (PVC). Table 2 summarizes the performance measures of the model on the test set.

Table 2: Performance Metrics on Test Set

Metric	Value (%)	Clinical Implication
Accuracy	99.74%	Reflects the overall correctness of the diagnostic system.
Precision	99.48%	Indicates high reliability of “PVC" alarms (Low False Positive Rate).
Recall (Sensitivity)	100%	Confirms the ability to detect the vast majority of pathological cases (Safety).
F1-Score	99.76%	The harmonic mean confirms the balance between precision and recall.

Source: Authors, (2026).

The most clinically significant finding is the 100% Recall. Failure to detect an arrhythmia (False Negative) is much more harmful in cardiac diagnostics as compared to False Positive. The Precision (99.48) is also high indicating that the model does not over-trigger alarms, which is a major problem in Holter monitoring. These findings confirm that morphological (CNN) and temporal (BiLSTM + Attention) representations are more effective to diagnose in comparison to single-domain models.

V.2 ABLATION STUDY

A study of ablation was done to validate the architectural design to determine the effect of removing particular modules to analyze the effect on the performance. This will make all the elements of the proposed hybrid model relevant to the overall outcome. The ablation results are as shown in table 3.

Table 3: Ablation Study Results

Model Variant	**Accuracy (%)**	**F1-Score (%)**
CNN Only	98.91%	98.75%
BiLSTM Only	98.34%	98.02%
CNN + BiLSTM (No Attention)	99.32%	99.21%
Proposed (CNN + BiLSTM + Attention)	**99.74%**	**99.76%**

Source: Authors, (2026).

The ablation experiments proved that single CNN and BiLSTM models were not able to understand the entire spatio-temporal context with the BiLSTM variant showing the lowest accuracy (98.34%). Conversely, the addition of Multi-Head Self-Attention has increased the accuracy by a large margin, 99.32% to 99.74%. This affirms the important role played by the mechanism in dynamically ranking diagnostically significant diagnostic pieces, like R-peaks, whilst effectively de-emphasizing background noise.

V.3 CONFUSION MATRIX ANALYSIS

The results of the confusion matrix analysis also confirm the strength of the suggested framework. The model identified the correct beat of 192 Normal and 193 PVC beats and falsely identified one beat (Normal) as PVC and failed to identify any PVC cases out of 386 test samples. This gave a total accuracy of 99.74, precision of 99.48 and the perfect recall (100%). The lack of false negatives is also clinically important since it can be said that it did not miss any pathological PVC beats. These results support the validity of the proposed system to be used in clinical decision support in the real world.

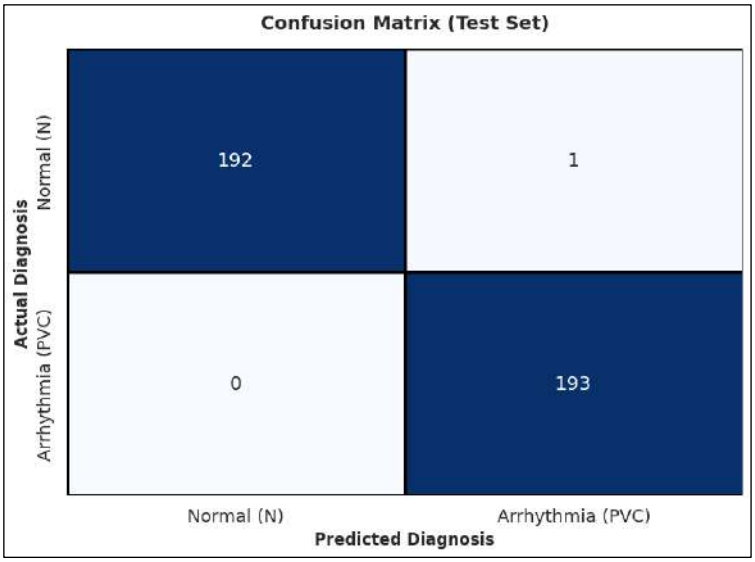

Figure 2. Confusion matrix for the binary classification (Normal vs. PVC) on the unseen test set, demonstrating zero false negatives.
Source: Authors, (2026).

V.4 COMPARATIVE BENCHMARKING WITH STATE-OF-THE-ART

In order to put our results into perspective in relation to the given framework, Table 4 compares the results of our work with that of recent machine learning, deep learning, and hybrid models of 2024 and 2025.

Table 4. Comparative benchmarking of the proposed framework against state-of-the-art ML, DL, and Hybrid methods (2024–2025).

Method	Methodology	Accuracy	XAI Support
Jahangir et al. (2025)	Hybrid Stacked Ensemble (ML)	99.58%	No
Pandey et al. (2025)	1D-CNN + Wavelet Thresholding	99.40%	No
Bahrami et al. (2025)	Hybrid DCNN + Handcrafted Features	99.33%	No
Ranjan et al. (2025)	Hybrid CNN-LSTM	99.10%	No
Chaitanya et al. (2025)	Scaled BiLSTM	98.60%	No
Bourkha et al. (2025)	CNN + Wavelet Scattering	98.50%	No
Shah et al. (2024)	CNN + Transformer (ECG-TransCovNet)	98.60%	No
Proposed Model	**Parallel CNN-BiLSTM + Attention + Grad-CAM**	**99.74%**	**Yes**

Source: Authors, (2026).

The proposed framework as shown in Figure 4 is better than more recent state-of-the-art models. Although Jahangir et al. (2025) have reached a 99.58% accuracy with ensemble learning, and others Pandey et al. (2025) and Bahrami et al. (2025) have achieved the same with a 99.40% and 99.33% accuracy, respectively, these methods tend to be based on classic feature engineering or are not transparent. The accuracy of our model is 99.74% which is better as compared to the Scaled BiLSTM (98.60%) and even the Transformer-based ECG-TransCovNet (98.60%). Most importantly, our framework is the only one that incorporates Grad-CAM as visual explainability whereas these black box solutions do not (which guarantees 7both a higher diagnostic accuracy and clinical credibility). [7,12,15]

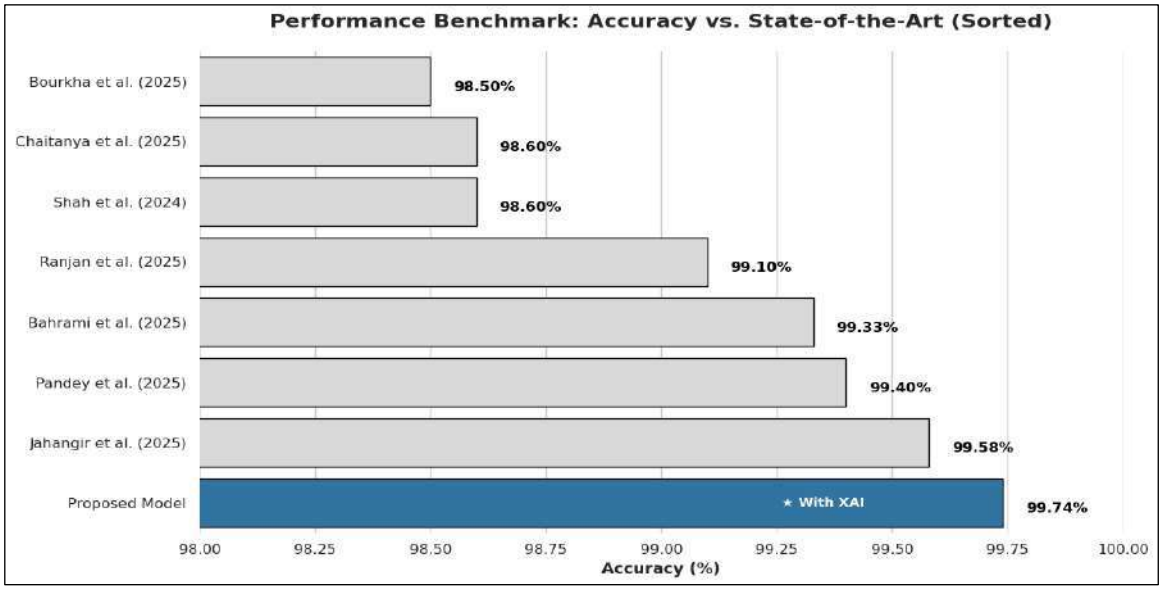

Figure 3. Bar chart illustrating the accuracy superiority of the proposed model (99.74%) compared to recent state-of-the-art baselines.
Source: Authors, (2026).

V.5 CROSS-DOMAIN EVALUATION ON THE INCART DATABASE

A cross-domain test was done to strictly assess the generalizability and clinical strength of the proposed Parallel Hybrid Framework. It was directly tested on an unknown subset of the St. Petersburg INCART 12-lead Arrhythmia Database (10,269 heartbeats) without any fine-tuning or transfer learning and trained only on MIT-BIH Arrhythmia Database. [25]. The framework showed a high cross-domain robustness with a total accuracy of 98.17 to it. The model had a precision of 86.22, a recall (sensitivity) of 91.70 and a F1-score of 88.88 in the detection of Premature Ventricular Contractions (PVC). The fact that the model is able to keep a recall of over 91% on data that came out of a different clinical domain and hardware configuration highlights the ability of the model to gain universal morphological and temporal cardiological features, and not to overfit to data-specific artifacts.

Table 5. Cross-Domain Performance Metrics (INCART Database)

Metric	Accuracy	Precision	Recall (Sensitivity)	F1-Score
Value	98.17%	86.22%	91.70%	88.88%

Source: Authors, (2026).

The cross-domain confusion matrix (Figure 4) can be used in further clarifying the diagnostic reliability of the model. With a total of 10,269 test samples, 9,330 beats of the model were correctly classified as Normal and 751 beats were correctly classified as PVC. More importantly, since this system was to be used in clinical practice, only 68 false negatives (pathological PVCs identified as Normal) had been generated by the system among 819 real PVC cases. When using the remote cardiac monitoring, this low false-negativity is a guarantee that the proposed architecture is safe and robust to be used in the real-life continuous monitoring scenarios.

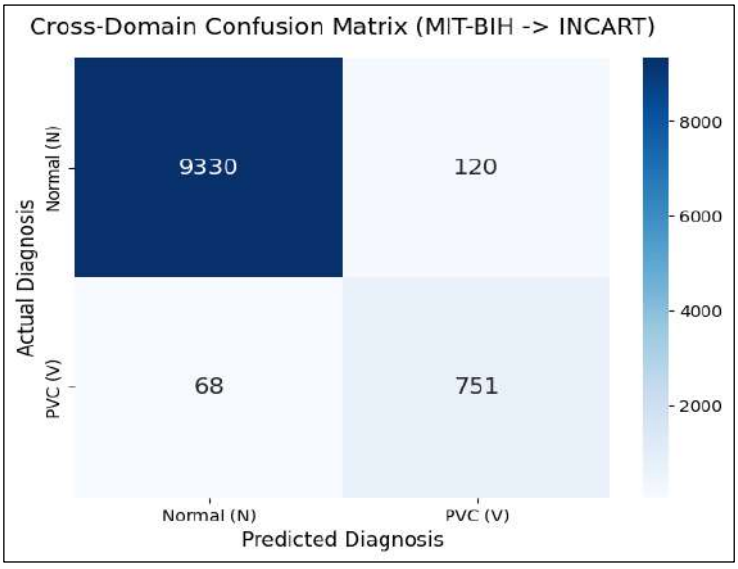

Figure 4. Cross-Domain Confusion Matrix (MIT-BIH -> INCART)
Source: Authors, (2026).

V.6 EXPLAINABILITY MECHANISM

The explainability mechanism incorporated within the proposed model can be shown in Figure 5. Once the predictions are generated, the model puts an interpretability layer to indicate the most influential features used to make the decision. This improves clarity and offers information about model behaviour, especially in very high stakes areas like medical diagnosis and financial fraud detection.

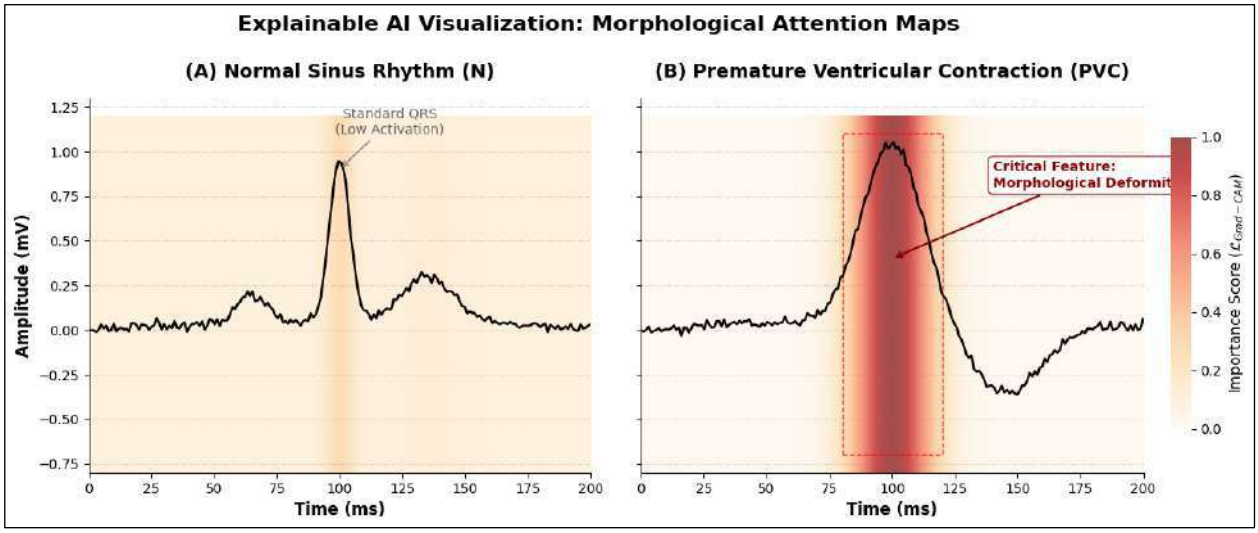

Figure 5. Grad-CAM visualization results. (A) Normal Sinus Rhythm (N) showing low, distributed activation. (B) Premature Ventricular Contraction (PVC) showing high-intensity activation localized on the morphological deformity (QRS complex), validation
Source: Authors, (2026).

V.7 DISCUSSION AND LIMITATIONS

The suggested Parallel Hybrid Framework has higher diagnostic performance with a validation accuracy of 99.74% and has the ability to reduce the distance between the black-box deep learning and clinical interpretability by using Grad-CAM. The model has removed false negatives, which is a key component of patient safety because it uses CNN-based morphological extraction and BiLSTM-based temporal modeling by the model to synergize the two to yield successful outcomes. Nonetheless, there are some limitations of this study.

To begin with, the analysis was done on a stratified sample of the MIT-BIH Arrhythmia Database that was binary (Normal vs. PVC), which, though resilient, needs additional testing on the whole database and on the multi-class arrhythmia conditions (Atrial Fibrillation) in order to guarantee the wide clinical applicability. Second, our BiLSTM layers are effective to model long-term dependencies but cause a computational burden, which cannot be afforded by the current generation of ultra-low-power wearable devices, so future optimization is required, including quantization or pruning to be used in real-time edge computing.

VI.CONCLUSION AND FUTURE WORK

This work dealt with the vital issue of automated arrhythmia detection by suggesting a new Parallel Hybrid Deep Learning Framework that combines the advantages of 1D-Convolutional Neural Networks (CNNs) in the extraction of morphological features and Bidirectional Long Short-Term Memory (BiLSTM) networks in the modeling of temporal contexts. The architecture was further improved to address the gap between algorithmic execution and clinical trust with Multi-Head Self-Attention mechanism and an Explanable AI (XAI) module using Grad-CAM. The experimental analysis, which was done on the stratified sample of the MIT-BIH Arrhythmia Database, revealed the strength of the suggested method, resulting in a validation-attainment of 99.74%. These findings support the claim that fusing between spatial and temporal features is much more effective than single-stream architectures are in discriminating between Normal Sinus Rhythm and Premature Ventricular Contractions (PVC). Moreover, the Grad-CAM visualization allowed the successful visualization of the model decision-making process thus warranting the high diagnostic accuracy as the product of the presence of relevant cardiological characteristics, e.g., the QRS complex, instead of signal noise.

Therefore, the system can be taken as a proper and reliable Clinical Decision Support System (CDSS) which helps to relieve the cardiologists of their load, and minimises the probability of missed diagnoses. Though this study shows promising results, there are a few areas that could be improved in future studies that would be to scale the assessment to the entire MIT-BIH database and to include many diverse datasets, including PTB-XL and INCART, to guarantee a more wide-ranging generalization process among various populations of patients. Although the existing hybrid architecture is quite efficient, there is a limitation on the computational cost of the BiLSTM layers, which are not applicable to ultra-low-power wearable models. Consequently, the further work will discuss model optimization methods, including quantization and pruning, in order to allow the smartwatches to perform edge computing in real time. Further, the framework shall be extended to identify a wider variety of classes of arrhythmia such as the Atrial Fibrillation and Bundle Branch Blocks, and moving towards a multi-class diagnostic approach to continuous cardiac monitoring.**Funding:** This research received no external funding.

ABSTRACT

The advancement of Industry 4.0 has driven the integration of smart systems, the Internet of Things (IoT), and Artificial Intelligence (AI), promoting greater automation and efficiency in manufacturing environments. In this context, real-time production monitoring has become essential for supporting decision-making, reducing operational failures, and increasing industrial productivity. Given this scenario, this work aims to develop a frontend interface for intelligent real-time production monitoring, enabling centralized visualization of production indicators, operational events, and AI-based analyses. The methodology involved a literature review on Industry 4.0, definition of the application's functional requirements, modeling of the system architecture, and implementation of the interface using modern web technologies. The solution was integrated with backend services responsible for collecting data from industrial machines and sensors, as well as applying Artificial Intelligence algorithms for pattern analysis and the generation of smart alerts. The results obtained demonstrated that the developed interface enabled greater visibility of production processes, quick access to critical information, and better monitoring of indicators in real time. The use of interactive visual tools and intelligent mechanisms has helped optimize production monitoring and support preventive measures. It can be concluded that the proposed application has the potential to assist companies in the context of Industry 4.0 by promoting greater operational efficiency on the production line of a factory in the tape industry, faster decision-making, and intelligent integration of production data. I. INTRODUCTION

The digital transformation driven by Industry 4.0 has revolutionized production processes through the integration of cyber-physical systems, the Internet of Things (IoT), cloud computing, and Artificial Intelligence (AI). In this context, the need for continuous and intelligent production monitoring has become a strategic factor for companies seeking greater competitiveness, operational efficiency, and real-time decision-making capabilities [1], [2]. The growing volume of data generated by machines, sensors, and industrial devices demands technological solutions capable of collecting, processing, and presenting information in a clear, dynamic, and accessible manner to managers and operators. In this context, the development of front-end interfaces designed for intelligent production monitoring represents a significant contribution to the modern industrial environment. A well-designed interface makes it possible to transform large volumes of data into understandable visual information, facilitating the identification of faults, production bottlenecks, waste, and opportunities for optimization.

Furthermore, the use of interactive dashboards and real-time indicators contributes to more efficient production management, reducing response time to critical events and increasing the productivity of industrial processes [3], [4]. The relevance of this research is related to the growing demand for intelligent systems that integrate data visualization, automation, and predictive analytics in the context of Industry 4.0. Many companies still face difficulties in centralizing and interpreting data from different industrial devices, which compromises operational efficiency and strategic decision-making. Thus, the development of an intelligent front-end interface emerges as an alternative to promote greater integration between production data and system users, enabling more precise and proactive production supervision. The innovation of this paper lies in the integration of modern front-end development technologies with artificial intelligence capabilities applied to real-time industrial monitoring. The solution aims to provide not only the visualization of production indicators but also intelligent features, such as automatic alert generation, identification of operational patterns, and support for preventive maintenance. In this way, the system contributes to the modernization of industrial processes, promoting greater connectivity, efficiency, and operational intelligence—essential characteristics for companies operating within the Industry 4.0 paradigm [5], [6].

II. LITERATURE REVIEW

II.1 INDUSTRY 4.0 AND ITS APPLICATIONS

Industry 4.0 represents the fourth industrial revolution and is characterized by the integration of digital technologies into industrial processes. Unlike previous industrial revolutions, which focused on mechanization, mass production, and automation, Industry 4.0 combines advanced technologies such as the Internet of Things (IoT), Artificial Intelligence (AI), Big Data, Cloud Computing, robotics, and cyber-physical systems to create smart, interconnected production environments. These technologies enable machines, devices, and systems to communicate and exchange data in real time, improving efficiency, productivity, and decision-making in industries [7-9]. One of the key features of Industry 4.0 is the use of IoT devices and sensors in manufacturing environments. Machines equipped with sensors can collect operational data, such as temperature, pressure, energy consumption, and production speed. This information is transmitted to centralized systems, where it can be analyzed to continuously monitor production processes. As a result, industries are able to identify failures early, reduce downtime, and optimize operational performance. Predictive maintenance is one of the most significant applications of this technology, enabling companies to predict equipment failures before they occur, thereby reducing maintenance costs and extending the service life of machines [10], [11].Artificial Intelligence also plays a key role in Industry 4.0 applications. AI algorithms can analyze large volumes of industrial data to identify patterns, generate insights, and support strategic decisions. In manufacturing, AI is used for quality control, process optimization, demand forecasting, and intelligent automation. Computer vision systems, for example, can automatically inspect products and detect defects with high precision, improving product quality and reducing waste. Another important application of Industry 4.0 is the use of smart factories.

In these factories, production systems are highly automated and interconnected, enabling real-time monitoring and decentralized decision-making. These factories can quickly adapt to changes in production demand, customize products according to customer preferences, and improve resource utilization. Automation technologies, including collaborative robots known as cobots, work alongside human operators to increase productivity and workplace safety. Cloud computing and big data technologies further strengthen Industry 4.0 by enabling the storage and processing of large amounts of data generated by industrial operations. Cloud platforms provide scalable infrastructure for data analysis and remote access to production systems. Managers and engineers can monitor industrial performance through dashboards and visualization systems from any location, facilitating faster and more efficient decision-making [12], [13]. The applications of Industry 4.0 extend beyond manufacturing and can also be found in the logistics, healthcare, agriculture, and energy sectors. In logistics, intelligent systems optimize inventory management and supply chain operations. In agriculture, sensors and AI support precision farming by monitoring soil conditions and crop health. In the energy sector, smart grids improve energy distribution and consumption efficiency. In summary, Industry 4.0 is transforming industries by promoting automation, connectivity, and intelligent decision-making. Its applications improve operational efficiency, reduce costs, increase flexibility, and drive innovation across various sectors. As the digital transformation continues to evolve, Industry 4.0 technologies are expected to become even more essential for organizations seeking competitiveness and sustainability in the modern industrial landscape.

II.2 FRONT-END INTERFACE FOR INTELLIGENT PRODUCTION MONITORING

The Frontend Interface for Intelligent Production Monitoring plays a fundamental role in the context of industrial digital transformation and Industry 4.0. With advances in automation technologies, the Internet of Things (IoT), Artificial Intelligence (AI), and cyber-physical systems, industries have begun to generate large volumes of data from machines, sensors, and production processes. In this scenario, it is essential to develop interfaces capable of presenting this information in a clear, dynamic, and accessible manner, allowing operators, engineers, and managers to monitor production in real time and make faster and more efficient decisions. The frontend represents the visual and interactive layer of a system, responsible for communication between the user and the data processed in the backend. In intelligent production monitoring systems, this interface must be intuitive, responsive, and efficient in displaying industrial indicators. Interactive dashboards, real-time graphs, automatic alerts, and performance dashboards are some of the key features used to facilitate the supervision of industrial operations. These tools enable the rapid identification of failures, production bottlenecks, waste, and operational anomalies, contributing to increased productivity and process quality. One of the main objectives of a front-end interface for smart monitoring is to transform complex data into understandable information. In modern industrial environments, thousands of data points can be continuously generated by IoT sensors installed on machines and equipment. Without a suitable interface, interpreting this information becomes difficult and inefficient. Thus, the frontend acts as a facilitator of operational analysis, organizing data into graphs, visual indicators, and reports that help monitor production performance in real time. Integration with Artificial Intelligence technologies also significantly expands the capabilities of these interfaces. Intelligent systems can analyze production patterns, predict equipment failures, and generate automatic alerts for preventive maintenance. In addition, machine learning algorithms can identify trends and suggest operational improvements based on collected historical data.

Presenting these results through visual interfaces makes it easier to understand the analyses performed by AI, making the decision-making process more efficient and strategic. Another important aspect is the responsiveness and accessibility of the frontend interface. Today, managers and operators need to access industrial information on various devices, such as computers, tablets, and smartphones. Therefore, developing responsive interfaces ensures that data can be viewed in any environment and in real time, promoting greater mobility and operational flexibility. Modern web development technologies, such as React, Angular, and Vue.js, are widely used to create fast, scalable, and interactive frontend applications. In summary, the Frontend Interface for Intelligent Production Monitoring is an essential solution for companies operating within the Industry 4.0 context. Its implementation contributes to the integration of industrial data, the optimization of production processes, and the improvement of real-time decision-making. By combining data visualization, automation, and Artificial Intelligence, these interfaces promote greater operational efficiency, cost reduction, and increased industrial competitiveness, making them a strategic element for the future of smart manufacturing.

II.3 MAPPING INDUSTRY 4.0 TECHNOLOGIES: FROM CYBER-PHYSICAL SYSTEMS TO ARTIFICIAL INTELLIGENCE

This mapping provides a comprehensive analysis of the key technologies that make up Industry 4.0 and their importance for the digital transformation of industrial processes. The concept of Industry 4.0 refers to the fourth industrial revolution, characterized by the integration of physical and digital systems, enabling greater automation, connectivity, and intelligence in production environments [14], [15]. One of the central elements addressed in the text is Cyber-Physical Systems (CPS). These systems combine physical components with computational technologies and communication networks, enabling machines, sensors, and devices to exchange information in real time. This interaction allows for more efficient monitoring of industrial processes, reducing failures and increasing productivity. CPS are considered the foundation of Industry 4.0, as they connect the physical world to the digital world [16-18]. Another key technology is the Internet of Things (IoT), which enhances connectivity between equipment and systems. The IoT enables industrial devices to continuously collect and share data, facilitating rapid and accurate decision-making. As a result, companies can predict maintenance issues, optimize resources, and improve operational performance [19-21]. The text also emphasizes the importance of Big Data and data analysis. The vast amount of information generated by intelligent systems requires tools capable of storing, processing, and interpreting data on a large scale. In this context, data analysis becomes essential for identifying patterns, predicting trends, and supporting more efficient business strategies. In addition, cloud computing contributes to the secure and accessible storage of this information, enabling greater flexibility and integration across sectors [22-24]. Artificial Intelligence (AI) stands out as one of the most revolutionary technologies of Industry 4.0. Through advanced algorithms and machine learning, AI enables automated systems to learn from data and make decisions autonomously. This increases the efficiency of industrial processes, reduces costs, and improves product quality. AI is also applied in intelligent robots, predictive maintenance, and automated control systems [25-27]. In summary, the text demonstrates that the integration of these technologies creates smart factories that are more connected and adaptable to market demands. However, it also highlights challenges related to information security, professional training, and high technological investments. Thus, Industry 4.0 represents not only a technological evolution but also an economic and social transformation that requires constant adaptation by companies and workers.

III. MATERIALS AND METHODS

The study was conducted as applied research, focusing on the development of a front-end interface for intelligent real-time production monitoring in the context of Industry 4.0. The proposal was directed at the system's production control module, taking into account the need to present data from machines, production orders, operational events, and industrial performance indicators in a visual, dynamic, and accessible manner. Applied research was adopted because it is directly related to solving a practical problem observed in the manufacturing environment: the difficulty of monitoring, in a centralized and real-time manner, the status of machines, production progress, operational deviations, and critical process alerts. Thus, the development of the frontend aimed to transform operational data into visual information useful for operators, supervisors, managers, and technical staff. Initially, the requirements of the production control module were analyzed, considering the main elements that should comprise the interface. Among these elements, the following stand out: an overview of the machines, monitoring of operational status, display of targets and daily production, calculation and presentation of indicators such as productivity, availability, quality, OEE, FPY, unplanned downtime, and real-time visibility, as well as the display of notifications and alerts based on criticality. Development was carried out incrementally, allowing features to be built, integrated, tested, and refined progressively. This approach enabled the gradual evolution of the system's screens, such as the main machine dashboard, the equipment metrics modal, the full-screen dashboard designed for display on TV, the notifications panel, and the email alert configuration interface. The use of incremental cycles facilitated continuous validation of components, the correction of visual inconsistencies, and the adaptation of the interface to the needs of the production environment. As with the overall system development, project management and incremental development principles already defined for the project were followed, including requirements gathering, software design, implementation, validation, testing, and evolutionary maintenance. In the specific case of the frontend, these stages were applied with an emphasis on the visual organization of screens, component layout, clarity of indicators, responsiveness, usability, and integration with the services provided by the backend.

III.1 METHODOLOGICAL PROCEDURES

As with the overall development of the system, we followed the project management and incremental development principles already established for the project, including requirements gathering, software design, implementation, validation, testing, and evolutionary maintenance. In the specific case of the frontend, these stages were applied with an emphasis on the visual organization of screens, component layout, clarity of indicators, responsiveness, usability, and integration with the services provided by the backend.

III.2 FRONTEND INTERFACE ARCHITECTURE

The frontend interface was designed as the presentation and interaction layer of the intelligent production system. Its function is to receive data processed by the backend and present it in a visually understandable way to end users. Thus, the frontend acts as a bridge between the industrial data processing layer and the users responsible for decision-making in the manufacturing environment. The interface architecture is organized into visual components, navigation pages, API communication services, and real-time update features. The visual components include indicator cards, tables, buttons, status badges, charts, gauges, event panels, modals, and configuration forms. The navigation pages organize these components into specific screens, such as the machine dashboard, the detailed view by equipment, the full-screen dashboard, and the notifications panel. Communication with the backend allows the interface to display up-to-date data on machine status, production orders, recent events, and operational indicators. This integration is essential so that the frontend functions not merely as a static display, but as a dynamic tool for monitoring and decision support. In industrial environments, this feature is important because production events can occur continuously and require a rapid response from the team. Figure 1 shows the general organization of the proposed frontend architecture for the production control module.

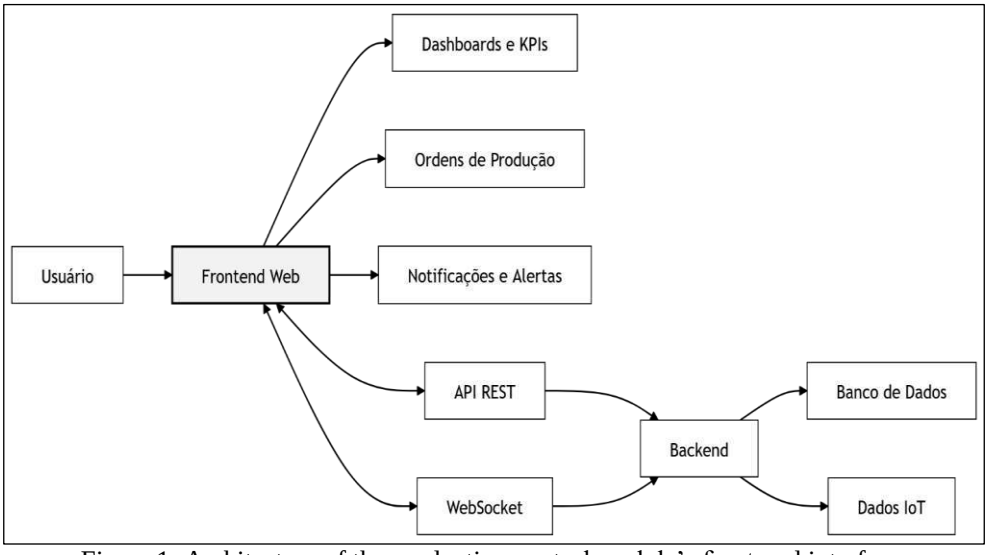

Figure 1: Architecture of the production control module's front-end interface.
Source: Authors, (2026).

III.3 TOOLS USED IN DEVELOPMENT

For the development of the front-end interface, tools were used to support coding, version control, task organization, and visual modeling. These tools made it possible to structure the development process, track the progress of features, and maintain control over changes made to the source code.

Table 1: Tools used in the development of the front-end interface.

Tool	Concept	Application in the project
Visual Studio Code	Source code editor with support for extensions, debugging, syntax highlighting, and version control integration.	Used as the primary development environment for the front-end interface, enabling the coding of components, screens, and communication services.
Git	A distributed version control system used to track changes to source code.	Used for code versioning, tracking development history, and facilitating collaboration among team members.
Draw.io	Tool for creating diagrams, flowcharts, and architectural models.	Used to create architectural diagrams, navigation flows, and visual representations of the system structure.
Trello	A task management tool based on grids and cards.	Used to track development tasks, interface adjustments, testing, and validation.
Navegador Web	An environment for running and viewing web applications.	Used to test the interface at different resolutions, validate responsiveness, navigation, data updates, and the visual behavior of components.

Source: Authors, (2026).

III.4 TECHNOLOGIES USED IN THE FRONTEND

The technologies used in frontend development were selected based on requirements for responsiveness, interactivity, API communication, real-time updates, and the visual presentation of industrial indicators. These technologies were chosen to enable the creation of a modular, scalable interface suitable for continuous production monitoring.

Table 2: Technologies used in the development of the frontend interface.

Tool	Concept	Application in the project
Vue.js	A JavaScript framework used to build reactive interfaces and single-page web applications.	Used in the development of screens for the production control module, including dashboards, tables, modals, notification panels, and interactive components.
TypeScript	A JavaScript superset that adds static typing to development.	Used to improve code organization, standardize data structures received from the backend, and reduce errors during integration between components.
Vue Router	The official routing library for Vue.js applications.	Used to organize navigation between the system's pages, such as machine dashboards, reports, management, and operational screens.
Axios	A JavaScript library used to make HTTP requests.	Used to communicate with backend APIs, enabling the retrieval of data on machines, metrics, production orders, events, and settings.
WebSocket	Real-time bidirectional communication protocol between client and server.	Used to receive automatic updates on machines, production, operational events, notifications, and alerts without having to manually refresh the page.
ECharts	JavaScript library for creating charts and data visualizations.	Used to display production metrics through charts and visual indicators, such as gauges for productivity, quality, availability, and OEE.
HTML5	A markup language used to structure web pages and applications.	Used to structure the visual elements of the interface, such as tables, buttons, forms, panels, and dashboard sections.

Source: Authors, (2026).

III.5 DEVELOPMENT OF THE PRODUCTION CONTROL MODULE SCREENS

The development of the screens was focused on creating a visual experience suitable for monitoring production in real time. To this end, the interface was organized into different levels of information, allowing users to view both an overview of the process and specific details about a machine or production order. The first level corresponds to the main machine dashboard. This screen displays cards with general indicators, a machine table, and a recent events panel. The top cards show information such as the number of active machines, average run time, average OEE, and total downtime. The central table presents operational data by machine, including production line, operator, status, daily target, parts produced, OEE, and available actions. This structure allows the user to quickly identify the overall status of the production process. The second level corresponds to the detailed view by equipment. By selecting a machine, the user has access to a metrics modal containing information such as runtime, notes, and performance indicators. The indicators are displayed via gauges, allowing for a quick readout of productivity, unplanned downtime, FPY, and real-time visibility. This approach facilitates individual analysis of each machine's performance. The third level corresponds to the full-screen dashboard, designed for display on televisions or monitors in a manufacturing environment. On this screen, the visual elements have been enlarged to make them easier to read from a distance. The dashboard displays information such as the machine being monitored, the production order, daily gross production, hourly target, percentage of target achieved, defects, hourly production, and side indicators for productivity, quality, availability, and OEE. The Production Order visualization interface was also developed, with a focus on tracking the production flow by machine and displaying the parameters associated with the execution of the PO.

This screen allows users to view information such as the order code, product to be manufactured, planned quantity, destination inventory, creation date, and completion status. In addition, the PO flow section displays the associated production process, the total order quantity, the cumulative official write-off points, the completion percentage, and operational alerts related to production progress. The interface also includes individual breakdowns by machine within the Production Order. In this feature, the user can view machine-specific parameters, such as PO quantity, total gross production, progress percentage, last closure, official release point indication, and production history by time. The hourly table displays gross production, actual cumulative total, cumulative total against the target, and the corresponding percentage of the PO. This functionality was incorporated into the frontend to enhance production traceability and allow operators and managers to track the order's progress not only in aggregate but also by machine and by execution period. The adjustments made to this interface were intended to improve the clarity of information related to production closure, surplus after the target is met, and the comparison between actual progress and the official progress of the production order. As a result, the frontend now provides visual support not only for monitoring general indicators but also for interpreting the production flow and the operational rules applied during order execution.In addition to the monitoring screens, notification and alert features were developed. The notifications panel displays recent system events, such as the automatic completion of production orders and alerts related to specific machines. Alerts are classified by severity level, using colors and icons to facilitate visual identification. A screen for configuring email alerts was also implemented, allowing users to define recipients and sending intervals based on the severity of the event.

III.6 INTERFACE VALIDATION CRITERIA

The front-end interface was validated based on functional, visual, and operational criteria. Functional tests were conducted to verify that the application components performed their actions correctly, including opening modals, loading data, changing filters, displaying notifications, navigating between screens, and updating indicators. The visual criteria considered the readability of information, the hierarchy of elements, color consistency, the appropriate use of icons, the distribution of components on the screen, and the differentiation between operational states.

In industrial dashboards, these aspects are fundamental for the user to quickly interpret the production status and identify events that require attention. The interface's responsiveness was also evaluated, considering its use on different screen sizes, including conventional monitors, laptops, and televisions used for full-screen display. In the case of the TV-based dashboard, readability from a distance was prioritized, with larger elements, centralized information, and visual indicators that are easy to interpret. Another criterion evaluated was the real-time updating of information. The interface was assessed for its ability to reflect changes in operational data, such as updates to indicators, completion of production orders, changes in machine status, and the generation of alerts. This criterion was considered essential for validating the application's behavior in a continuous monitoring scenario. Finally, usability aspects were analyzed, such as ease of navigation, clarity of labels, button organization, ease of access to detailed information, and comprehensibility of alerts. The validation demonstrated that the developed interface is well-suited to support real-time production monitoring, providing organized and visually accessible information to system users.

IV. RESULTS AND DISCUSSIONS

The development of the front-end interface resulted in a functional production control module, consisting of dashboards, operational tables, visual indicators, screens for tracking production orders, notification panels, and alert configuration features. The developed solution enabled the centralization of relevant production process information within a web application, facilitating real-time monitoring of machines, order progress, and key industrial indicators. The interface was designed to transform operational data into visual information accessible to system users. Thus, the frontend began to act as a layer for interpreting and presenting the data processed by the application, allowing operators, supervisors, and managers to monitor production in a clearer, more dynamic, and organized manner. The results obtained are presented in the following subsections, according to the main functionalities developed.

IV.1 MAIN MACHINE DASHBOARD

Figure 2 shows the main machine dashboard of the production control module. This screen provides an overview of operations, displaying key metrics related to the number of active machines, average cycle time, average OEE, and total downtime. Below these indicators, the interface displays a table of registered machines, containing information such as production line, operator, operational status, daily target, parts produced, OEE, and actions available for detailed viewing.

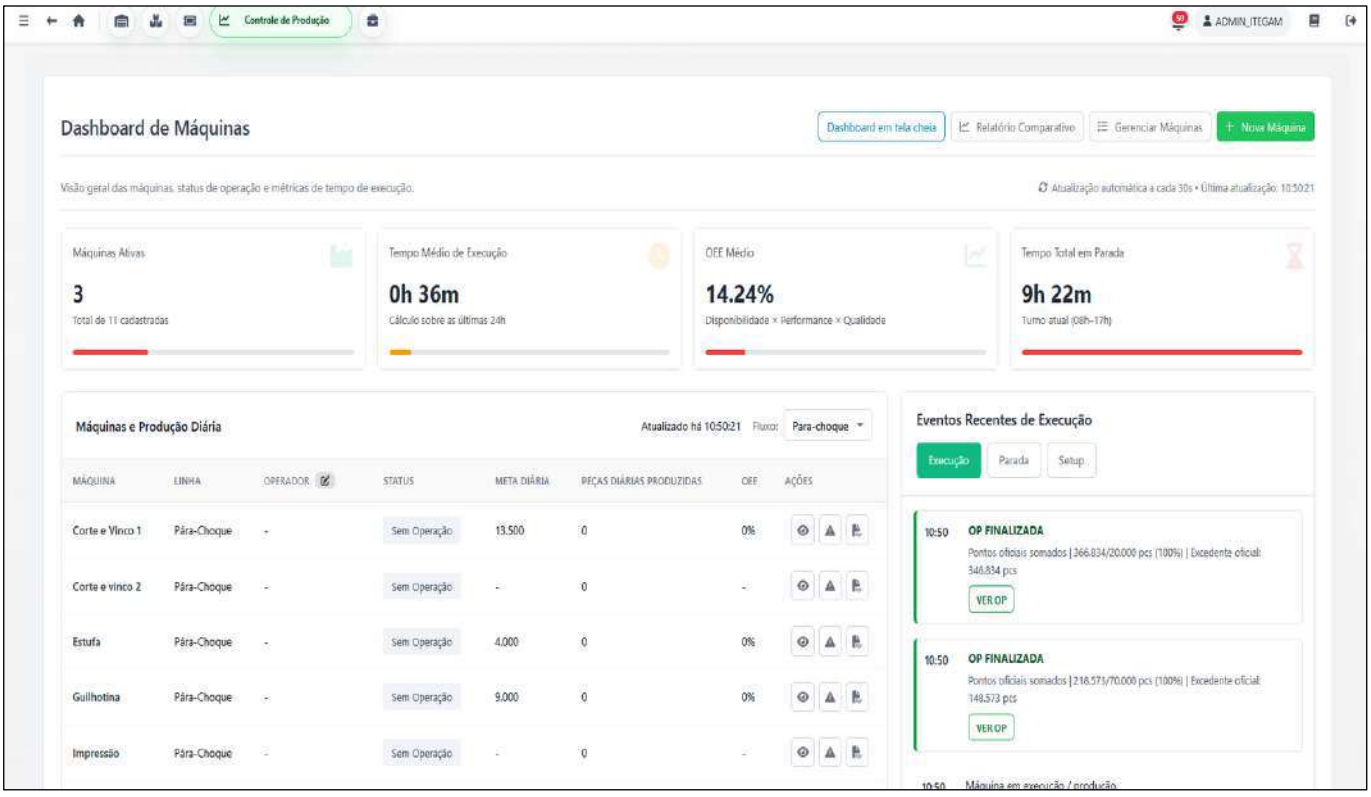

Figure 2: Main dashboard of the production control module, featuring general metrics, a machine table, and recent events.
Source: Authors, (2026).

The layout of the main dashboard has helped consolidate, on a single screen, information that was previously scattered across different queries or operational records. The top cards facilitate a quick overview of key indicators, while the table allows for an individual analysis of registered machines. The presence of filters by production flow also makes it possible to restrict the view to a specific process, making the query more appropriate to the context of use for the operator, supervisor, or manager. The use of colors, status badges, and visual bars helped differentiate operational states. Machines not in operation, machines in operation, and alert situations became easier for the user to identify. This feature is relevant in production environments, where the rapid interpretation of machine status can reduce response time in the face of downtime, failures, or production deviations.

In addition, the main dashboard features a recent events area, allowing users to track occurrences related to execution, downtime, and setup. This functionality helps increase the traceability of actions and facilitates the identification of relevant events within the production flow.

IV.2 INDIVIDUAL MACHINE METRICS

Figure 3 shows the individual machine performance metrics screen. This feature was developed to enable a more detailed analysis of a piece of equipment selected on the main dashboard. The screen displays information such as the operator, runtime, notes, and machine-specific indicators.

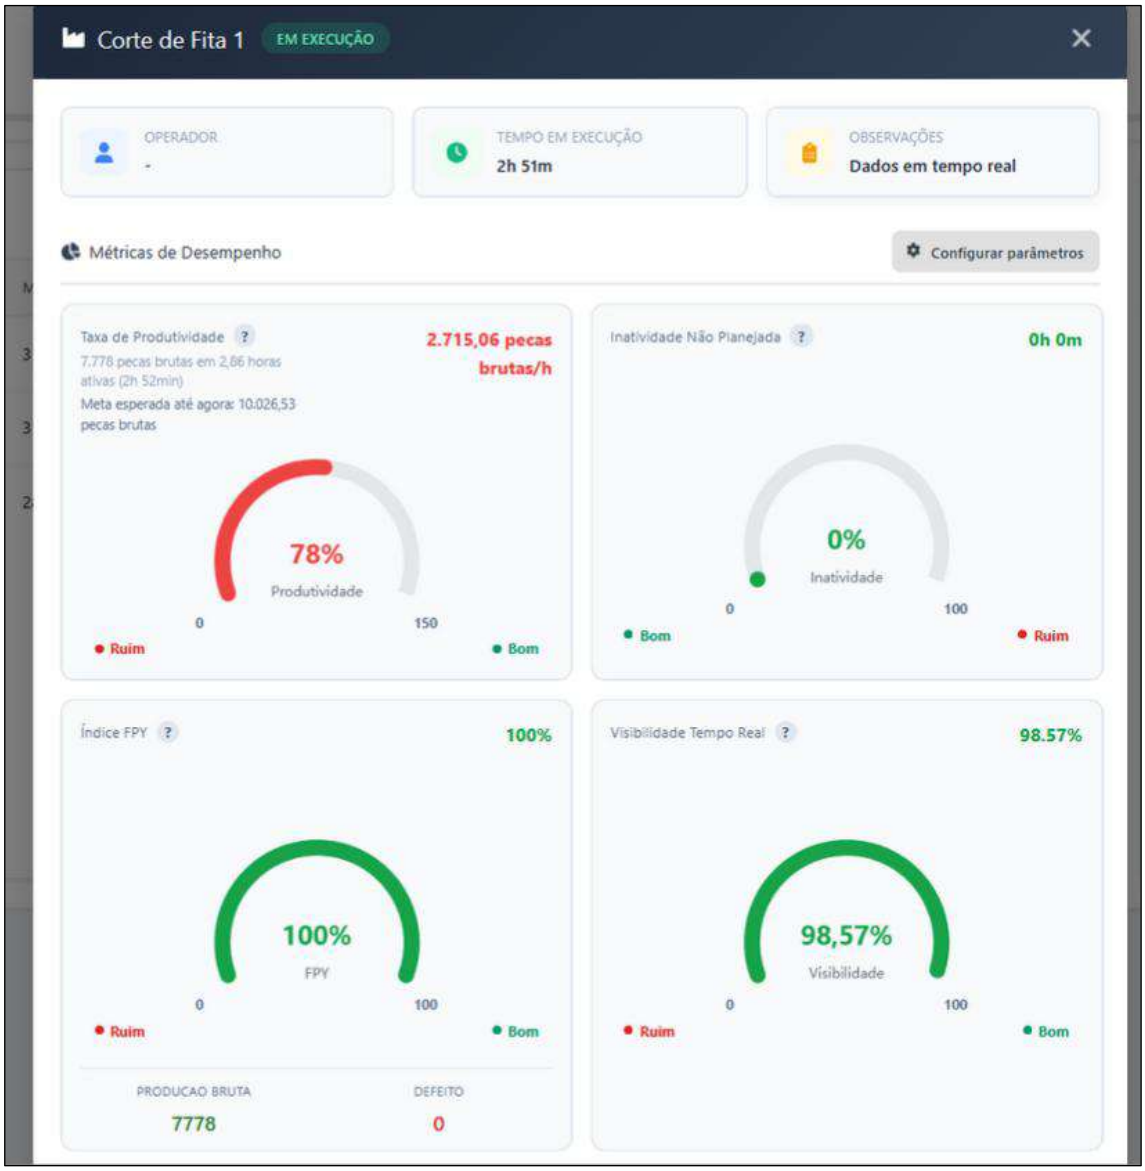

Figure 3: Individual machine performance dashboard showing real-time indicators for productivity, downtime, FPY, and visibility.
Source: Authors, (2026).

The indicators were presented using gauge-style visual meters, including productivity rate, unplanned downtime, FPY index, and real-time visibility. This format proved suitable for displaying percentage and operational indicators, as it allows users to quickly determine whether a given value falls within or outside the expected range. In the example shown, the interface displays productivity, downtime, FPY, and real-time visibility on separate cards, allowing each indicator to be analyzed individually. This visual separation prevents information overload and facilitates the identification of critical points. While the main dashboard offers an overview of production, the individual breakdown allows for observing the specific performance of each piece of equipment, enabling more targeted analyses. In this way, the metrics modal has helped make the interface more analytical, allowing the user to switch from a general view of the process to a specific machine view. This strengthens the role of the frontend as a tool to support operational supervision and not merely as a data display panel.

IV.3 FULL-SCREEN DASHBOARD FOR MANUFACTURING ENVIRONMENTS

Figure 4 shows the full-screen dashboard, developed for display on televisions or industrial monitors. This screen was designed for use on the factory floor, prioritizing larger elements, high visual contrast, and readability from a distance.

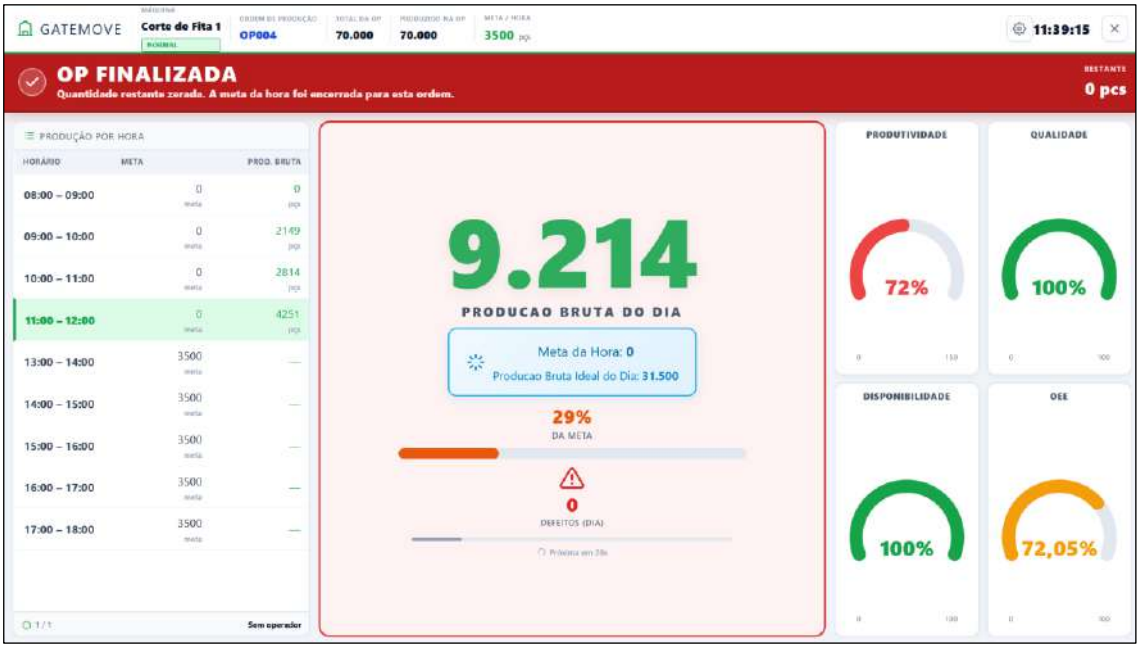

Figure 4: Full-screen dashboard for monitoring production in a manufacturing environment.
Source: Authors, (2026).

The dashboard displays information such as the monitored machine, production order, total planned quantity, gross daily production, target achievement percentage, number of defects, hourly production, and side indicators for productivity, quality, availability, and OEE. This organization allows operators and supervisors to monitor production progress without relying on manual reports or consulting more detailed screens. The full-screen mode represents one of the main outcomes of the interface, as it allows critical information to be continuously displayed within the production environment. The screen centralizes the gross daily production value, highlighting it as the primary information. Around this indicator, complementary elements are organized, such as hourly production, hourly target, percentage of target achieved, and performance indicators. The hourly production table makes it possible to identify periods with production, absence of production, or variations in relation to the target. Meanwhile, the side indicators provide a summarized view of productivity, quality, availability, and OEE. Thus, the full-screen dashboard contributes to increasing the visibility of the production process, making information accessible in real time to users present in the manufacturing environment.

IV.4 PRODUCTION ORDER MONITORING

Another relevant result was the implementation of the Production Order visualization screen. Figure 5 presents the interface developed for consulting the general PO data and monitoring the production flow.

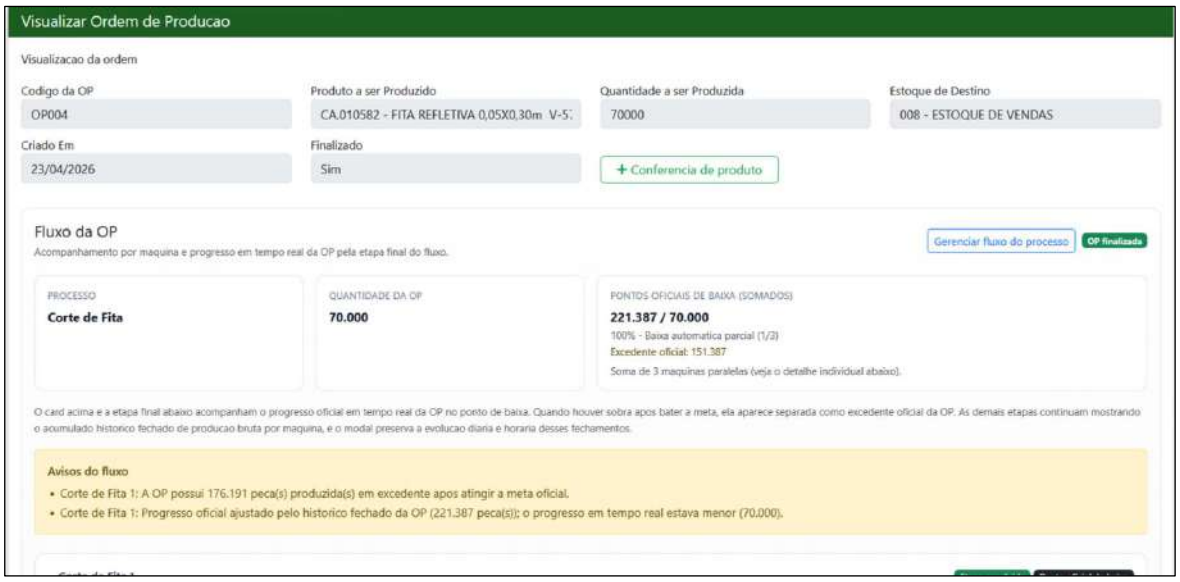

Figure 5: Production Order visualization interface with production flow monitoring.
Source: Authors, (2026).

This screen displays information such as the order code, product to be manufactured, planned quantity, destination stock, creation date, and completion status. In the PO flow section, the associated production process, total order quantity, summed official reporting points, completion percentage, and operational warnings related to production progress are presented.

The Production Order screen expanded the frontend's traceability capabilities, as it allowed production progress to be monitored not only from the machine perspective but also from the perspective of the executed order. This feature is important because the PO represents a central control unit in the production process, connecting the product, planned quantity, involved machines, production reporting, and stage completion. The PO flow section proved especially relevant for interpreting the order's progress. The interface displays the official reporting points, indicates when the PO has been completed, and shows warnings related to excess production or adjustments in official progress. These warnings help the user understand situations in which the recorded production exceeds the planned target or when official progress is adjusted based on closed historical records. Thus, the interface no longer displays only numerical values but also contextualizes the data according to the applied operational rules. This functionality makes the visualization more understandable for the user and reduces the need for manual interpretation of production records.

IV.5 PRODUCTION PARAMETERS BY MACHINE

Figure 6 presents the machine production detail modal within the Production Order. This screen displays machine-specific parameters in the context of the PO, such as order quantity, total gross production, PO percentage, last closing, and indication of the official reporting point.

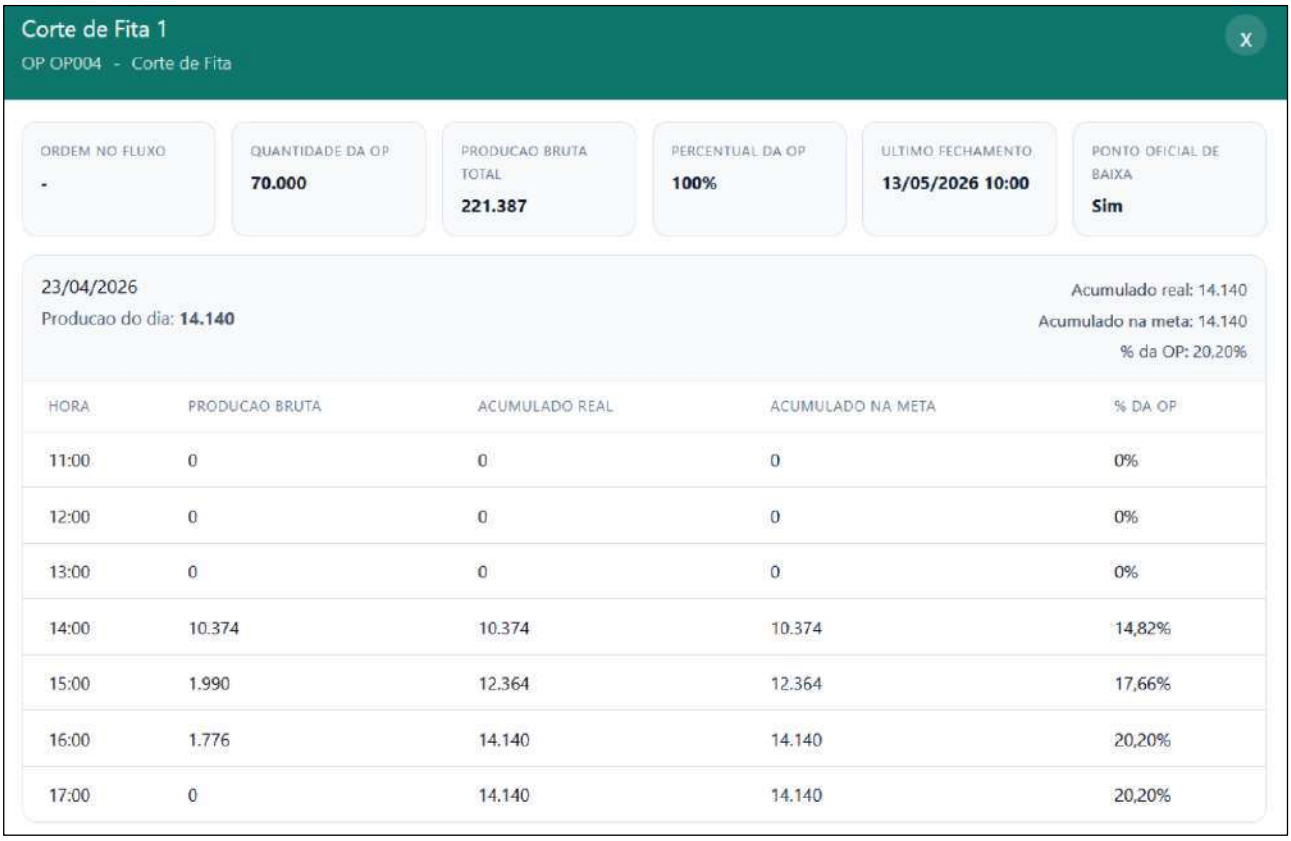

Figure 6: Machine production detail modal with Production Order parameters and hourly history.
Source: Authors, (2026).

In addition to the general parameters, the interface presents an hourly history table containing gross production, actual accumulated production, accumulated production considered toward the target, and the corresponding percentage of the order. This machine-level detail was an important result for monitoring PO execution, as it allows analysis of how each piece of equipment contributed to the order's progress over time. The hourly table makes it possible to observe production evolution during different periods of the shift, identifying hours with higher or lower production. It also allows comparison between the actual accumulated production and the accumulated production considered for the target, supporting data verification and the analysis of possible discrepancies between recorded production, valid production, and the official progress of the PO. The display of the last closing and the official reporting point contributes to production traceability. These fields help clarify which records were considered in the official PO progress and which values correspond to accumulated production. In this way, the frontend provides a more transparent visualization of production closing and reporting rules, supporting operational analysis and result verification. This functionality also reinforces the importance of the frontend as a support layer for production control. By enabling visualization of PO parameters by machine, the interface brings technical production process data closer to the users' daily monitoring routine, making it easier to identify inconsistencies, excess production, and actual production progress.

IV.6 NOTIFICATION PANEL AND RECENT EVENTS

In addition to the dashboards and monitoring screens, a notification panel was developed to display recent system events. Figure 7 presents this feature, where notifications of completed POs, critical alerts, and medium-level alerts associated with specific machines are displayed.

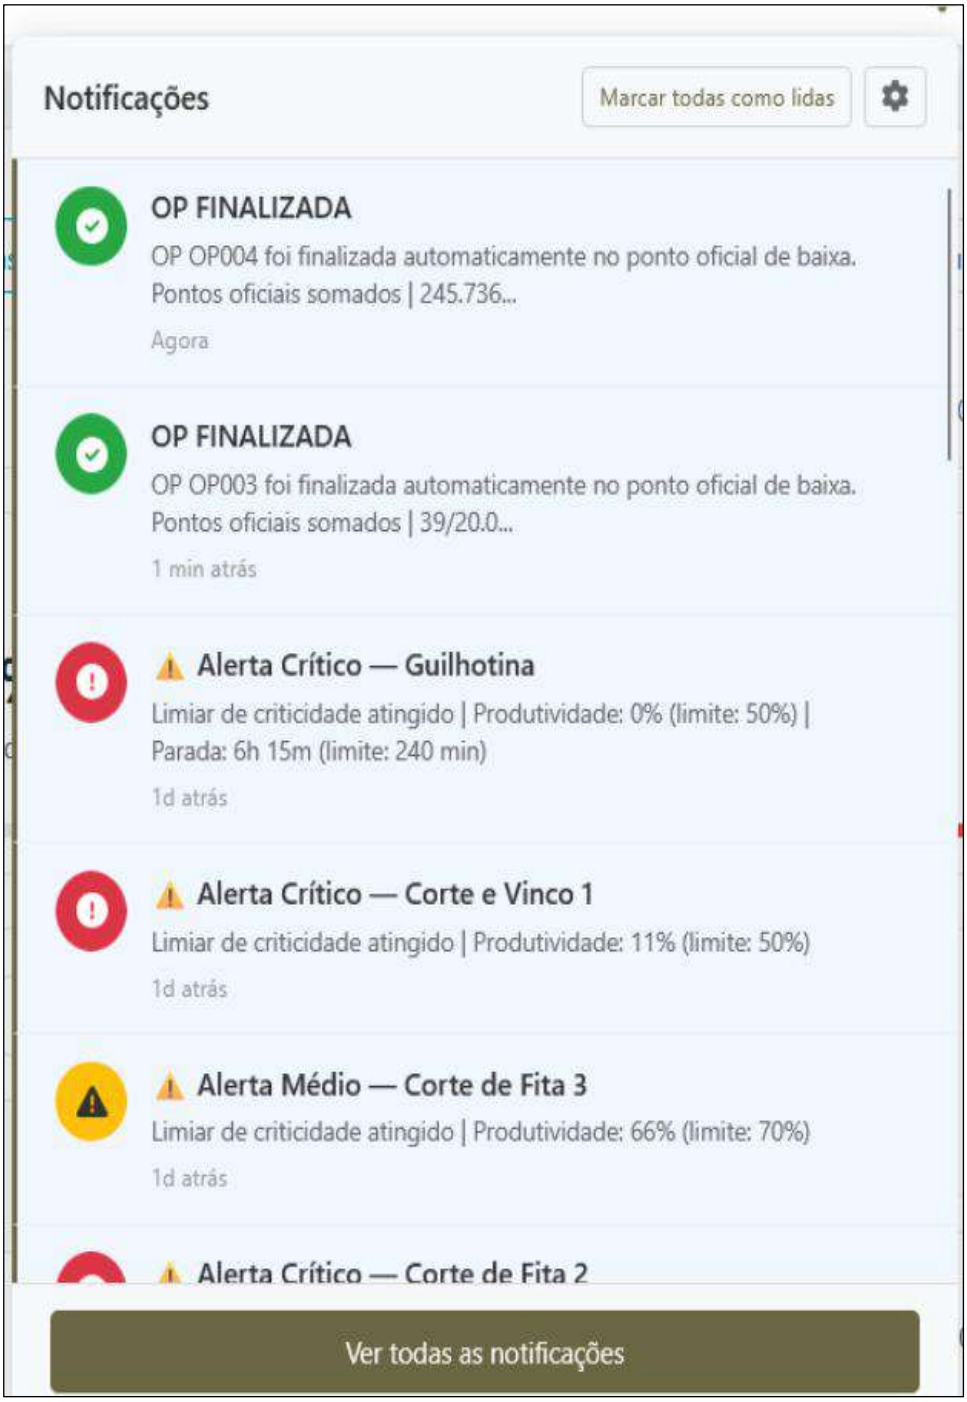

Figure 7: Notification panel with recent events and operational alerts.
Source: Authors, (2026).

The notifications are organized with icons, colors, and descriptive messages, allowing differentiation between positive events, warning situations, and critical occurrences. This feature contributed to making the frontend more active in production supervision. Instead of being limited to the presentation of static indicators, the interface began highlighting relevant events generated by the system. Among the displayed events are notifications of automatic completion of production orders, alerts related to criticality thresholds, and warnings associated with specific machines. This behavior supports rapid team response to situations requiring attention, such as low productivity, excessive downtime, or events related to the production flow. The use of different visual alert levels facilitates the prioritization of occurrences. Critical alerts are highlighted with greater visual intensity, while completed PO notifications are displayed with a positive indication. This differentiation helps users quickly understand the nature and urgency of the event, contributing to more efficient supervision.

IV.7 E-MAIL ALERT CONFIGURATION

Figure 8 presents the e-mail alert configuration interface. This feature allows recipients to be defined for different criticality levels, such as critical, high, medium, and low, in addition to configuring the cooldown interval for each type of alert.

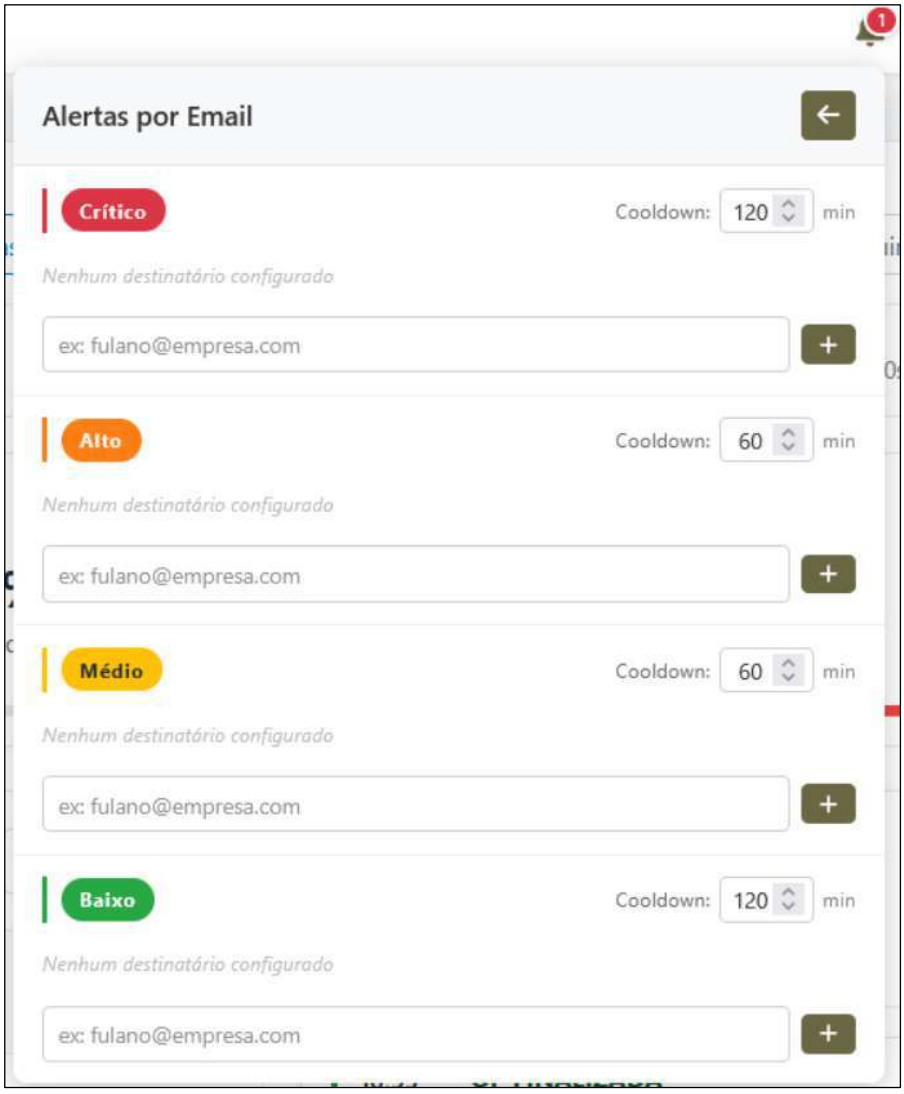

Figure 8: E-mail alert configuration interface according to criticality level.
Source: Authors, (2026).

The e-mail alert configuration expanded the operational reach of the frontend, as it enabled critical events to be communicated even outside the direct visualization of the dashboard. Defining recipients according to criticality level makes communication more organized, allowing higher-severity alerts to be forwarded to those responsible for decision-making or technical intervention. The cooldown feature helps reduce operational noise by preventing multiple notifications from being sent within a short period for the same condition. This adjustment is important in industrial environments, where repetitive events may generate excessive notifications and make it more difficult to prioritize truly critical occurrences. With this functionality, the interface came to encompass not only data visualization but also the configuration of operational communication rules. This demonstrates that the developed frontend acts as a layer of interaction and system parameterization, allowing users to adapt alert behavior according to operational needs.

IV.8 GENERAL ANALYSIS OF THE RESULTS

Overall, the results demonstrated that the developed frontend interface achieved the objective of transforming industrial data into useful visual information for monitoring and decision-making. The combination of cards, tables, gauges, full-screen dashboards, Production Order screens, machine parameters, notifications, and alert configuration made it possible to address different levels of analysis: overall production overview, equipment-level detail, PO monitoring, TV-based supervision, and event management. The solution also demonstrated adherence to Industry 4.0 principles, especially regarding connectivity, process digitalization, system integration, and real-time monitoring. The developed frontend materializes this proposal by providing interfaces capable of representing machines, orders, indicators, and events in a centralized and understandable manner. Another observed aspect was the interface's contribution to system usability. Dividing the information into specific screens reduced the complexity of analysis and facilitated the interpretation of production data. The main dashboard provides a summarized production overview; the modals enable detailed analysis; the full-screen dashboard supports shop-floor usage; the Production Order screens enhance traceability; and the alerts support responses to critical events. Finally, the developed module contributed to increasing operational visibility of production, allowing operators, managers, and technical teams to monitor machine performance, order progress, recent events, and criticality alerts. The interface also proved suitable for different usage contexts, including workstation consultation, detailed modal analysis, and full-screen monitoring in the manufacturing environment. Therefore, the developed frontend does not act merely as a display layer, but as a strategic component for supervision, traceability, and decision-making support within the intelligent manufacturing system.

V. CONCLUSIONS

The development of the frontend interface for intelligent real-time production monitoring demonstrated the importance of the visual and interactive layer in industrial systems within the context of Industry 4.0. The developed solution enabled the centralization of relevant operational information, such as machine status, performance indicators, Production Order progress, production parameters by equipment, recent events, and critical alerts, making industrial data more accessible and understandable for operators, supervisors, and managers. The presented results showed that the dashboards, tables, gauges, Production Order monitoring screens, notification panel, and e-mail alert configuration contributed to increasing the visibility of the production process and supporting real-time decision-making. The full-screen dashboard, intended for use in the manufacturing environment, also proved relevant by facilitating continuous production monitoring through objective and easy-to-read information.Thus, it can be concluded that the developed frontend does not act merely as a data presentation layer, but as a strategic component for production supervision, traceability, and operational control. The proposed interface strengthens the integration between users and the intelligent system, contributing to greater agility in identifying deviations, improving operational communication, and advancing digital transformation in the industrial environment.

ABSTRACT

The development of intelligent machine parameterization systems represents a significant advancement in the context of Digital Transformation and Industry 4.0, promoting greater efficiency, productivity, and autonomy in industrial processes. In this scenario, the integration of Artificial Intelligence (AI), the Internet of Things (IoT), and automated systems enables the creation of solutions capable of monitoring, analyzing, and adjusting operational parameters in real time. The objective of this work is to develop an intelligent machine parameterization system using Artificial Intelligence techniques to optimize industrial processes, reduce operational failures, and improve decision-making in the manufacturing environment. For this purpose, an integrated system was implemented. The adopted methodology was based on the application of IoT sensors to collect operational data from machines, combined with machine learning algorithms for predictive analysis and automatic parameter adjustment through a collector installed in an integrated and automated manner. The system was structured within an integrated architecture, allowing real-time communication between equipment, databases, and an intelligent monitoring platform. The obtained results demonstrated an increase in operational efficiency, a reduction in machine setup time, a decrease in human errors, and an improvement in the quality of production processes. Furthermore, a greater capacity for machine adaptation to variable production conditions was observed. The conclusion highlights that the use of intelligent systems based on AI and IoT significantly contributes to industrial modernization, making processes more autonomous, efficient, and aligned with the principles of Industry 4.0, thereby strengthening competitiveness and technological innovation within organizations.

I. INTRODUCTION

Digital transformation has promoted significant changes in industrial processes, driving the adoption of advanced technologies focused on automation, connectivity, and operational intelligence. In this context, Industry 4.0 emerges as a new production paradigm, characterized by the integration of cyber-physical systems, the Internet of Things (IoT), Artificial Intelligence (AI), cloud computing, and real-time data analysis. These technologies enable greater efficiency, flexibility, and autonomy in industrial environments, contributing to increased competitiveness and technological innovation within organizations [1-3]. Among the main challenges faced by modern industry is the need to optimize machine parameterization, a fundamental process to ensure quality, productivity, and waste reduction in production. Inadequate parameterization can lead to operational failures, increased energy consumption, low production efficiency, and a higher incidence of human errors. In this scenario, the development of intelligent systems capable of automating and optimizing machine configuration becomes a strategic alternative for industrial modernization [4-7].

The development of an intelligent machine parameterization system using Artificial Intelligence represents an important contribution to the advancement of Industry 4.0. The application of intelligent algorithms makes it possible to analyze large volumes of data collected in real time by IoT sensors installed on industrial equipment, enabling the identification of operational patterns, prediction of failures, and automatic adjustment of machine parameters according to production conditions. This integration between AI and IoT promotes greater operational accuracy, reducing dependence on human intervention and increasing the reliability of production processes. Furthermore, the use of intelligent systems provides significant gains related to operational efficiency, cost reduction, product quality improvement, and increased machine availability. The connectivity provided by IoT enables continuous equipment monitoring, facilitating data-driven decision-making and supporting predictive maintenance strategies. In this way, organizations begin to operate in a smarter, more dynamic, and integrated manner, aligning themselves with the demands of digital transformation [8-11]. The relevance of this study is directly related to the growing need for industries to adopt innovative technological solutions capable of making production processes more efficient and sustainable. The proposal of an intelligent machine parameterization system contributes to strengthening industrial automation and to the evolution of traditional production models, promoting greater integration between humans, machines, and digital systems. Consequently, the innovation of this research lies in the development of a technological solution capable of combining Artificial Intelligence, IoT, and industrial automation within an integrated real-time environment, providing greater autonomy to machines and expanding the adaptability of industrial processes to market demands. Thus, the study reinforces the importance of digital transformation as an essential element for the advancement of Industry 4.0 and for the development of smarter, more connected, and more efficient industrial systems.

II. THEORETICAL REFERENCE

II.1 INTELLIGENT SYSTEM FOR MANUFACTURING

Intelligent systems applied to manufacturing have played a fundamental role in the modernization of industrial processes, especially in production environments that require high precision, speed, and quality, such as tape-cutting factories. With the advancement of Industry 4.0, companies have increasingly invested in technologies capable of automating processes, reducing waste, and increasing operational efficiency. In this context, intelligent systems emerge as innovative solutions that integrate Artificial Intelligence (AI), the Internet of Things (IoT), industrial sensors, and real-time data analysis to optimize machine operation and improve decision-making within the industrial environment [12-15]. In a tape-cutting factory, the production process requires a high level of control over parameters such as width, length, cutting speed, material tension, and spool alignment. Small errors in these parameters can result in raw material waste, failures in the final product quality, and increased operational costs. Therefore, the use of intelligent systems makes it possible to automate the parameterization of cutting machines, making processes more precise, safe, and efficient. The application of Artificial Intelligence in this industrial environment enables systems to learn from data collected during production. Sensors installed on the machines continuously monitor operational variables such as temperature, vibration, speed, and motor performance. This information is sent to intelligent platforms that analyze the data in real time, identifying patterns and automatically adjusting machine parameters whenever necessary. This process significantly reduces the need for manual intervention and minimizes operational errors [16], [17].

Another important aspect is the use of the Internet of Things (IoT), which promotes connectivity among equipment, systems, and operators. In a tape-cutting factory, IoT enables remote machine monitoring, facilitating production tracking and industrial operation management. In addition, connectivity allows the implementation of predictive maintenance strategies, in which failures can be identified before they occur, reducing unexpected downtime and increasing equipment availability [14], [18]. Intelligent systems also directly contribute to improving the quality of manufactured products. Precision in controlling cutting parameters ensures greater standardization of the produced tapes, reducing rework and waste. Furthermore, intelligent automation provides greater production flexibility, enabling rapid adjustments in machine settings according to different production demands. The implementation of these technologies represents an important advancement in the digital transformation process of industries. Companies that adopt intelligent systems can increase market competitiveness, reduce operational costs, and improve the efficiency of production processes. In addition, the use of solutions based on Artificial Intelligence and IoT supports industrial sustainability, as it reduces material waste, energy consumption, and operational failures [12-15]. Therefore, intelligent systems applied to manufacturing in tape-cutting factories represent an innovative solution aligned with the principles of Industry 4.0. The integration of automation, Artificial Intelligence, and industrial connectivity provides greater efficiency, quality, and reliability in production processes, contributing to the development of more modern, intelligent, and competitive industries.

II.2 MACHINE PARAMETERIZATION

Machine parameterization is a fundamental process in industrial automation and consists of configuring operational parameters required to ensure the proper functioning of equipment and production systems. These parameters may include speed, temperature, pressure, operating time, alignment, force, tension, among other factors that directly influence the efficiency, quality, and safety of industrial processes. Proper parameterization allows machines to operate in an optimized manner, reducing failures, waste, and operational costs. One of the main characteristics of machine parameterization is the ability to adapt equipment operation according to the specific needs of each production process. In modern industrial environments, different products require distinct configurations, making machine flexibility essential to meet production variations. In this way, parameterization enables fast and accurate adjustments, contributing to higher productivity and reduced setup time[19-21]. Another important characteristic is the automation of operational parameters through intelligent systems. With the advancement of Industry 4.0, technologies such as Artificial Intelligence (AI), the Internet of Things (IoT), and intelligent sensors have been integrated into industrial systems, allowing machines to perform automatic real-time adjustments. These systems continuously monitor equipment performance, collecting operational data and identifying patterns that support decision-making and the optimization of production processes [22-25]. Precision is also an essential characteristic of machine parameterization. Small errors in parameters can compromise the final quality of products, resulting in raw material waste, rework, and financial losses.

Therefore, modern systems use control and monitoring software capable of ensuring high reliability in operational configurations, significantly reducing the occurrence of human errors. The applications of machine parameterization are broad and present across various industrial sectors. In the manufacturing industry, for example, parameterization is used in cutting, machining, welding, and automated assembly machines. In the food industry, parameters control temperature, cooking time, and production speed. In the textile industry, parameterization ensures precision in cutting, sewing, and finishing processes [19], [24-26]. In addition, parameterization is widely applied in robotic systems and automated production lines, where different equipment must operate synchronously and efficiently. Integration with intelligent systems enables greater control of industrial processes, supporting predictive maintenance, reducing energy consumption, and promoting continuous production improvement. Therefore, machine parameterization represents a strategic element for industrial modernization, contributing to more efficient and safer processes aligned with the principles of digital transformation and Industry 4.0.

II.3 DIGITAL TRANSFORMATION AND INDUSTRY 4.0

Digital Transformation and Industry 4.0 represent one of the greatest technological and organizational changes of the modern era, promoting the integration of digital technologies, automation, and computational intelligence into the production and administrative processes of companies. These changes have impacted various sectors of the economy, especially industry, making processes more efficient, connected, and intelligent. Digital Transformation is related to the strategic use of digital technologies to improve operations, products, services, and business models, while Industry 4.0 corresponds to the application of these technologies within the industrial environment. One of the main characteristics of Digital Transformation is the digitalization of processes, enabling information to be collected, stored, and analyzed in real time. Technologies such as cloud computing, Big Data, Artificial Intelligence (AI), the Internet of Things (IoT), and industrial automation are widely used to increase operational efficiency and improve decision-making. Furthermore, connectivity among systems and equipment allows greater integration between sectors, promoting agility and cost reduction [27-29]. Industry 4.0, also known as the fourth industrial revolution, is mainly characterized by the integration between physical and digital systems through cyber-physical systems. In this industrial model, machines, sensors, and software operate in a connected and intelligent manner, enabling continuous monitoring of production processes. Another important characteristic is advanced automation, in which machines can make automatic decisions based on data collected in real time.

Production flexibility also stands out in Industry 4.0. Smart factories can quickly adapt their production lines to market demands, increasing product customization and reducing waste. In addition, predictive maintenance is a relevant application, enabling the identification of possible failures before they occur, reducing unexpected downtime and increasing equipment availability. The applications of Digital Transformation and Industry 4.0 are present in several industrial sectors. In manufacturing, for example, they are used in automated production systems, industrial robotics, intelligent machine control, and remote process monitoring. In logistics, digital technologies enable real-time product tracking and optimization of transportation and storage. In the energy sector, intelligent sensors assist in consumption control and energy efficiency. These technologies contribute to improving product quality, reducing operational costs, and increasing business competitiveness. The integration of Artificial Intelligence, IoT, and automation promotes smarter, safer, and more sustainable industrial environments [27], [29-31]. Therefore, Digital Transformation and Industry 4.0 represent a significant advancement in industrial modernization, promoting innovation, connectivity, and efficiency in production processes. These technologies make organizations better prepared to face the challenges of the global market and drive the development of smart and highly automated factories.

III. MATERIALS AND METHODS

The method employed in this work was based on an applied, incremental, and multidisciplinary approach for the development of an industrial IoT architecture aimed at monitoring operational variables in smart manufacturing environments aligned with the principles of Industry 4.0. The development process was structured into integrated stages involving requirements gathering, system architecture modeling, embedded hardware development, firmware implementation, communication infrastructure, data persistence, and experimental validation in a real industrial environment. Initially, requirements engineering and analysis of the industrial environment were conducted, involving the mapping of production processes, identification of the monitored machines, and definition of the operational variables relevant to the data acquisition system. At this stage, aspects related to electrical infrastructure, electromagnetic conditions of the environment, instrumentation points, connectivity requirements, and operational constraints of the industrial process were evaluated. In parallel, the production flow was modeled, enabling the definition of the functional architecture of the IoT solution, as well as the integration requirements among the hardware modules, firmware, and computational backend.

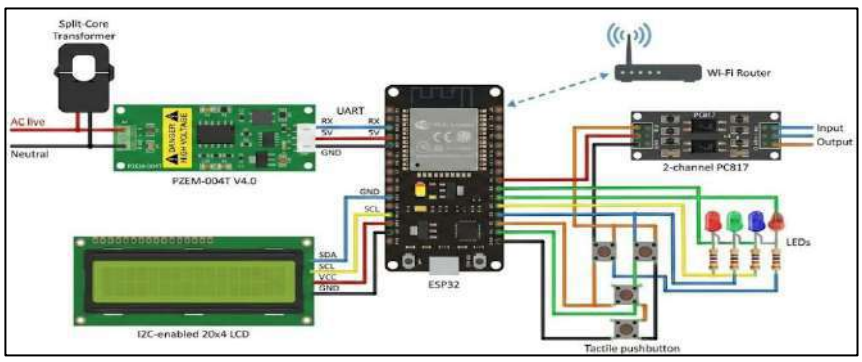

Figure 1: Collector Architecture.
Source: Authors, (2026).

At the hardware layer, an embedded IoT collector was designed and developed for the continuous acquisition of electrical quantities and production variables from industrial machines. The electronic architecture of the prototype incorporated power supply subsystems, analog signal conditioning, electrical isolation, protection against surges and electromagnetic interference, as well as serial communication interfaces and voltage and electric current sensing modules. The electronic design was conceived considering industrial robustness criteria, electromagnetic compatibility, operational reliability, and scalability for future industrialized versions of the device. The embedded firmware was developed in the C programming language due to its high computational efficiency, low memory overhead, and compatibility with real-time applications in microcontroller-based systems. Dedicated routines were implemented for analog signal acquisition, digital filtering, metrological calibration, local processing of monitored variables, and periodic data transmission to the central server. Additionally, communication management mechanisms, fault handling, and automatic network reconnection features were incorporated in order to increase the operational reliability of the IoT system in industrial environments. In the computational infrastructure, a backend architecture based on Node.js was implemented using a service-oriented model and asynchronous communication for receiving, processing, and managing data from the embedded collectors. This approach enabled high scalability, modularity, and efficiency in handling continuous industrial telemetry streams in near real time.

For data persistence, the PostgreSQL database management system was used, selected due to its transactional robustness, referential integrity, and high capacity for storing and processing large volumes of industrial data. The database modeling was structured in a normalized manner, enabling historical traceability, information consistency, and support for the future application of analytical techniques and industrial data mining. Additionally, a provisioning and device-enablement interface for IoT devices within the industrial network infrastructure was developed, allowing secure authentication, Wi-Fi connectivity configuration, operational parameterization, and remote management of the collectors. This functionality significantly contributed to reducing the complexity of installation, maintenance, and lifecycle management of field devices. Finally, the experimental validation of the solution was conducted through the deployment of IoT collectors on real industrial machines, enabling the evaluation of communication stability, integrity of transmitted data, embedded system performance, and operational robustness under adverse factory environment conditions, including electrical noise and electromagnetic interference typical of industrial applications.

IV. RESULTS AND DISCUSSIONS

The experimental results obtained demonstrated the technical and operational feasibility of the proposed IoT architecture for industrial monitoring applications in smart manufacturing environments. The developed solution showed a high integration capability among the embedded hardware subsystems, communication infrastructure, and data persistence layer, enabling continuous acquisition, distributed processing, and reliable real-time transmission of the monitored variables. The implementation of the database architecture constituted a fundamental stage for the consolidation of the platform, being responsible for the storage, organization, and management of telemetry information from the IoT collectors installed on the monitored machines. The structure was designed to support the continuous recording of electrical and operational variables, including voltage, current, operational status of the devices, connectivity parameters, collector identification, and temporal information related to data acquisition. The relational modeling was developed using the PostgreSQL database management system, adopting principles of normalization, referential integrity, and transactional consistency. This approach enabled the construction of a robust and scalable architecture capable of ensuring temporal traceability, storage reliability, and efficient management of the large volume of data continuously generated by the embedded devices distributed throughout the industrial environment.

Figura 2: Table.
Source: Authors, (2026).

Figure 2 presents the structure of the main telemetry data storage table used in the developed platform. The organization of the attributes responsible for identifying the collector devices, storing the monitored electrical variables, communication parameters, and temporal records of the performed measurements can be observed. The adopted structural standardization favored the integration between the data acquisition layer and the application backend, in addition to optimizing query processes, historical analysis, and analytical processing of operational information. The implemented computational architecture presented satisfactory performance regarding the persistence and retrieval of industrial telemetry data, maintaining information integrity even under simultaneous operation of multiple IoT devices. The conducted tests demonstrated stability in communication between the embedded modules and the backend infrastructure, showing low latency, reliability in data packet transmission, and automatic reconnection capability under typical industrial operating conditions. The proposed structure was designed with a focus on interoperability and future platform expansion, enabling integration with supervisory systems, predictive analysis tools, applications based on Artificial Intelligence, and advanced data mining techniques. In this way, the developed solution establishes a consistent technological foundation for applications aligned with the paradigms of Industry 4.0, contributing to the advancement of intelligent architectures aimed at industrial monitoring and the digital transformation of manufacturing environments. The communication tests between the embedded collectors and the backend infrastructure confirmed stability and reliability in the transmission of operational data. The system demonstrated robust behavior under typical industrial operating conditions, maintaining low communication latency, automatic reconnection capability, and integrity of transmitted packets, which are essential factors for continuous industrial IoT monitoring applications.

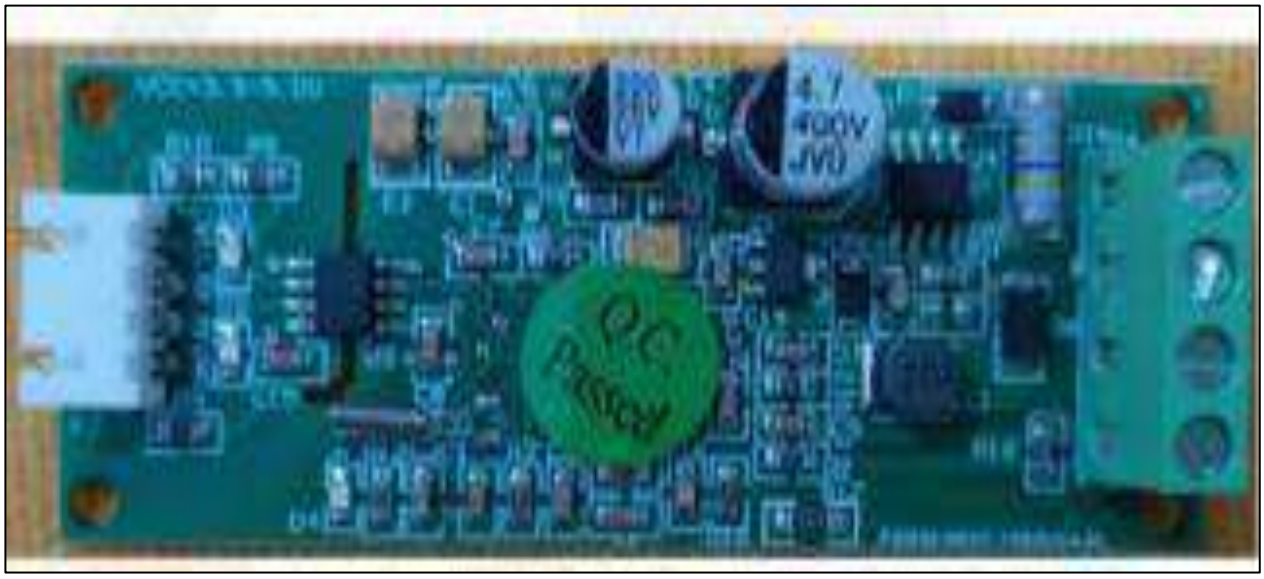

Figure 3: Voltage and Current Sensor Reading Circuit.
Source: Authors, (2026).

From an electromechanical and electronic perspective, the integration of voltage and current sensors into the embedded system enabled continuous monitoring of the electrical quantities associated with industrial machines, allowing accurate acquisition of parameters related to energy consumption and the operational status of the equipment.

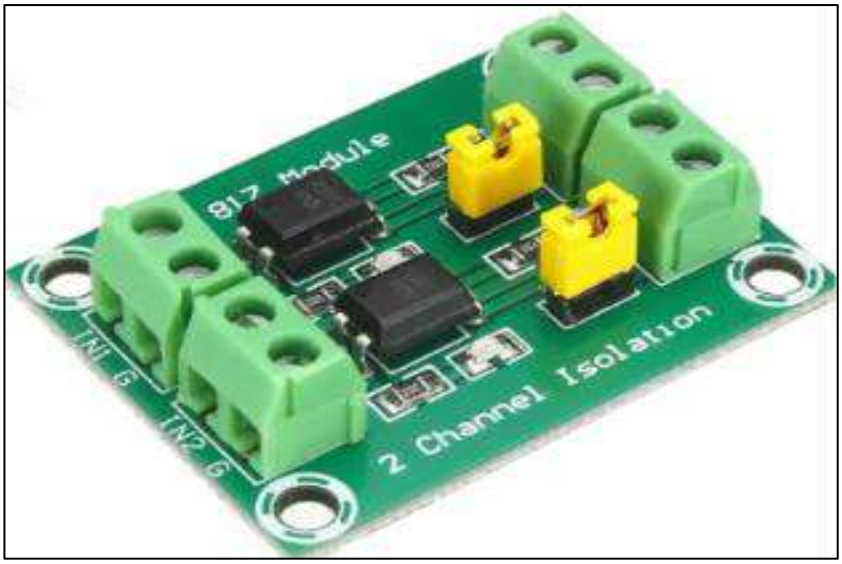

Figure 4: 2-Channel Optocoupler Module.
Source: Authors, (2026).

The 2-channel optocoupler module was implemented with production counting mechanisms based on inductive and infrared sensors, enabling correlation between electrical variables and productive indicators of the industrial process. During the validation phase in a real industrial environment, electromagnetic interference associated with the operation of industrial pneumatic devices, especially solenoid valves, was identified, causing degradation in the integrity of the digital signals used for production counting. The technical analysis indicated that the conducted and radiated noise present in the industrial electrical infrastructure generated spurious pulses in the input circuits of the embedded system, compromising the reliability of signal acquisition from the sensors.

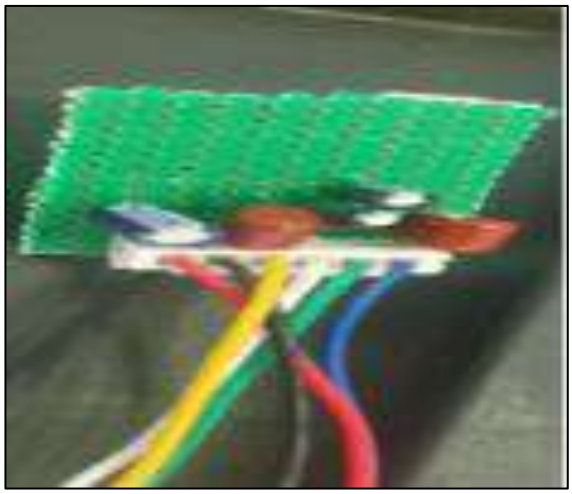

Figure 5: Capacitive Filter.
Source: Authors, (2026).

The experimental analysis of the system showed that industrial environments characterized by the presence of inductive loads, power drives, frequency inverters, electric motors, and electronic switching devices represent a significant source of electromagnetic interference capable of compromising the performance of the embedded modules responsible for the acquisition and transmission of telemetry data. During the operational tests carried out on the developed IoT architecture, it was observed that electrical noise propagated both through the power supply network and communication lines directly affected the stability of the measurements and the reliability of the real-time data acquisition process. The identified interferences presented different spectral and behavioral characteristics, including high-frequency noise, switching transients, electromagnetic surges, and oscillations resulting from the simultaneous activation of industrial loads. Such phenomena may cause distortions in the analog signals acquired by the sensors, instabilities in the logical levels of digital inputs, and intermittent failures in communication between the embedded devices and the backend infrastructure. In connected industrial systems, these occurrences represent a critical factor, since they can compromise the integrity of the collected information and reduce the operational reliability of the monitoring platform. In view of this scenario, mitigation strategies aimed at electrical conditioning and filtering of the signals acquired by the embedded modules were proposed and implemented. The adopted techniques had the main objective of increasing the electromagnetic immunity of the IoT architecture, reducing the susceptibility of the circuits to external interference, and ensuring greater stability in the acquisition, processing, and transmission of the monitored variables.

Among the approaches employed, the implementation of capacitive filters in the power supply circuits and analog acquisition interfaces stands out. The use of decoupling and filtering capacitors made it possible to reduce voltage oscillations, minimize high-frequency noise, and stabilize the power supply to the microcontrollers and sensors connected to the system. These elements play a fundamental role in suppressing electromagnetic disturbances conducted through the electrical network, acting as barriers against undesirable high-frequency components that could compromise the proper functioning of electronic devices. In addition to capacitive filters, improvements were applied to the decoupling circuits distributed throughout the electronic architecture of the IoT collectors. Proper decoupling among electronic components contributed to reducing the unwanted coupling of noise between different circuit stages, especially among the processing, communication, and analog acquisition modules. The adoption of ceramic capacitors positioned close to the power supply terminals of the integrated circuits reduced instantaneous voltage variations and improved the electrical stability of the system during transient operating conditions. Another relevant aspect considered during the mitigation process was the adequacy of the electrical grounding infrastructure of the embedded devices and sensors connected to the platform. In industrial environments, grounding failures or potential differences between equipment may favor the circulation of parasitic currents and the emergence of electromagnetic interference capable of significantly degrading the quality of the acquired signals. Therefore, practices aimed at standardizing functional and protective grounding were adopted in order to minimize ground loops, reduce induced noise, and ensure greater electromagnetic stability for the system.

The physical reorganization of the power and communication cables also constituted an important measure to reduce the effects of electromagnetic interference. The separation between power cables and low-voltage signal lines contributed to reducing inductive and capacitive electromagnetic coupling between adjacent conductors. Additionally, routing and shielding criteria were employed to minimize the incidence of noise on the data acquisition channels and serial communication interfaces used in the IoT architecture. In the context of digital inputs, optimizations were carried out on the acquisition interfaces with the objective of increasing the system immunity against electrical oscillations and false switching caused by industrial noise. The implementation of the ESP32 internal pull-up resistors associated with logic filtering and software timing techniques made it possible to reduce occurrences of incorrect reading of digital signals from sensors and external devices. These strategies contributed to increasing the reliability of the acquisition process and avoiding incorrect interpretations of the operational status of the monitored machines.

Additionally, electrical isolation techniques applied to the critical interfaces of the system were analyzed, especially in channels subject to higher levels of electromagnetic interference. The use of optocouplers and galvanic isolation circuits represents an efficient approach to reducing noise propagation between different subsystems of the embedded architecture, as well as increasing the protection of electronic devices against surges and potential differences present in industrial environments. The results obtained after the implementation of the mitigation strategies demonstrated significant improvements in the operational stability of the IoT platform. A reduction in the occurrence of inconsistent readings, greater reliability in the acquisition of monitored electrical variables, and increased robustness of communication between the embedded modules and the application backend were observed. The platform presented more stable behavior even under industrial conditions characterized by high electromagnetic activity, demonstrating the effectiveness of the adopted conditioning and filtering techniques. From a metrological perspective, the implemented improvements contributed to increasing the accuracy and repeatability of the measurements performed by the sensors connected to the system.

The reduction in electrical noise levels enabled greater integrity of the acquired signals, favoring the reliability of operational analyses and the information stored in the platform database. This aspect is particularly relevant in continuous industrial monitoring applications, in which small distortions in signals can directly impact supervision processes, decision-making, and predictive maintenance. In addition to the immediate benefits observed in the operational stability of the developed solution, the implemented mitigation strategies establish an important foundation for future expansions of the IoT architecture in industrial environments with greater electromagnetic complexity. The adoption of appropriate electromagnetic compatibility, filtering, and signal conditioning practices becomes essential to ensure scalability, reliability, and interoperability in connected systems aligned with the concepts of Industry 4.0 and smart manufacturing. Thus, it can be concluded that the implementation of signal conditioning and filtering techniques played a fundamental role in improving the operational robustness of the proposed IoT platform. The adopted solutions made it possible to significantly increase the electromagnetic immunity of the system, reduce susceptibility to external interference, and ensure greater reliability in the acquisition and transmission of industrial data, contributing to the development of a more stable, secure, and suitable technological architecture for the demands of modern industrial environments.

Figure 6: Collector Installed on the Machine.
Source: Authors, (2026).

The obtained results demonstrate that the developed architecture presents high potential for application in scenarios associated with Industry 4.0, especially in solutions for remote monitoring, industrial telemetry, energy supervision, and distributed industrial data acquisition. Furthermore, the modularity of the conceived architecture enables future expansions involving predictive maintenance techniques, intelligent data analysis, integration with cyber-physical systems, and the application of machine learning algorithms aimed at optimizing industrial production processes.

V. CONCLUSIONS

The Voltage and Current Sensor Reading Circuit showed stable performance in the acquisition of electrical parameters, ensuring measurement accuracy and appropriate conversion of analog signals for digital processing. The results indicated good sensitivity and fast response to the operational variations of the monitored machine. The 2-Channel Optocoupler Module played a fundamental role in the electrical isolation between the power and control circuits, providing greater system safety and reducing electromagnetic interference. This characteristic significantly contributed to the stability of the readings and the protection of electronic components. The Capacitive Filter applied to the circuit enabled the reduction of noise and undesirable oscillations in the electrical signals, improving the quality of the collected information and increasing the reliability of real-time monitoring. In summary, the Collectors installed on the machines confirmed the practical feasibility of the proposed solution, operating continuously and efficiently under real operating conditions. The obtained results demonstrate that the developed system has strong potential for applications in predictive maintenance, industrial automation, and intelligent equipment monitoring on the factory floor.

ABSTRACT

The advancement of Industry 4.0 has driven digital transformation in manufacturing environments, promoting greater integration between machines, processes, and teams through smart technologies. In this context, this paper proposes the development and implementation of an integrated smart manufacturing platform based on Artificial Intelligence (AI), the Internet of Things (IoT), and Data Mining, aiming to optimize production processes and enhance the digital maturity of the company that manufactures bumper strips: Guillotine, Crease Cutting, Rewinder, and Reflective Film (Slitter). The main objective is to integrate systems, automate data collection, and enable real-time monitoring, predictive maintenance, and support for autonomous decision-making on the factory floor. The materials and methods involve detailed mapping of production processes, identification of bottlenecks, and definition of strategic points for installing IoT sensors on 11 cutting machines (side strip). The system architecture consisted of sensors, microcontrollers, gateways, a database, APIs, and interactive dashboards, integrated with existing corporate systems such as ERP and R&D Core. Data mining and machine learning techniques were applied for pattern analysis, anomaly detection, and prediction of operational failures. In addition, the system was validated in a real manufacturing environment, followed by training for the teams involved. As the results were effective in practice, they demonstrated greater operational efficiency, reduced waste, improved quality, increased traceability, and faster decision-making. It can be concluded that the implementation of the platform will contribute significantly to the consolidation of smart manufacturing, providing cyber-physical integration, greater industrial competitiveness, and a solid foundation for continuous innovation and future expansion of the solution in light of the maturity level of Industry 4.0.

I. INTRODUCTION

Digital transformation has driven significant changes in industrial processes, spurring the adoption of technologies capable of making production more efficient, connected, and intelligent. In this context, Industry 4.0 represents a new manufacturing model based on the integration of physical and digital systems, utilizing technologies such as Artificial Intelligence (AI), the Internet of Things (IoT), Big Data, and Data Mining. These tools enable real-time monitoring, process automation, and data-driven decision-making, contributing to increased productivity, cost reduction, and improved industrial competitiveness, as was the case in the research application [1-4]. Despite technological advances, many industries still operate with limited digital integration across departments, machines, and processes.

In many cases, production controls rely on manual records or isolated systems, hindering the continuous flow of information and reducing the ability to identify failures, bottlenecks, and operational losses. This limitation compromises production efficiency, process predictability, and the speed of decision-making. Given this scenario, this paper proposes the development and implementation of an integrated smart manufacturing system, based on the combined use of Artificial Intelligence, the Internet of Things, and Data Mining. The initiative aims to expand the company's existing smart manufacturing platform (GateMove), incorporating Industry 4.0 principles onto the factory floor. The objective was to integrate machines, processes, and teams into a single digital platform, enabling continuous monitoring, greater operational predictability, and automated responses to production deviations in the manufacture of tapes using machines for bumpers: Guillotine, Crease Cutter, Rewinder, and Reflective Film (Slitter) [5]. The proposal involved the use of IoT sensors installed at strategic points along the production line to automatically collect data related to operational performance, cycle times, production volume, and machine downtime.

This information was transmitted in real time to central processing systems, enabling greater traceability and control of industrial operations. In addition, the collected data was integrated into the company's corporate systems, promoting a continuous flow of information between the shop floor and management levels. Another important aspect of the research is the application of Data Mining and Machine Learning techniques. Through the analysis of historical and operational data, intelligent algorithms enabled the identification of patterns, the detection of anomalies, and the prediction of failures before they occur. This approach enabled the implementation of predictive maintenance strategies, reducing unplanned downtime and increasing production efficiency [6-8]. In addition to the operational benefits, the implementation of the platform helped strengthen the company's culture of technological innovation, promoting greater team training in the process and encouraging data-driven decisions, given that the company has achieved Maturity Levels 1 (Computerization) and 2 (Connectivity) of Industry 4.0 according to the Acatech Manual. Thus, the research represented an important initiative to consolidate the digitization of the manufacturing environment and enhance industrial competitiveness by raising the Maturity Level to Level 3 (Visibility). Consequently, the developed solution delivered significant gains in productivity, quality, waste reduction, and operational agility. The integration of AI, IoT, and Data Mining enabled the creation of a smarter manufacturing environment that is more connected, efficient, and prepared for the challenges of Industry 4.0.

II. BIBLIOGRAPHY REVIEW

II.1 NATURE OF THE TECHNOLOGICAL CHALLENGE

This paper presents a highly complex technological challenge, characterized by the need to integrate different fields of knowledge, such as industrial automation, data science, process engineering, and embedded systems development. The objective is to develop a novel solution aimed at creating an intelligent system capable of monitoring, interpreting, and reacting in real time to critical events in production processes, which requires the conduct of applied research and experimental development activities. The proposal involves building novel solutions for industrial environments, which require the generation of technical and scientific knowledge aimed at solving practical problems and innovating in production processes. The nature of the challenge is rooted in the need to integrate physical devices, control systems, artificial intelligence algorithms, and digital interfaces into an ecosystem capable of operating intelligently, autonomously, and in real time. Such integration requires overcoming technical uncertainties related to communication between devices, the processing of time-sensitive data, precise control of industrial operations, and ensuring the reliability of information for decision-making. Among the main technological challenges to be addressed, the following stand out:

a. The definition and control of the operating frequency, latency, and memory capacity of the devices responsible for collecting and tracking manufacturing data, ensuring stability in the transmission and reception of critical information [9], [10].;

b. The development of analytical models capable of identifying complex patterns in productivity and quality metrics, in order to generate alerts, key performance indicators (KPIs), and automated decision recommendations for operators and managers [11], [12].

c. The implementation of integration mechanisms between hardware and software layers, with a focus on minimizing data loss and maximizing event synchronization, ensuring consistency in the data feed to Business Intelligence systems [13], [14];

d. The creation of intelligent strategies for dynamic production replanning based on predictive analysis of failures, non-conformities, and adjustments to manufacturing schedules, using graphical visualizations and dashboards to support decision-making [15-17].

Among the key technical aspects of the paper, the following challenges stand out: controlling the frequency and memory capacity of traceability devices; efficient processing of data from production and inspections; integration between hardware and software with minimal loss of information; and the generation of dynamic reports and graphs to aid in fault mitigation, non-conformity management, and the continuous improvement of key performance indicators (KPIs). Thus, the technical aspects of this project are in accordance with the levels of technological challenge defined in the legislation:

a. Level 3 – Conducting experimental development: involving systematic work based on pre-existing knowledge, aimed at developing new systems, improving industrial processes, and integrating technological solutions into a real manufacturing environment;

b. Level 4 – Conducting applied research: characterized by original investigation aimed at acquiring technical and scientific knowledge focused on specific practical problems, such as the intelligent analysis of production data and the generation of automated decisions.

II.2 APPLICATIONS OF INDUSTRY 4.0 IN INDUSTRIAL PROCESSES.

Industry 4.0 represents the fourth industrial revolution and is associated with the integration of advanced digital technologies into production processes. This concept emerged in Germany with the goal of promoting smart factories that are highly connected and capable of operating autonomously, flexibly, and efficiently. Industry 4.0 combines technologies such as the Internet of Things (IoT), Artificial Intelligence (AI), Big Data, cloud computing, advanced robotics, cyber-physical systems, and real-time data analysis.

These technologies enable communication between machines, equipment, systems, and people, providing greater integration and automation in industrial environments [18]. In practice, Industry 4.0 is applied across various industrial sectors, such as automotive, electronics, chemicals, food, and energy. In smart factories, sensors installed on machines continuously collect data, enabling real-time monitoring of production. This data is analyzed by intelligent systems capable of identifying faults, predicting maintenance needs, and optimizing production performance. In addition, the use of collaborative robots and automated systems reduces operational errors, increases productivity, and improves product quality. Another important aspect is the integration of the supply chain, allowing suppliers, manufacturers, and customers to share information quickly and efficiently [18]. Manufacturing processes have also undergone profound transformations with Industry 4.0. Traditional manufacturing, based on rigid and inflexible production, is being replaced by intelligent and adaptive processes. In this context, smart manufacturing stands out, in which machines and systems are able to make decisions autonomously based on collected data.

Key advancements include predictive maintenance, automated quality control, product traceability, large-scale customized production, and the integration of the physical and virtual environments through digital twins. These capabilities help reduce waste, lower operating costs, and increase energy and production efficiency. In addition, the digitization of processes promotes greater agility in decision-making and a better ability to respond to market demands [20]. To assess companies' level of digital development, Acatech developed the "Industrie 4.0 Maturity Index," a maturity model consisting of six evolutionary levels. The first level is Computerization, characterized by the basic computerization of industrial processes. The second level is Connectivity, in which systems and equipment begin to communicate via a network. The third level is Visibility, in which process data can be monitored in real time. The fourth level is Transparency, which allows for understanding the causes of production events through data analysis. The fifth level is Predictive Capability, in which algorithms can predict failures and future behaviors. Finally, the sixth level is Adaptability, considered the most advanced stage, in which industrial systems become autonomous and capable of automatically adapting to changes in the production environment. This model helps companies build strategic roadmaps for the gradual implementation of digital transformation [18].

II.3 THE CHALLENGES OF THESE TECHNIQUES

II.3.1 Intelligent Systems

Intelligent systems represent one of the main pillars of digital transformation and Industry 4.0, characterized by their ability to collect, process, interpret, and use information to support decision-making autonomously or semi-autonomously. These systems combine technologies such as Artificial Intelligence, machine learning, the Internet of Things, cloud computing, neural networks, and Big Data analytics to perform complex tasks with a high level of efficiency and precision [21]. Currently, intelligent systems are widely used in industrial, logistics, medical, energy, and urban environments, providing advanced automation, increased productivity, and improved process quality [22]. One of the key characteristics of intelligent systems is their learning capability. Through machine learning algorithms, these systems can analyze large volumes of data, identify patterns, and continuously improve their performance without the need for explicit programming for each situation. This characteristic enables applications such as predictive maintenance, automatic fault detection, pattern recognition, and optimization of production processes.

In addition, intelligent systems are adaptable, allowing them to adjust their operation in response to changes in the operating environment and working conditions [23], [24]. Another key feature is connectivity. Smart systems operate in an integrated manner, sharing information among sensors, machines, devices, and digital platforms. This communication occurs primarily through the Internet of Things (IoT), enabling real-time monitoring, remote control, and decision-making based on continuously updated data. In industrial settings, for example, sensors installed on equipment can detect variations in temperature, vibration, or energy consumption, sending this information to central systems capable of identifying potential problems before critical failures occur [25], [26]. Despite the numerous benefits, smart systems face various technical, economic, and operational challenges.

One of the main challenges relates to cybersecurity. Since these systems depend on the constant exchange of information over digital networks, they become vulnerable to cyberattacks, intrusions, and data breaches. The protection of industrial information and the security of critical infrastructure require the development of advanced security protocols, encryption, and user authentication. Another significant challenge relates to technological integration. Many companies still use outdated equipment and legacy systems that have difficulty communicating with new digital platforms. Integrating different technologies, protocols, and automation architectures requires substantial financial investment and specialized technical expertise. Furthermore, implementing smart systems demands robust data storage and processing infrastructure, particularly in applications that utilize Big Data and Artificial Intelligence in real time [27]. Data quality and reliability also pose significant challenges. Intelligent systems rely directly on accurate and consistent data to perform precise analyses.

Incomplete, inconsistent, or improperly collected information can compromise algorithm performance and lead to incorrect decisions. In this context, the development of efficient strategies for data collection, processing, and management becomes essential. Another key aspect is the need for professional training. Digital transformation requires professionals skilled in areas such as data science, programming, automation, artificial intelligence, and information security. However, many organizations still struggle to find skilled workers capable of developing, operating, and maintaining intelligent systems. Therefore, the challenge related to implementation costs stands out. The adoption of intelligent systems involves investments in sensors, software, communication infrastructure, cloud storage, and technical training. Despite this, the benefits associated with operational efficiency, cost reduction, increased productivity, and improved decision-making make these technologies essential for industrial competitiveness and for advancing digital transformation within organizations.

II.3.2 Internet of Things (IoT)

The Internet of Things (IoT) is a technology based on connecting physical devices to the internet, enabling the collection, exchange, and analysis of data in real time. These devices may include sensors, machines, industrial equipment, measuring instruments, and automated systems capable of communicating with one another without direct human intervention.

The IoT has become one of the main pillars of Industry 4.0, promoting greater integration between the physical and digital environments and contributing to the development of smarter, more efficient, and automated industrial processes [28], [29]. In process engineering, the Internet of Things has wide-ranging applications in sectors such as oil and gas, the chemical industry, food, mining, energy, and manufacturing. Smart sensors installed on industrial equipment are capable of monitoring key variables such as temperature, pressure, flow rate, vibration, humidity, and energy consumption. This information is continuously transmitted to digital platforms and supervisory systems, enabling real-time monitoring of production operations. One of the main applications of IoT in process engineering is the remote monitoring of industrial systems. Through this technology, engineers and operators can monitor the performance of equipment and processes remotely, reducing response times in the event of failures and increasing operational efficiency. In addition, the IoT contributes significantly to predictive maintenance, allowing for the identification of anomalies and the prediction of failures before unexpected production shutdowns occur.

This reduces maintenance costs, extends equipment lifespan, and improves the reliability of industrial processes. Another important application relates to energy optimization and resource management. Connected sensors enable real-time monitoring of energy, water, and raw material consumption, helping to reduce waste and improve industrial sustainability. In chemical and petrochemical processes, for example, the IoT aids in the precise control of reactions and operating conditions, ensuring higher quality and safety in production processes [30]. Despite the benefits, the implementation of IoT faces challenges related to cybersecurity, systems integration, and the storage of large volumes of data. Connectivity between devices increases vulnerability to digital attacks, requiring robust information protection protocols. Furthermore, many companies still use legacy systems that hinder integration with modern technologies [31]. Thus, the Internet of Things is transforming process engineering by enabling smarter, more connected, and more efficient operations, contributing to increased productivity, cost reduction, and the advancement of industrial digital transformation.

II.3.3 Data Mining

Data mining is the process of extracting useful information, patterns, and insights from large volumes of data. This technique combines methods from statistics, machine learning, artificial intelligence, and databases to identify hidden relationships and relevant trends that aid in decision-making. The rapid growth of data generation in industrial, commercial, scientific, and digital environments has made data mining an essential tool for organizations seeking to transform raw data into strategic knowledge [32], [33]. The data mining process involves several stages, including data collection, cleaning, integration, selection, transformation, and analysis. After the information is processed, specific algorithms are applied to identify patterns, classify data, detect anomalies, and make predictions. Among the most commonly used techniques are artificial neural networks, decision trees, classification algorithms, clustering, and association analysis. Data mining applications are wide-ranging and span various industries. In manufacturing, data mining is used to optimize production processes, monitor equipment, and predict failures through predictive maintenance. Sensors installed on machines continuously generate data, allowing for the identification of behavioral patterns and the anticipation of operational problems.

This reduces maintenance costs, increases productivity, and improves the efficiency of industrial systems [34], [35]. In the financial sector, data mining is applied to fraud detection, credit analysis, and risk forecasting. Banks and financial institutions use intelligent algorithms to analyze suspicious transactions and identify unusual behavior in real time. In e-commerce and digital marketing, data mining enables a better understanding of consumer behavior, the personalization of product recommendations, and the development of more efficient sales strategies. In the healthcare sector, data mining aids in the diagnosis of diseases, the analysis of medical tests, and the identification of epidemiological patterns. Furthermore, in smart cities and transportation systems, data mining helps improve urban mobility and optimize public resources. Despite these benefits, the use of data mining faces challenges related to privacy, security, and data quality. Inconsistent or incomplete information can compromise the accuracy of analyses. Thus, data mining has become a fundamental tool for supporting strategic decisions and promoting innovation in various fields of knowledge and industry [32], [34], [35].

II.3.4 Artificial Intelligence

Artificial Intelligence (AI) is a branch of computer science dedicated to the development of systems capable of simulating human intelligence. These systems can learn, reason, make decisions, recognize patterns, and solve problems autonomously or semi-autonomously. AI uses techniques such as machine learning, artificial neural networks, natural language processing, and computer vision to analyze large volumes of data and perform complex tasks with high efficiency [36]. Currently, Artificial Intelligence has applications in various industrial, scientific, and commercial sectors. In industry, AI is widely used in automation systems, predictive maintenance, quality control, and production process optimization. Sensors and intelligent algorithms monitor machines in real time, identifying failures before they occur and reducing operational costs. In smart manufacturing environments, AI helps increase productivity, improve energy efficiency, and reduce waste [37]. In the healthcare sector, Artificial Intelligence assists in diagnosing diseases, interpreting medical tests, and developing personalized treatments. AI-based systems can analyze medical images with high precision, helping doctors identify diseases at an early stage. In the financial sector, AI is used for fraud detection, risk analysis, and the automation of banking services. Another important application is in transportation systems and smart cities, where intelligent algorithms help manage traffic, optimize routes, and improve urban mobility. In addition, virtual assistants, chatbots, and recommendation platforms in digital services use Artificial Intelligence to offer more personalized experiences to users [37], [38]. Despite these benefits, AI faces challenges related to data privacy, cybersecurity, ethics, and the need for qualified professionals. Even so, Artificial Intelligence continues to evolve rapidly and plays a fundamental role in the digital transformation and technological advancement of modern society.

II.3.5 Digital Transformation

Digital transformation refers to the integration of digital technologies into organizations' processes, products, and business models. In industry, this transformation is directly linked to the concepts of Industry 4.0, promoting greater connectivity, automation, intelligence, and operational efficiency.

Technologies such as the Internet of Things (IoT), Artificial Intelligence (AI), Big Data, cloud computing, and cyber-physical systems enable machines, sensors, and systems to exchange information in real time, making industrial processes smarter and more integrated [39], [40]. The applications of digital transformation in industry are wide-ranging. One of the main ones is advanced industrial automation, which uses robots and intelligent systems to perform tasks with greater precision, productivity, and safety. Another important application is predictive maintenance, in which sensors continuously monitor machine performance to predict failures before they occur, reducing costs and unexpected downtime. Digital transformation also contributes to quality control, product traceability, and energy consumption optimization. In addition, the use of real-time data analysis assists managers in making strategic decisions and increasing industrial competitiveness [39], [40]. Despite the benefits, the implementation of digital transformation faces challenges related to cybersecurity, high investment costs, and the need for professional training. Even so, digital transformation has become essential for the modernization of industries and for the development of more efficient, sustainable, and intelligent production processes.

III. MATERIALS AND METHODS

The study was conducted as applied research, utilizing existing secondary data and direct information collection within the manufacturing environment. Data collection and observations will be conducted with managers, administrators, and operational technicians to ensure that the project's development is fully aligned with the company's actual needs and the specific characteristics of its production process. Project execution will be the responsibility of a multidisciplinary team composed of developers, engineers, and technicians. Each team member will be assigned well-defined responsibilities, in accordance with the competencies required at each project phase, ensuring efficiency, clear communication, and adherence to established deadlines and goals. For the planning, execution, and management of the project, a methodology based on the principles of the PMBOK (Project Management Body of Knowledge), an international reference for best practices in project management, will be adopted. As illustrated in Figure 1, the five process groups that structure the conduct of the research will be followed.

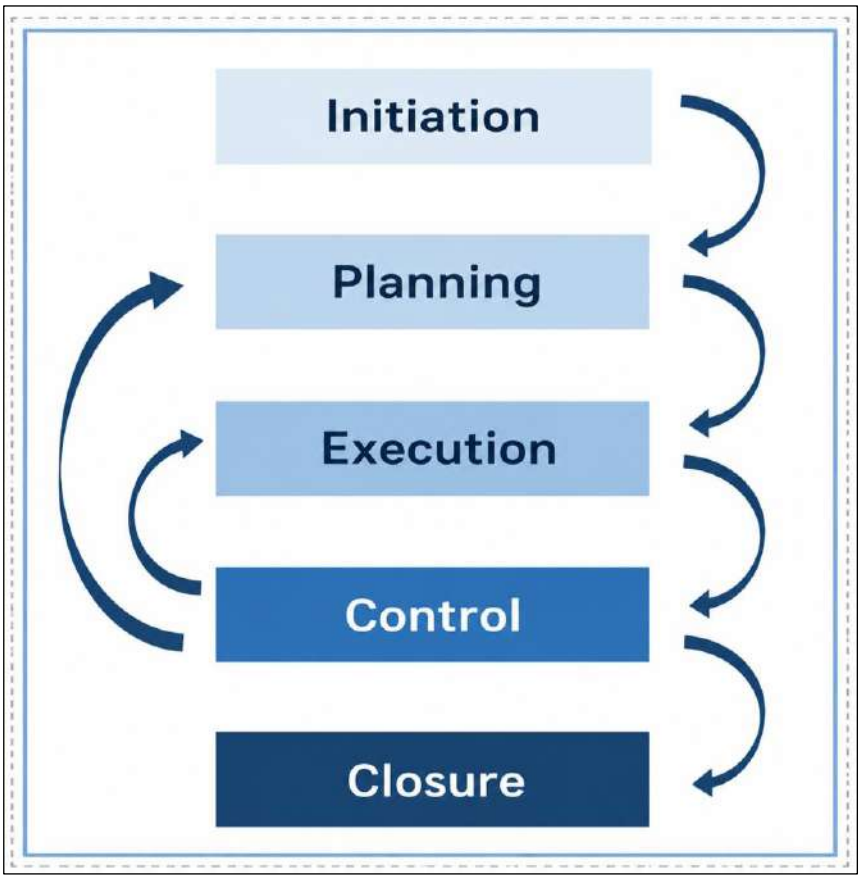

Figure 1: PMBOK Project Management Model.
Source: Authors, (2026).

Each process group will be broken down into practical activities tailored to the company's context, using tools such as detailed schedules (Gantt charts), RACI matrices, risk analysis, cost controls, and performance indicators. Management will be conducted in an iterative and delivery-oriented manner, ensuring the traceability of results and the effective implementation of the proposed solution. In addition, the incremental methodology will be adopted as the approach for software development. In this model, the system will be built progressively through iterative cycles, in which functional and integrated parts of the system will be implemented in each iteration. This method allows critical components to be delivered and validated in advance, providing greater control over the product's quality and evolution. The adoption of the incremental approach enables clear measurement of the process phases, such as: requirements gathering and analysis, functional modeling, modular development, partial testing, continuous integration, and validation with end users. This aims to reduce risks, improve alignment with the company's needs, and facilitate adjustments throughout development, as shown in Figure 2.

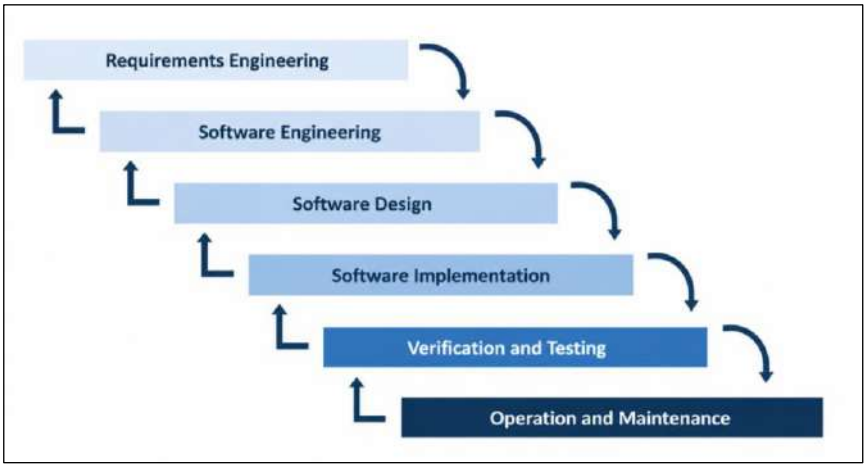

Figure 2: The software development lifecycle.
Source: Authors, (2026).

• Requirements Engineering: In this phase, the software requirements will be defined, specifically for the module to be developed, so that the solution meets the company's needs while taking into account visual and behavioral elements, actions, criteria, and constraints.
• Software Engineering: In this phase, diagrams and documentation regarding the module and implemented features will be developed. This document should address the software design by describing the limitations, use cases, features, technologies, and technical definitions of the functional and non-functional requirements.
• Software Design: In this phase, the software design will be developed based on user interaction interfaces, visual identity definitions, element layout, actions, behaviors, and company standards, taking into account operational limitations.
• Software Implementation: In this stage, the process of developing, defining, and executing the coding of the functionalities specified in the requirements document and strategies to achieve the module to be delivered will be carried out.
• Validation and Testing: This stage involves activities to validate and test the developed application and module. To this end, functionality, integrity, security, unit, and installation tests will be performed to assess product quality, identify and fix bugs, and carry out code refactoring.
• Operation and Maintenance: This phase will involve code refactoring and adjustments; depending on new requirements or technological updates, maintenance may be required, which will involve coding work during this phase.

Research Development Tools

To carry out this project, it will be necessary to use support tools that enable the creation of scenario projections and technical drawings, as well as the coding of the items described in Table 1.

Table 1: Creation of scenario projections, technical drawings, and coding of items.

Tool	Concept	Application in the project
Proteus VSM	Software that allows users to design circuits, simulate, and create layouts for analog and digital applications, including microcontrollers.	It will be used for the development of electronic boards and connections.
Solid Works	Software designed for creating three-dimensional virtual mechanical prototypes. It also allows users to simulate the operation of parts, assemblies, and movements, among other things.	In this project, the software will be used to model mechanical parts and devices. Based on 3D prototypes, 2D drawings will be generated and sent to the machining process..
PMBOK Guide	It is a set of project management practices established by the PMI and is considered the foundation of project management knowledge by professionals in the field.	It will be used to manage the project, from the initial stage through to completion.
Visual Studio Code	A source code editor developed by Microsoft for Windows, Linux, and macOS. It includes support for debugging, built-in Git version control, syntax highlighting, and intelligent code completion.	Development environment
Draw io	An online graphic editor that allows you to create drawings, graphics, and other designs without the need for expensive, resource-intensive software. It offers tools for creating any type of design and includes a section dedicated to information architecture.	Architecture design and flowchart diagrammer.
Trello	A collaboration tool that organizes projects into boards. At a glance, Trello shows what's being worked on, who's working on what, and where something is in the process.	Activity Manager
GIT	Version control and development history tool for code and artifacts	Code Versioning

Source: Authors, (2026).

Technologies for Research Development

The technologies to be used and applied in the project were selected based on their alignment with the technical requirements defined in the scope, which includes the application of the Internet of Things (IoT) and Intelligent Systems, with the aim of efficiently meeting the demands of the proposed solution as presented in Table 2.

Table 2: Application of the Internet of Things (IoT) and Intelligent Systems.

Technology	Concept	Application in the project
NodeJS	A server-side JavaScript runtime environment based on asynchronous, event-driven architecture, enabling the development of scalable web applications, APIs, and real-time processing services.	Used as the foundation for developing the system's backend, enabling the creation of APIs, the processing of data received from IoT devices, and the execution of business rules.
Express	A Node.js framework for developing modern, scalable web applications	Used to structure API routes, receive requests from IoT devices and the frontend, organize controllers, and make processed data available to the platform's consumer modules.
Swagger	A tool and specification used for documenting, standardizing, and testing REST APIs, allowing users to view endpoints, parameters, HTTP methods, request structures, and expected responses.	Used to document and test backend endpoints, facilitating integration between IoT devices, frontends, dashboards, and other systems that consume the API.
Redis	An in-memory database used for caching, queues, temporary state management, and performance optimization in applications that require low latency.	Used to support real-time event processing and updates, reducing the load on the main database.
Docker	A containerization platform that allows you to package applications and their dependencies into isolated, standardized, and portable environments.	Used to streamline the deployment of backend services, databases, and other infrastructure components, ensuring greater standardization across development, testing, and production environments.
TypeScript	A JavaScript superset that adds static typing to the code, improving the application's security, readability, and maintainability.	Used in the backend to improve code organization, reduce typos, standardize entities, services, and controllers, and facilitate the maintenance of business rules.
Websockets	WebSocket is a technology that enables bidirectional communication over full-duplex channels using a single Transmission Control Protocol (TCP) socket. It is designed to run on browsers and web servers that support HTML5, but can be used by any client or application server.	Used to enable real-time communication between the backend and dashboards, allowing for the automatic transmission of updates regarding machines, production orders, operational events, and metrics.
Postgres	Relational database	Used to store data from machines, production orders, IoT readings, operational events, historical data, logs, and information needed to calculate industrial metrics.

IV. RESULTS

IV.1 SOLUTION WORKFLOW

With the advancement of Industry 4.0 enabling technologies, integration between the shop floor and digital systems has become essential for achieving greater operational efficiency, real-time traceability, and data-driven decision-making. In this context, the project proposes a technological architecture that connects sensors installed on machines and equipment in the Bumper Tape, Reflective Film, and Side Strip processes of the production line to a central platform for processing, storing, and visualizing information, enabling continuous monitoring of industrial processes. Figure 3 illustrates the functional flow of this solution, showing how data will be collected directly from the operation, sent to a secure processing environment, and made available to different user profiles through user-friendly interfaces updated in real time. This structure aims to ensure complete production visibility, early detection of failures, improved decision-making, and integration among the company's technical, operational, and managerial areas.

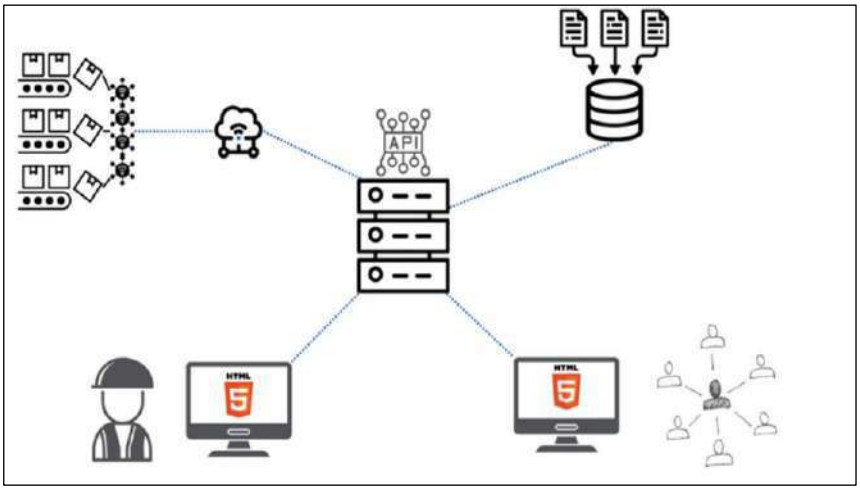

Figure 3: Operational flowchart of the intelligent production monitoring and control system.
Source: Authors, (2026).

Figure 3 illustrates the operational workflow of the intelligent production monitoring and control system, based on Industry 4.0 technologies. On the left is a production line equipped with connected sensors that monitor variables such as the presence of parts, quantity produced, cycle time, and machine downtime. These sensors send the collected data in real time to the cloud using wireless or wired connections. At the center of the architecture is the main server, responsible for processing this information. This server has an API that enables communication between the data collection devices, the database, and the visualization systems. The API also allows integration with other company systems, such as ERPs and production management platforms. At the top right, the database stores all received information, organizing the records so they can be used for both immediate visualization and historical analysis and management reports. At the bottom of the image are the system users. On the left, the plant operator uses a simple, visual interface—developed in HTML5—to monitor production data in real time, identify faults, and validate process steps.

In the center, managers and analysts have access to more comprehensive dashboards, featuring key performance indicators (KPIs), productivity metrics, and machine status. On the right, other users—such as engineers, maintenance teams, and even external partners—can also access the system with different permission levels, facilitating decision-making and promoting more transparent and connected management. In short, the flowchart illustrates how data flows directly from the shop floor, passes through a secure processing infrastructure, and is made available in real time to different levels of the operation, contributing to greater efficiency, traceability, and control of the production process. Implementing the proposed solution requires a robust hardware and connectivity infrastructure capable of supporting everything from field data collection to advanced data processing, with high availability and reliability. Each item to be procured will play a strategic role in enabling this architecture, forming an integrated ecosystem that supports the project's objectives. Each item to be procured will play a strategic role in enabling this architecture, forming an integrated ecosystem that supports the project's objectives. At the heart of this acquisition, the ESP32 WiFi and Bluetooth 38-pin CP2102 module serves as the foundation for developing smart IoT nodes. This microcontroller, with wireless connectivity and multiple communication interfaces, will enable the creation of embedded devices capable of collecting, processing, and transmitting data directly to the cloud or local servers without the need for physical cabling, ensuring scalability and flexibility in deployment. A stable power supply for these modules is ensured by the 5V 3A Micro USB Switching DC Power Supply, whose ability to provide continuous current with surge and short-circuit protection will be crucial for preventing operational failures and data loss. The development and adaptation of interface circuits will require essential components such as the 500 Resistor Kit, indispensable for current adjustments, voltage division, and sensor biasing, and the PC817 Integrated Circuit (optocoupler), which protects microcontrollers against surges and noise from industrial environments, ensuring safe electrical isolation between different voltage levels.

Physical control interfaces are provided by the 22mm Industrial Pushbuttons, which will enable manual actuation, event simulation, and enhanced safety on test benches. For local display and debugging, the 20x4 LCD display with I2C will provide a visual representation of data and messages from the embedded system, while the DS3231 RTC clock module will ensure temporal accuracy in logs, which is essential for event correlation and traceability. The communication and network infrastructure is supported by the Ubiquiti UniFi Indoor 122m Access Point, which will ensure high-availability Wi-Fi connectivity in industrial environments, supporting multiple devices simultaneously. For high-performance wired connections, the Furukawa SohoPlus Cat6 Network Cable and Shielded Cat6 RJ45 Connectors will ensure stable data transmission, reducing interference and signal loss, and meeting industrial technical standards. Complementing the physical integration, the NPN 24V to 5V 8-Channel Signal Converter Module is designed to ensure electrical compatibility between industrial sensors and low-power controllers.

For real-time visualization and immediate decision-making on the factory floor, the Samsung 55" UHD 4K Smart TV will be installed at a strategic location, displaying dynamic dashboards with operational and quality indicators. The prototyping and adaptation of specific supports and parts will be enabled through 3D Printer Filaments, allowing for rapid additive manufacturing of functional and structural elements. The 4-Way Shielded Cable protects sensitive signals from electromagnetic interference, ensuring data integrity between sensors and controllers, while the 4-Way Wago-Style Connectors facilitate quick and secure connections during prototype assembly. Visual status indicators will be provided by the 5mm High-Brightness LED Kit, which will provide immediate feedback during testing and operations. At the heart of the processing and storage infrastructure, the Dell PowerEdge R260 Rack Server will be responsible for continuously receiving and processing sensor data, running data mining and failure prediction algorithms, hosting interactive dashboards, and managing the historical database. Its high processing capacity, redundancy, and scalability ensure stable operation even under high-demand conditions.

To protect and organize this infrastructure, the Dell APC NetShelter SX 24U Rack will provide secure installation, adequate ventilation, and ease of maintenance, meeting the robustness and physical protection requirements demanded by industrial environments. Working together, each acquisition will contribute to forming a complete chain of data capture, processing, communication, and visualization. From data collection on the factory floor to the display of strategic information, all components have been pre-selected to ensure electrical compatibility, operational reliability, resilience against adverse conditions, and the capacity for future expansion. This combination of equipment and materials will not only enable the technical operation of the system but also ensure that the final solution meets the performance, safety, and scalability requirements established for the project, supporting its operation in critical industrial environments.

However, during the refinement process, technical detailing of requirements, and development, it is possible to determine that some initially planned components may be replaced or adjusted to better meet the actual demands for performance, compatibility, and reliability. This review will ensure that the final selection of equipment is aligned not only with the proposed solution architecture but also with the operating conditions and strategic objectives of the research.

IV.2 DEVELOPMENT OF THE INTELLIGENT SYSTEM'S BACKEND LAYER

The development of the intelligent system focused on building a backend layer capable of integrating data from the manufacturing environment, processing it in a structured manner, and making it available to the other modules of the platform. This layer was designed to act as the computational core of the solution, connecting data collection devices, databases, business rules, and real-time visualization interfaces. Figure 4 presents the backend architecture of the integrated smart system, illustrating the data flow from the IoT devices installed on the machines to the provision of information for dashboards and client systems. The structure demonstrates the central role of the backend in receiving data, validating it, applying business rules, storing it in the database, generating indicators, and triggering events in real time.

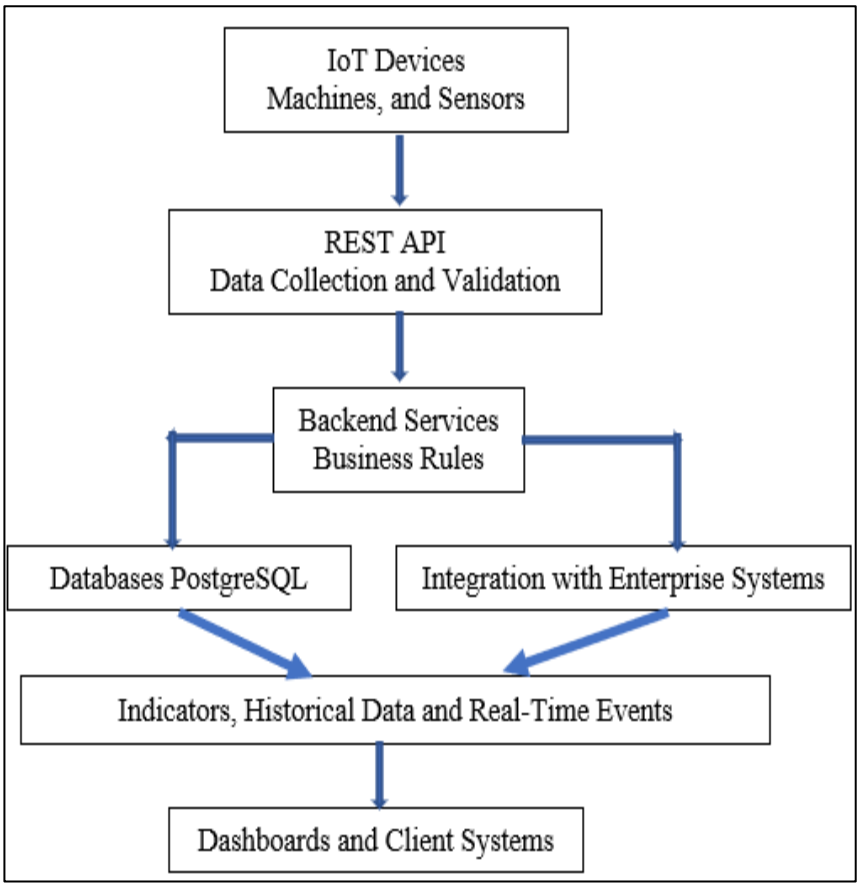

Figure 4: Backend Architecture of the Intelligent System.
Source: Authors, (2026).

The backend architecture was designed around services responsible for receiving, processing, storing, and distributing industrial data. Information collected on the factory floor—such as production volume, machine operational status, production order progress, cycle times, and downtime events—is sent to the server via defined communication channels. Upon receipt, the data undergoes validation and standardization processes to ensure greater reliability before being stored or used in the calculation of indicators. The API layer was developed to enable communication between IoT devices, the database, and the applications that consume the information. Through these routes, the system receives operational records, queries historical data, returns consolidated information on machines and production orders, and provides indicators used by the dashboards.

This architecture enables different modules of the platform to access data in a standardized manner, reducing dependencies and facilitating the system's evolutionary maintenance. The backend architecture was designed around services responsible for receiving, processing, storing, and distributing industrial data. Information collected on the factory floor—such as production volume, machine operational status, production order progress, cycle times, and downtime events—is sent to the server via defined communication channels. Upon receipt, the data undergoes validation and standardization processes to ensure greater reliability before being stored or used in the calculation of indicators. The API layer was developed to enable communication between IoT devices, the database, and the applications that consume the information.

Through these routes, the system receives operational records, queries historical data, returns consolidated information on machines and production orders, and provides indicators used by the dashboards. This organization enables different platform modules to access data in a standardized manner, reducing coupling and facilitating the system's evolutionary maintenance. Figure 5 shows the backend API documentation interface via Swagger, highlighting the organization of the endpoints used for integration between IoT devices, the database, and the platform's consumer modules. This documentation helps standardize requests, facilitates route testing, and supports the system's ongoing maintenance.

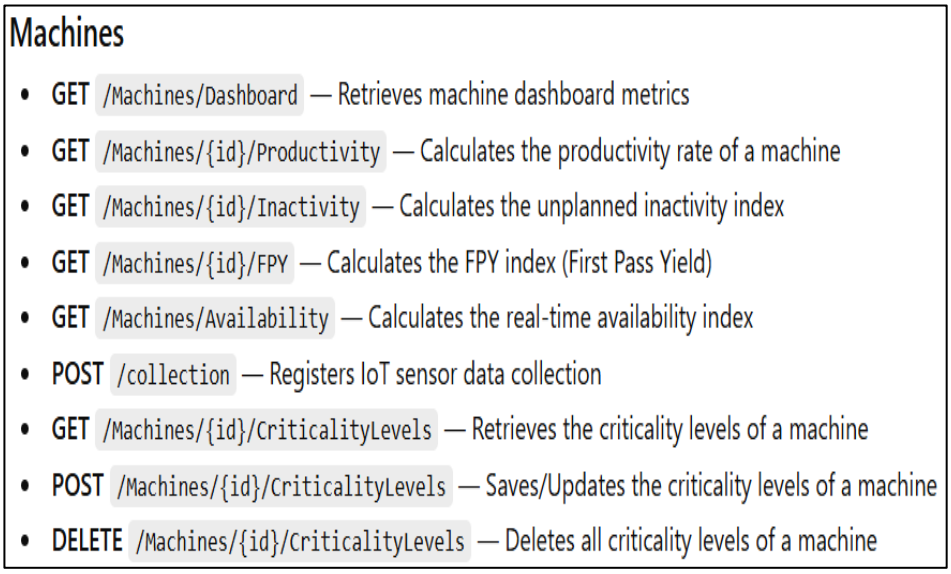

Figure 5: Documentation of the backend API endpoints in Swagger.
Source: Authors, (2026).

As noted, the available endpoints cover both query operations—such as productivity, downtime, FPY, and real-time visibility—and data recording and updating operations, such as collection routes and machine criticality levels. This architecture reinforces the API's role as an intermediary layer between IoT devices, the database, and the modules that consume the information. One of the central focuses of the backend was the modeling and persistence of industrial data. The database was organized to store information related to machines, production orders, completed collections, operational events, equipment status, and productivity histories. This structure enables the traceability of operations and allows for queries by period, machine, and development; aspects of data reliability and integrity were also considered. Since industrial data can be generated at high frequency and from different sources, it became necessary to implement validations, handle inconsistent values, control duplicate records, and organize the received events.

These measures help reduce errors in interpreting the information and increase the reliability of the indicators presented by the platform. The implementation of the intelligent system demonstrated the importance of the backend as a central element of the proposed digital transformation. By integrating machine data, processing it, storing it, and making it available in real time, the solution creates a technological foundation for continuous production monitoring and for future stages of advanced analysis. This structure also enables the subsequent application of data mining techniques, pattern identification, anomaly analysis, and support for dynamic production replanning. Overall, the developed backend contributes to the consolidation of a modular, scalable, and data-driven architecture. The separation between data collection, processing, persistence, and availability facilitates system maintenance and allows for its expansion to new machines, lines, production orders, or event types.

As a result, the system no longer relies exclusively on manual records and now has a structured historical database for analysis and decision-making. In addition to data persistence, the backend is also responsible for enforcing the system's business rules. These rules involve interpreting the received data, associating the data points with their respective machines and production orders, identifying the operational status of the equipment, and preparing the information to be presented to users. As a result, the backend acts as an intermediate intelligence layer, transforming raw data from the operation into organized and useful information for monitoring production. Another key aspect was the handling of industrial indicators. Based on the stored and processed data, the backend provides information related to productivity, machine status, production history, recent events, and production order tracking.

This data serves as the basis for the performance indicators used on the platform, enabling supervisors and managers to monitor operations with greater precision and faster response times. To meet the need for continuous updates, the backend was also designed with real-time communication mechanisms. This strategy allows changes in machine status, new data collections, or relevant events to be sent to client interfaces without relying solely on manual queries or periodic refreshes. Real-time communication is especially important in an industrial context, as it allows operational deviations, downtime, and order completions to be identified more quickly. During production campaigns or indicator tracking. Thus, the intelligent system applied to the manufacturing environment now offers greater traceability, operational visibility, and support for data-driven decision-making.

V. CONCLUSION

The proposal to develop an intelligent system represents a significant step forward for digital transformation in the industrial sector at the Manaus Industrial Hub (PIM). The flowchart presented in the results, Figure 6, illustrates a structured and efficient architecture, beginning with data collection by IoT devices, machines, and sensors, which continuously monitor production processes in real time. The use of REST APIs for collecting and validating information ensures data reliability, security, and standardization, allowing backend services to process business rules and facilitate integration across different industrial sectors. Storage in a PostgreSQL database combined with integration with corporate systems provides greater traceability, organization, and interoperability of production information. In addition, the generation of indicators, historical data, and events in real time enables more accurate analyses and efficient support for decision-making. Dashboards and client systems make data accessible in a visual and intuitive way, contributing to increased productivity, reduced failures, and the optimization of industrial resources. Thus, the proposed system strengthens smart manufacturing, promoting greater competitiveness, automation, and operational efficiency in modern industries within the context of real-time digital transformation.

ABSTRACT

Cross-Site Scripting (XSS) attacks remain one of the most impactful attacks and a major threat to web applications, especially when malicious payloads are stuffed via email input. Although advanced learning solutions have achieved significant detection, their computational and time-consuming heuristics often prevent their deployment in resource-limited environments, such as shared hosting or edge sites. This paper presents a lightweight machine learning approach designed to instantly detect XSS attacks originating from web forms. The model is capable of operating independently without relying on external resources or systems (such as cloud services or large detection engines). The proposed solution focuses on a combined feature set consisting of fast-to-calculate syntactic and lexical indicators (such as tag count, suspicious token frequency, coding markup, and entropy). Simple and well-established classifiers—logistic regression, random forest, and LightGBM—were used, focusing on detection effectiveness (precision, recall, F1, and AUC) and operational constraints (inference time per sample and model size). To reflect real-world conditions, the experiments combine generic XSS payloads, benign sample templates, and synthetically modified payloads that mimic the obfuscation and encryption techniques used by attackers. The results are lightweight, low-effort, and highly accurate, and they compete with heavier competitors, with significantly lower semantic and memory footprint costs.

I. INTRODUCTION

I.1 CROSS- SITE SCRIPRING (XSS) ATTAC CONCEPTS

In the modern digital ecosystem, web applications form the backbone of e-commerce, social networking, online banking, and enterprise operations [1]. Their functionality relies heavily on user-provided input through mechanisms such as HTML forms, URL query parameters, HTTP headers, and the delivery of dynamic content via AJAX or API endpoints [2].While these mechanisms are essential for delivering interactive and personalized experiences, they also present significant security vulnerabilities, particularly injection-based attacks [3], [4].Among these threats, cross-site scripting (XSS) remains one of the most prevalent and impactful, consistently ranking among the top 10 most common security risks on OWASP's list [5]. XSS attacks allow attackers to inject and execute malicious scripts within the context of a victim's browser, enabling serious exploits including session hijacking, credential theft, phishing via content spoofing, cross-browser cryptocurrency mining, and client-side malware [6]. Beyond the compromise of individual users, XSS vulnerabilities can form the backbone of large-scale breaches, undermining user trust and an organization's reputation [7], [8]. Traditional defenses against XSS—such as input sanitization libraries, context-aware cryptographic functions, and signature-based web application firewalls (WAFs)—have demonstrated partial effectiveness [9]. However, attackers routinely circumvent these measures by using advanced evasion strategies, including multi-layer encryption, Unicode/HTML entity obfuscation, DOM-based injection chains, and polymorphic payload generation [10].

Consequently, XSS payload detection has evolved from simple pattern matching to more sophisticated techniques based on machine learning (ML) and deep learning (DL)[11], [12]. Recent academic and industry research demonstrates that ML- and DL-based detectors outperform rule-based systems in identifying complex and obfuscated attack vectors [13].

I.2 PROBLEM STATEMENT

The threat of Cross-Site Scripting (XSS) persists in web applications because attackers continuously develop new payload structures and obfuscation methods. These solutions depend on computationally intensive models which include CNNs, RNNs and deep ensemble architectures that need substantial memory resources and processing power and result in extended inference times. The computational requirements of these systems prevent their practical use in resource-limited environments including:

- Shared hosting servers with limited CPU quotas.
- Content delivery network (CDN) edge nodes where the processing time per request must be kept to a minimum.
- Web portals integrated with the Internet of Things (IoT) with strict power and latency constraints.

The research indicates a need for a solution that achieves detection performance at a lower computational cost than deep models. The proposed solution develops a lightweight machine learning framework which functions independently to detect XSS payloads in model-based inputs.

I.3 CONTRIBUTIONS OF THIS STUDY

The research delivers three essential contributions to the field. The research presents a new engineering method which detects model-based XSS payloads by optimizing discrimination power and computational efficiency. The proposed model functions independently because it does not need external resources or systems including cloud services or large-scale detection engines. The research combines accuracy-focused feature development with resource-sensitive classification to achieve real-time XSS attack detection while maintaining operational scalability. The research advances web application security through its contributions which create more secure efficient and resilient systems against advanced client-side threats.

II.RELATED WORK

Researchers have developed ensemble-based approaches to improve robustness. Shahid et al [14]. proposed a deep framework of embedded convolutional networks (CNNs) and long short-term memory (LSTM) networks to detect XSS and SQL attacks, significantly improving the severity of false positives. in [15] Oshoiribhor and A. John-Otumu, presented XSS-Net, a custom machine learning model optimized for construct optimizations, which demonstrates improved robustness beyond traditional methods. At the same time, multiple learning architectures are gaining momentum, along with the ability to automatically learn complex types of raw data. in [16] Yan et al. presented a multiple convolutional neural network that detects XSS payloads embedded in obfuscated scripts, achieving superior performance over traditional learning models. In [17] implemented an LSTM-based model specifically designed for cloud environments, emphasizing the importance of sequential contextual learning for complex control trends. Recently, large-scale hybrid models between email and modern technologies have disrupted fast emails. In [18]

Alluraini, proposed a bipartite graph representation of XSS combined with aggregated DL classifications, enhancing previously unseen innovations. Furthermore, in [19] Lewon developed XSShield, a lightweight hybrid DL model powered by new aggregated data, enabling high-performance and low-latency inference for creative content applications. Furthermore, some optimization-driven work is exported. In [20] Babaey and A. Ravindran developed GenXSS, an AI-driven detector framework that uses genetic algorithms to dynamically optimize models, improving their adaptability to advanced innovations. Similarly, in [21] Zheng et al. combined XGBoost, LightGBM, and SMOTE to balance imbalanced datasets and detect payment security system applications, demonstrating their adaptability to XSS detection tasks. Overall, while we observed the bulk of the monitors dedicated to effective learning in legacy payload control, hybrid learning and ensemble models are adaptable and resilient against aggressively designed XSS attacks and zero-day attacks. However, challenges remain in model versatility, interpretability, and adaptability to the readiness stage.

Table 1: The summary of related works on detecting XSS attack.

Authors	Methodology	Application / Dataset Type	Advantages	Limitations
[14]	Deep framework of embedded CNN + LSTM	Detection of XSS and SQL attacks on mixed datasets	Significantly reduces false positives; captures sequential + spatial features	Computationally expensive; requires large datasets
[15]	XSS-Net (custom ML model with construct optimizations)	Web application form inputs	Improved robustness beyond traditional methods	Requires fine-tuning for different environments
[16]	Multiple CNN architecture	Obfuscated XSS payloads embedded in scripts	Superior performance over traditional ML; strong obfuscation handling	May not generalize well to novel attack types outside training scope
[17]	LSTM-based sequential contextual model	Cloud environment datasets	Captures long-term dependencies; suited for complex control trends	Slower inference speed in large-scale deployments
[18]	Bipartite graph + aggregated DL classifications	Large-scale hybrid datasets (email + web)	Novel representation improves detection of unseen patterns	Graph-based models require more preprocessing
[19]	XSShield: Lightweight hybrid DL model with	Creative content & real-time applications	High performance with low latency	Limited evaluation on large-scale enterprise traffic

	aggregated data			
[20]	GenXSS (genetic algorithm optimized DL model)	Adaptive XSS detection frameworks	Dynamically optimizes model parameters; improved adaptability	Higher complexity; optimization adds overhead
[21]	XGBoost + LightGBM + SMOTE	Payment security and XSS detection tasks	Balances imbalanced datasets; robust detection in multiple domains	Training time increases due to SMOTE and en

III. METHODOLOGY

This section outlines the end-to-end methodology adopted in this work, covering dataset construction, preprocessing, feature engineering, model selection and training, evaluation protocols, deployment considerations, and the self-contained operational capability of the proposed system.

III.1 DATASET CONSTRUCTION

To create a representative, reproducible, and diverse evaluation set, this study relied on a multi-source dataset construction strategy that combined real-world attack payloads, legitimate user inputs, and synthetically generated in-depth variables. The design goal was to ensure that the dataset captured both the breadth of XSS attack vectors and the diversity of benign user behaviors, enabling the trained models to generalize effectively to unseen scenarios. The construction process consisted of three integrated components:

III.1.1 Public Malicious Xss Payload Sets

A selection of malicious XSS payloads was obtained from widely known security repositories, including the OWASP XSS Cheat Sheet and PayloadsAllTheThings. These repositories are maintained by the security community and have been widely consulted in previous research, providing a core set of attack vectors covering multiple encryption schemes, script injection patterns, and contextual exploitation scenarios (such as DOM-based, reflected, and stored XSS). This component ensured that the dataset reflected known, verified, and reproducible attack patterns.

III.1.2 Realistic Benign Input Acquisition

To accurately model legitimate user behavior, benign samples were acquired from two main channels:

•Synthetic benign data generation, which produced realistic, typical inputs such as names, comments, search queries, and email-like text strings using context-aware text generators.
•Publicly available datasets containing typical user-generated web content were extracted from open forums, discussion forums, and datasets such as Common Crawl.
•This step ensured semantic and structural diversity in the benign samples, reducing the risk of overfitting models to narrow benign input patterns.

III.1.3 Synthetic Mutation of Malicious Payloads

To simulate evasive and polymorphic attack strategies, malicious payloads were subjected to an automated transformation pipeline that applied layered obfuscation techniques, including:

• Multi-pass URL encoding (percent encoding).
• HTML entity encoding for critical characters.
• Base64 wrapping to hide payloads.
• Unicode escape sequences to replace special characters.
• Whitespace injection to disable pattern matching.
• Character scrambling within benign-looking wrappers to bypass naive filters.

These transformations mimic real-world adversarial behavior, forcing the detection system to learn deeper structural patterns rather than relying on simple keyword matching.

III.1.4 Labeling and Class Balance

All samples were binary labeled: malicious samples were assigned a label of 1, and benign samples were assigned a label of 0. A balanced or slightly imbalanced distribution (e.g., 70% benign, 30% malicious) was maintained to prevent bias toward either class, with a synthetic oversampling technique (SMOTE) applied in cases of imbalance. The total dataset size ranged from 20,000 to 50,000 samples, providing sufficient statistical power for deep learning training while maintaining computational feasibility.

III.1.5 Temporal Splitting for Realism

To simulate concept drift and test the robustness of the model under sophisticated attack conditions, temporal splitting of the data was applied. In this setup, older data was used for training, while newer samples (including new obfuscations) were saved for testing, reflecting the practical challenge of emerging zero-day vulnerabilities and XSS variants in operational environments.

III.2 PREPROCESSING

After creating the dataset, a systematic preprocessing pipeline was implemented to ensure data consistency, eliminate noise, and transform the raw samples into a machine learning-ready format. This step is critical for security-oriented text classification tasks, as improper preprocessing can inadvertently remove key attack signatures, or conversely, retain irrelevant noise that hinders model generalization. The preprocessing process consists of the following steps:

III.2.1 Data Cleaning and Normalization

•Duplicate Removal - Identical payloads or non-malicious inputs were removed to prevent model bias toward duplicate samples, ensuring that performance metrics accurately reflect generalization ability rather than memorization.
•Case Normalization - All text was converted to uniform case (lowercase) to reduce feature rarity while maintaining semantic equivalence. This step was implemented with caution, as some XSS payloads exploit case differences in tags (e.g., <ScRiPt> vs. <script>).
•Whitespace and Control Character Handling - Unnecessary whitespace and invisible control characters (such as \r, \n, \t) were normalized or removed, except in cases where intentional obfuscation was part of the attack signature, in which case these patterns were retained as distinguishing features.

III.2.2 Encoding Standardization

Because XSS payloads often use multiple encoding schemes to evade detection, a controlled partial decoding process was implemented:

• Single-pass decoding of URLs and HTML entities was applied to detect embedded malicious structures, without completely removing the multi-layer obfuscation.
• Retention of obfuscated variant alongside the decoded models allowed the model to learn from both explicit and hidden attack representations, increasing its resilience against polymorphic threats.

III.2.3 Tokenization Strategy

•A hybrid encoding approach was adopted, combining character-level and word-level encoding. Character-level encoding is essential for capturing subtle manipulations in payloads (such as inserted special characters and punctuation marks), while word-level encoding helps identify semantic patterns in otherwise intact texts.
•Custom code boundaries were defined to ensure proper separation between HTML tags, JavaScript snippets, and encoded segments. Particular attention was paid to ensuring that the compositional balancing did not result in duplicate or overly similar payloads, which could inflate the evaluation metrics. The dataset was divided into subsets for training (70%), validation (15%), and testing (15%).
•For temporal evaluation, an alternative splitting strategy was used, where the training set included older samples, while the test set included newer, unseen payloads to assess robustness against concept drift. Using this multi-stage preprocessing, the final dataset was transformed into a structured, information-rich representation that preserves key attack characteristics while minimizing irrelevant noise. This careful preparation ensures that the subsequent modeling phase benefits from high-quality and representative input data, which is essential for building reliable and generalizable XSS detection systems.

III.3 FEATURE ENGINEERING

After the preprocessing phase, feature engineering was performed to transform the cleaned and normalized dataset into an improved representation that enhances the discriminative ability of machine learning models. In the context of XSS detection, feature engineering is not simply a dimensionality reduction task; it is a strategic process for capturing semantic, syntactic, and structural cues that distinguish malicious payloads from benign inputs:

III.3.1 Character-Level Features

To effectively capture the characteristics of obfuscated and malicious XSS payloads, three categories of features were designed. These features address lexical patterns, structural markers, and randomness indicators, thereby improving both detection accuracy and robustness, such as in Figure 1.

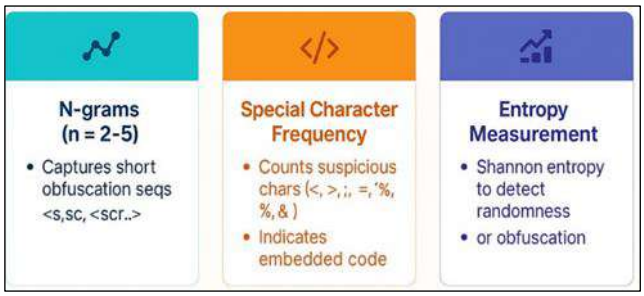

Figure 1: Extracted Feature Categories.
Source: Authors, (2026).

III.3.2 Token-Level Features

•Keyword Presence Markers: Boolean indicators of the presence of important keywords (e.g., script, onerror, onclick, alert, eval) that frequently appear in XSS payloads.

•Tag Structure Analysis: HTML tag sequences were analyzed to detect irregular or incomplete structures that could bypass filters.

III.3.3 Encoding Pattern Indicators

• Depth multi-layer encryption: The number of consecutive encryption/decryption layers detected, which is useful for identifying advanced evasion techniques.

• Encryption type flags: The presence of Base64, Unicode escape codes, or double URL encoding.

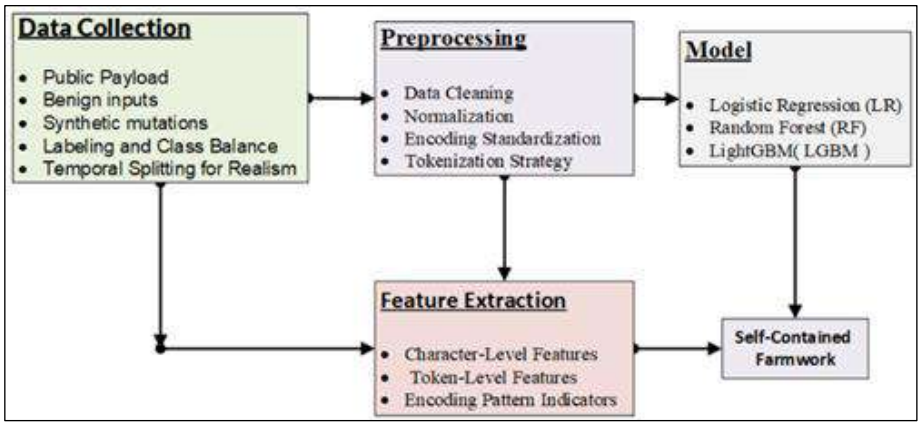

Figure 2: The overview of the proposed system.
Source: Authors, (2026).

III.4 MODEL SELECTION WITH SELF-CONTAINED OPERATIONAL CAPABILITY

The model selection process aims to identify an approach that not only achieves high detection accuracy but also supports fully autonomous and self-sufficient operation a hallmark of the proposed framework:

III.4.1 Proposed Detection Model

Three traditional machine learning algorithms were initially shortlisted based on their proven effectiveness in binary classification and computational efficiency for real-time deployment:

•Logistic Regression (LR) – In Logistic Regression, each predictor X_ij is assigned an independent coefficient indicating its contribution to the.

$$\ln\left[\frac{P(Y=1|X_{ij})}{1-P(Y=1|X_{ij})}\right] = \beta_o + \beta_1 X_{ij} + \beta_2 X_{i2} + \cdots . + \beta_P X_{iP} \quad (1)$$

expression $\ln\left[\frac{P(Y=1|X_{ij})}{1-P(Y=1|X_{ij})}\right]$ represents the natural logarithm of the odds of the binary outcome Y. The transformation of both sides through exponentiation converts log-odds into odds which results in an exponential form of the expression. The probability can be found by rearranging the equation to solve for the probability term [22]. The derivation results in the logistic function (Eq. 2) which defines probability through an exponentiated linear combination of predictors.

$$P(Y=1|X_{ij}) = \pi(X_i) = \frac{e^{\beta_0+\beta_1 X_{i1}+\beta_2 X_{i2}+\cdots+\beta_p X_{ip}}}{1+e^{\beta_0+\beta_1 X_{i1}+\beta_2 X_{i2}+\cdots+\beta_p X_{ip}}} \quad (2)$$

Here, the vector of predictor variables is defined as.

$$X_i = (X_{i1}, \quad X_{i2}, \ldots . , X_{ip})$$

where X_{ij} represents the predictor variable for observation i. The coefficients of these predictors are denoted by $\beta_o, \beta_1, \beta_2, \ldots . , \beta_p$ where corresponds to the intercept term. The probability of the binary $\pi(X_i)$ outcome = (Y = 1) for observation i, given its associated predictor variables X_{ij}[23].

•Random Forest (RF) – It is a supervised ensemble learning method that constructs multiple decision trees, with the final output determined by majority voting on the individual tree predictions. Each tree is trained on a random subset of features, and the best split is selected using the Gini index, as shown in Equation (3) [24].

$$Gini\ index = 1 - \sum_{i=1}^{C} (p_i)^2 \quad (3)$$

•Light Gradient-Boost Machine (LGBM)– Machine learning (ML) and artificial intelligence (AI) are rapidly growing fields, and the LightGBM (LGBM) algorithm is one of the most successful machine learning algorithms due to its high accuracy, efficiency, and low memory consumption. LightGBM creates multiple decision trees, with each new tree using the residual errors of previous learners, and the final output is the sum of the predictions from all the trees. Its advantages include fast training via feature pooling, support for graphics processing units (GPUs), large-scale data processing, and high accuracy. However, its incremental (leaf-like) growth can cause overfitting, especially on small datasets [25].

III.4.2 Self-Contained Operational Capability

•A key design goal was to ensure the detection system's independence and scalability without relying on external services. Once the model is trained, it operates entirely within the host environment, performing the following:
•Local Feature Extraction - All preprocessing and feature engineering are performed locally, avoiding network latency and preserving data confidentiality.
•Device Inference - Malicious payload detection is performed in real-time, ensuring decisions are made in sub-milliseconds.
•Incremental Learning - The system can incorporate new labeled data into its knowledge base without requiring full retraining, enabling it to adapt to emerging XSS attack vectors.
•Autonomous Operation - It does not rely on cloud APIs or third-party processing; the framework can be deployed within Web Application Firewalls (WAFs), Intrusion Detection Systems (IDSs), or autonomous edge devices.

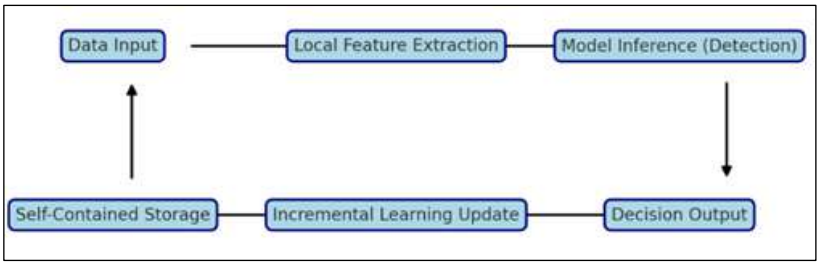

Figure 3: self-contained operational flow of proposed model.
Source: Authors, (2026).

This integrated architecture not only improves speed and reliability but also enhances security and privacy, as sensitive input data never leaves the local environment. Furthermore, the incremental learning capability ensures that the model remains resistant to conceptual drift and continues to evolve alongside attackers' methodologies.

IV. EVALUATION METRICS

The confusion matrix serves as a fundamental evaluation tool for binary classification tasks to assess model performance. The true negative (TN) represents benign instances that were correctly identified as benign while false positive (FP) occurs when benign samples are mistakenly classified as XSS attacks. The classification of XSS instances as benign when they should be attacks is known as false negative (FN) while true positive (TP) represents correct detection of XSS attacks as attacks. The evaluation process required multiple performance metrics including accuracy, precision, recall, F1-score, misclassification rate and AUC-ROC. The main performance metrics along with their mathematical definitions are presented in Table 2.

$$Accurac = \frac{TP+TN}{TP+TN+FP+FN} \quad (4)$$

$$Precision = \frac{TP}{TP+FP} \quad (5)$$

$$Recall(R) = \frac{TP}{TP+FN} \quad (6)$$

$$\text{F1} - \text{score} = \frac{2*\text{Recall} * \text{P recision}}{\text{Recall} + \text{P recision}} \quad (7)$$

V. RESULTS AND DISCUSSION

The proposed lightweight machine learning model for XSS attack detection in web forms was experimentally evaluated using a hybrid dataset that combined publicly available XSS samples with manually collected malicious payloads. The resulting dataset consisted of 5,000 benign and 5,000 malicious instances, ensuring a balanced class distribution. This design choice was made to minimize bias and to support fair and reliable model training and evaluation.

V.1 EXPERIMENT ENVIRONMENT CONFIGURATION

The system's cross-device compatibility assessment required testing on two different platforms which included Google Colab as a cloud-based virtual platform and Raspberry Pi 5 Model B as an edge computing device. The experimental framework used Python 3.10 and TensorFlow 2.15 on both setups to maintain consistency. The system evaluations took place without GPU acceleration to demonstrate its lightweight operation and its performance under limited resources. The hardware specifications of the two environments are illustrated in Figure 4, which provides a side-by-side comparison between the edge device and the cloud environment.

Figure 4: system environments.
Source: Authors, (2026).

V.2 EXPERIMENT RESULTS

The proposed self-contained framework implemented three supervised learning algorithms which included Logistic Regression (LR), Random Forest (RF) and LightGBM (LGBM) to evaluate performance. The algorithms were selected because they have shown effectiveness in text-based security tasks and they have different computational characteristics and model complexity. The performance of the models was evaluated using standard classification metrics which included accuracy, precision, recall, F1-score and ROC-AUC to ensure a comprehensive evaluation. Confusion matrix analysis was performed for each classifier to determine the misclassification patterns and ROC curves were constructed to show the trade-off between true and false positive rates.

The LightGBM-based self-contained framework performed the best among the tested algorithms with an accuracy of 99%, precision of 98%, recall of 98% and an F1-score of 99%. The model achieved a ROC-AUC score of 0.987 which shows that it can discriminate between benign and malicious inputs and outperforms the other baseline classifiers. The confusion matrix revealed a low false positive rate, making LightGBM particularly suitable for real-time XSS filtering, where reducing unnecessary blocking of legitimate user input is critical. Additionally, LightGBM's lightweight computational profile enables accelerated inference times, even in resource-constrained environments. Figure 5 depicts the confusion matrix for the LightGBM model, while Figure 6 illustrates its ROC curve, highlighting the model's excellent separability.

V.3 COMPARATIVE ANALYSIS

Figure 7 compares the accuracy, precision, recall, and F1 score across the self-contained framework models and Figure 8 depicts the time consumption, showing that LGBM slightly outperforms RF and LR in detection accuracy and stability. While RF offers robustness against feature noise, and LR outperforms in training speed and scalability, LGBM's balance of accuracy, low computational cost, and stability makes it the most suitable candidate for real-time XSS detection in web forms.

The confusion matrix in Figures 9 and 10, compared with Figure 5, as well as the comparative ROC curves for all models (Figure 11), further confirm LGBM's marginal advantage in separability. Table 3 summarizes all evaluation metrics for the classifiers.

V.4 LIMITATION

While the proposed lightweight machine learning framework for XSS attack detection shows promising results, several limitations must be acknowledged to provide a balanced perspective on its applicability and generalization capabilities.

- Although the dataset combines generic XSS samples with hand-compiled payloads, it may not fully reflect the diversity of real-world attack patterns, potentially limiting detection effectiveness against new evasion techniques.
- Feature engineering approaches, which focus on syntactic features (n-grams, special character occurrences, JavaScript keywords, and HTML tag patterns), may be less effective against obfuscation, encryption, or zero-day attacks, highlighting the need for semantic and dynamic analysis.

Table 4: Comparison Table of Related Works and Our Proposed Framework.

Ref	Approach / Model	Dataset	Reported Performance	Remarks
[15]	XSS-Net (custom ML model)	XSS dataset (web payloads)	Acc ≈ 96%	Tailored ML with feature optimizations
[18]	Bipartite Graph + DL ensemble	Graph-structured XSS	Acc ≈ 97%	Strong on complex graph features
[20]	GenXSS (GA + ML)	WAF-based dataset	Acc ≈ 97–98%	Adaptive genetic optimization
[21]	XGBoost + LGBM + SMOTE	Payment security dataset	Acc ≈ 95–96%	Tackled class imbalance

VI. CONCLUSION AND FUTURE WORK

This study proposes a lightweight, integrated machine learning framework for XSS detection that requires minimal external resources and enables direct deployment in live web applications. Using LGBM along with RF and LR for comparison, the model achieved high accuracy, precision, and recall while maintaining low computational cost. The integrated design ensures easy integration, scalability, and applicability in resource-constrained environments. The importance of this work lies in its balance between detection performance and computational efficiency, enabling practical integration in live web applications without significant performance degradation. Furthermore, the study contributes to the field by demonstrating that well-engineered traditional models can match or exceed the performance of more resource-intensive approaches for specific security tasks. Future work will focus on incorporating incremental learning to adapt to evolving attack vectors, expanding datasets with more diverse realistic payloads, and improving detection through semantic and dynamic analysis techniques.

ABSTRACT

Microgrids combine battery energy storage devices and renewable resources with the utility grid. An intelligent energy switching approach between solar, battery and grid ensures continuous supply of power by dynamically adjusting to resource availability and load requirements. In this paper, a novel microcontroller-based energy management scheme (MCU-based EMS) is proposed by combining both on-grid and off-grid power management systems allowing microgrids to function smoothly in both grid-connected and islanded modes. In the off-grid management, a Maximum Power Point Tracking (MPPT) algorithm is used for maximizing the extraction of available PV power. Further, a DC-DC boost converter is employed for boosting the voltage to match the battery's charging need and loads. In on-grid management, an H-inverter along with a synchronizer circuit is used to supply loads during peak shaving hours. Besides, a bidirectional buck-boost converter ensures battery charging and discharging. The microcontroller intelligently controls the transition between operating modes by continuously assessing power demand and availability to identify the best source. A key component of the system is the Adaptive Spatio-Temporal Graph Convolutional Learning (ASTGCL) model, which enables proactive and dynamic energy management by forecasting the best power dispatch based on environmental data, resource availability, and load demand. Real-time monitoring, performance tracking, and remote control for increased efficiency are made possible with IoT integration. Real-time hardware implementation and simulation studies are used to validate the proposed model. The simulation results show that the proposed technique outperforms conventional models in terms of achieving quick, seamless switching, guaranteeing a continuous supply and maximizing the usage of renewable energy. With a mode-switching time of only 24 ms, the proposed MCU-based EMS significantly outperforms other conventional methods like MGIB (120 ms), NILM (95 ms), M-GRU-based NILM (110 ms) and FF-SHMS (105 ms).

I. INTRODUCTION

Fossil fuel depletion globally has started to shift our interests towards the utilization of renewable energy resources. Presently, microgrids (MGs) are gaining attention since they have the ability to enhance the controllability and reliability of power systems [1]. Microgrid is an integrated source of power from utility grid, energy storage devices and renewable sources that can operate either in standalone or in grid-tied mode [2]. However, this integration poses new challenges for managing and controlling power to meet demand needs and supply the load. Energy management and control strategies are divided into upper and lower-level controls. The primary control (lower-level control) is responsible for frequency and voltage stabilization.

The Energy Management System (EMS), that is upper-level control is responsible for predicting the availability of load demand and renewable power resources. It is also responsible for scheduling available load demand and energy production within a MG [3]. Photovoltaic (PV) power producers which can operate in off-grid mode are attractive sources of power in mountainous or remote places, where the installation of grid supply is not possible. A common configuration for isolated PV system consists of three converters namely a buck and boost converter for PV charging and discharging and one for regulating loads [4], [5]. Normally, electric meters measure the energy consumption at each house and billing is produced at the end of each month which inhibits remote tracking of energy usage.

With the help of IoT, the remote monitoring of house current consumption on web application is made possible [6]. The integration of IoT in EMS helps the individuals, companies and industries to control their devices based on the energy consumption ensuring optimal use of power. Many techniques developed for managing energy is limited in handling highly dynamic AC loads and grid disturbances [7]. In this paper, a novel MCU-based EMS is proposed for managing power flow between different power sources ensuring an uninterrupted power supply to loads and also reducing harmonics in grid. The main contributions of this paper are,

- An off-grid power management system is developed using PV panels to prioritize solar energy during maximum solar power generation with MPPT and switch to battery during low generation, where bidirectional buck-boost converters are used for effective battery charging and discharging.
- An on-grid power management system is proposed for intelligently switching between solar, grid, and battery power, wherein a bidirectional converter is used for effective grid-based battery charging and synchronizer circuit for continuous AC load operation.
- Real-time performance tracking, remote monitoring, and user-driven modifications based on usage patterns are all made possible by IoT.
- IoT is used for monitoring the system remotely to gain real-time performance insights and user-driven modifications.
- The proposed method reduced consumption costs, increased energy efficiency, decreased grid dependency and ensured a more sustainable power supply while maximizing the use of solar power.

This research paper's contents are classified into the following sections: A survey of various literatures on energy management in microgrids is discussed in section 2; section 3 deals with the working of the proposed methodology in detail; the hardware and simulation results are presented in section 4 and section 5 talks about the conclusion of this paper.

II. LITERATURE REVIEW

In this section, various literatures on energy management in residential settings is discussed. The purpose, methods, advantages and disadvantages of different literatures is mentioned below.In [8] developed an efficient energy management plan to satisfy energy requirements and provide a steady supply of electricity under various load scenarios. A smart communication system based on IoT is created for a hybrid microgrid that combines Vanadium Redox Flow Battery (VRFB) storage, PV and a biogas plant. The microgrid operation is monitored and controlled in real time through Raspberry Pi while the system circuits for the hybrid microgrid electrical interface is realized through a PSCAD simulation research. In [9] presented a Fuzzy logic-based Framework for Smart Home Monitoring Systems (FF-SHMS) that uses IoT to improve energy efficiency. In order to manage resource-constrained loads and promote sustainability, the presented fuzzy architecture optimizes the design of intelligent microgrids with integrated storage. Additionally, the framework optimizes the microgrid's economic benefits by enhancing electricity and storage utilization of renewable energy sources.

By effectively assessing various criteria the suggested framework undergone simulation to obtain superior performance. In [10] utilized a Non-Intrusive Load Monitoring (NILM) technology for managing energy in home microgrids integrated with PV and battery storage with the help of IoT. The usage of energy in each home is monitored by Artificial Neural Network (ANN) optimized with Particle Swarm Optimization (PSO). Then the monitored energy is sent through ThingSpeak IoT to the customers. The NILM technique eliminates the smart meter setup thereby reducing the cost for installation. In [11] implemented a Multi-task Gated Recurrent Unit (M-GRU)-based NILM model for handling energy in residential microgrid. M-GRU-based NILM is used for extracting individual customer's energy consumption from smart meters. Then, the extracted information is given to the microgrid for managing energy consumption. The operating cost of the model is reduced by 45% while user satisfaction is increased by 65%. In [12] developed a hierarchical IoT-based renewable energy self-consumption approach for Microgrid-Enabled Intelligent Buildings (MGIBs) aiming to automate and digitalize energy supply and consumption.

Initially, a 2D fusion layered architecture is implemented for the microgrids to interact with the loads. Then, a state transition strategy is employed for maintaining the operating states of consumers and suppliers based on event and temporal triggers. Finally, self-regulated coordination between power generation and demand is achieved by power balance control approach. Monitoring consumption, generation and supply data is handled by the FIWARE framework. In [13] designed a smart Home Energy Management System (HEMS) for prosumers to handle energy efficiently. K-means clustering combined with ANN is utilized for load forecasting to predict energy needs. Energy usage is scheduled using Teaching-Learning-Based Optimization (TLBO), which aims to minimize energy drawn from the grid and lower overall costs by identifying the best times to charge or discharge batteries and when to shift or reduce energy consumption. In [14] formulated an intelligent demand response approach for uninterrupted supply of energy from batteries, renewables and grids. Only lights and AC are currently controlled according to the SoC value of battery. The model maximized the use of renewables thereby reducing electricity cost, peak demand and carbon emissions. According to the existing literatures, the use of real-time MPPT at the hardware conversion step is not highlighted. The proposed system uses MPPT-based DC-DC converters, which allow for the best possible solar energy extraction in a range of irradiance levels. This efficiently guarantees the optimal use of the PV electricity that is available.

III. PROPOSED METHODOLOGY

The working mechanism of the proposed MCU-based EMS is discussed in this section and the block diagram of the proposed technique is illustrated in Figure 1(a). Inputs such as weather characteristics (irradiance, temperature, etc.), historical PV output, battery SoC data, grid data and load demand are collected at each time step of the historical time window of previous observations.

These inputs are used by the ASTGCL framework, which predicts the optimal power contribution from each source for the next day. The microcontroller or smartphone then receives the predicted power dispatch and uses it to carry out the suggested actions by alternating between power sources and choosing the proper operating mode (off-grid or on-grid) as needed. The off-grid or island mode is where the solar panels or battery storage devices supply power to the loads without the use of grid power. With the availability of solar power, the loads are supplied with solar energy. The excess solar power not used by the loads is used to charge the batteries without violating their battery SoC.

When solar power is not available, the batteries supply power to the loads. In on-grid mode, the solar panels, batteries and grid operate together for supplying power to loads. When solar power is available, the loads are supplied energy from solar panels and excess solar is stored in batteries. When solar is not available, battery supplies power. If both become outage, grid supplies power to AC loads. When the grid demand is low, the batteries are charged from them and during grid outage periods, this stored energy will be supplied to the loads. Ultimately, IoT is integrated into the system for monitoring real-time energy consumption updates, grid status, battery State of Charge (SoC) and grid condition.

III.1 ADAPTIVE SPATIO-TEMPORAL GRAPH CONVOLUTIONAL LEARNING (ASTGCL)

The proposed system uses a dynamic selection process amongst three potential sources—solar panels, battery storage, and the utility grid—to guarantee a continuous supply of electricity to the demand. Environmental sensors track sun irradiance to ascertain the availability of solar electricity, while a microprocessor uses relay control to manage the switching mechanism. Power flow is anticipated and planned in advance using an optimization method since switching between sources may cause brief periods of disruption in energy dispatch. In particular, depending on the previous records, the ASTGCL model is utilized to anticipate the ideal share of power to be pulled from each source at every time step. Reliability and efficiency are achieved in hybrid energy management by combining real-time relay-based switching with predictive dispatch planning. The block diagram of the ASTGCL architecture is provided in Figure 1(b).

III.1.1 Feature Data Augmentation

When gathering input data, problems such as noise, sensor faults, communication errors and missing values often arise. The presence of these irregularities can decrease the precision of power dispatch forecasting in the microgrid system. In order to surmount this obstacle and enhance the forecasting model's resilience against absent or corrupted solar data, three strategies for feature-level data masking are developed: short-term, long-term and regional data masking.

Short-Term Data Masking: Short-term data masking is used to mimic transient disturbances in input data like temperature, PV output or irradiance. Even with the presence of actual input data, the masking system selectively masks them to imitate transient environmental disturbances. The robustness of power dispatch forecasting by each source is increased by training the model under these circumstances, which helps it maintain accuracy even in the face of abrupt changes or missing data. In order to handle the short-term missing data, the following formula is used to mask each input data.

$$\hat{I}_f^t = \begin{cases} I_f^t, if\ E_f^t \geq T_{short} \\ -1, otherwise \end{cases} \quad (1)$$

Here, $\hat{I}_f^t$ is the masked data of each input feature f at time t, I_f^t is the original input data f at time t, E_f^t is a randomly generated masking indicator and T_{short} is the masking threshold for simulating brief missing or corrupted data.

Long-Term Data Masking: Long-term data masking simulates situations in which sensor malfunctions or maintenance outages may render irradiance or temperature to be completely inaccessible for prolonged periods of time. For example, the temperature probe may be unavailable for days or the irradiance sensor may malfunction for a few hours.

The model learns to rely on the remaining features and maintain accurate predictions during extended data loss by being trained with such long-term masked inputs. The following equation is adopted to model long term data masking for each input feature like irradiance, temperature, etc.

$$\hat{I}_f = \begin{cases} I_f, if\ E_f \geq T_{long} \\ -1, otherwise \end{cases} \tag{2}$$

Here, T_{long} is the masking threshold for simulating extended loss in data caused by sensor malfunctions.

Regional Data Masking: Multiple input feature failures at the same time are represented by regional data masking. Extreme weather events like storms, grid outages, inverter tripping or communication system malfunctions that impact multiple sensors at once might cause this. For instance, because the monitoring system goes offline during a strong rainstorm, readings for temperature, panel voltage and irradiance may all be absent for a while. The forecasting model learns to maintain stability and continue prediction even when multiple critical inputs are lost at the same time by simulating such multi-feature outages during training.

$$\hat{I}^t = \begin{cases} I^t, if\ E^t \geq T_{region} \\ -1, otherwise \end{cases} \tag{3}$$

Here, $\hat{I}^t$ is the masked multi-feature input, E^t is a random masking indicator that determines whether the multi-feature data is available or missing at time t and T_{region} is the probability of missing or corrupted data.

III.1.2 Topology Data Augmentation

In the proposed model, the loads are provided with electricity by one or more sources, such as the grid, solar panels or batteries, depending on the grid status, battery SoC and solar energy availability at the time. The model employs two matrices to dynamically manage this power allocation: a fixed adjacency matrix F_A that depicts the potential connection between the sources and loads and a real-time optimized matrix O_A that modifies the strength of these connections in real-time based on available data. The system can determine the strength of each link at any given time by using this dynamic matrix. For instance, during times of high solar generation, the load-to-solar panel connection is strengthened, the grid connection is decreased and battery-to-solar panel connection is enhanced.

By combining the matrices using Hadamard product and addition operations, the microcontroller may intelligently switch power sources by determining the effective power flow between various sources and loads at any given time. The addition operation adds the fixed and optimized matrices connection strengths to capture local features—such as direct and immediate power flows like solar panels providing electricity to a nearby load or charging a connected battery. The product operation highlights global aspects, which reflects greater system-wide interactions such as coordinated power balancing between the grid, solar panels and batteries during periods of high demand. The local L_A and global G_A adjacency matrices are given by Equations, respectively.

$$L_A = F_A \oplus O_A; F_A, O_A \in R^{S \times S} \tag{4}$$

$$G_A = F_A \otimes O_A; F_A, O_A \in R^{S \times S} \tag{5}$$

Here, R is a set of real numbers and S denotes the power sources and loads connected to microgrid.

Both L_A and G_A are given to graph neural modules for producing learned feature representations both locally GNN_l and GNN_g globally to capture power flow behaviours within the system.

III.1.3 Spatio-Temporal Contrastive Learning

Spatial Contrastive Learning

The system effectively learns and distinguishes between localGNN_l and global GNN_g representations with the aid of spatial contrastive learning. The microgrid system is trained by the model to identify and align patterns that appear in both global and local representations. It helps the system acquire relevant energy flow behaviours by increasing the similarity between related local and global patterns while differentiating unrelated patterns with the help of loss function, which is mathematically modeled by the Equation (6).

$$L_{spatial} = -\frac{1}{N}\sum_{j=1}^{N} log \frac{exp\left(cos\left(GNN_l^j, GNN_g^j\right)/\tau\right)}{\sum_{k=1}^{N} exp\left(cos\left(GNN_l^j, GNN_g^k\right)/\tau\right)} \tag{6}$$

where, batch size is denoted by N, local and global representations for the j-th sample are represented by GNN_l^j and GNN_g^j, respectively, cosine similarity is indicated by $cos(.)$ and the τ parameter controls the concentration of the distribution. The similarity between related local-global pairings is captured by numerator, while the denominator accounts for all pairs including unrelated pairs.

Temporal Contrastive Learning

Temporal contrastive learning aims to differentiate between similar and dissimilar time steps in order to improve the model's capacity to learn intrinsic temporal dynamics. It creates GNN_t by concatenating two representations, GNN_l and GNN_g, at each time step t. The model chooses the least (negative sample GNN_t^-) and most similar (positive sample GNN_t^+) time steps from other intervals for each time step and the temporal loss function is given as:

$$L_{temp} = -\frac{1}{T}\sum_{t=1}^{T} log\frac{exp(cos(GNN_t, GNN_t^{+})/\tau)}{exp(cos(GNN_t, GNN_t^{-})/\tau)} \quad (7)$$

Here, T is the total number of time steps and t is the current time step.

III.1.4 Joint Learning

The joint representation GNN_R is formed by GNN_l and GNN_g representations, which is then fed into power dispatch prediction module for determining the optimal power allocation of solar, battery or grid sources to loads. The model is optimized to minimize a dispatch loss function $L_{dispatch}$ that concurrently takes into account the supply side and the demand side of the microgrid operation in order to provide precise energy dispatch. To avoid scheduling resources in an impractical manner, the supply-side term assesses the difference between the actual supply capacity at each time step and the expected power contribution from the available sources (grid, solar, and wind). However, in order to guarantee that consumption needs are sufficiently satisfied, the demand-side term records the discrepancy between the actual demand and the anticipated power delivered to the load. According to formal definitions, the dispatch loss is:

$$L_{dispatch} = 0.5 * \left|\hat{P}_{T+1}^{supply} - P_{T+1}^{supply}\right| + 0.5 * \left|\hat{P}_{T+1}^{load} - P_{T+1}^{load}\right| \quad (8)$$

Where: $P_{T+1}^{supply} = P_{T+1}^{solar} + P_{T+1}^{battery} + P_{T+1}^{grid}$.

The joint learning is facilitated by integrating auxiliary loss functions $L_{spatial}$ and L_{temp} and the total loss function is modeled as follows:

$$L = L_{dispatch} + 0.5 * L_{spatial} + 0.5 * L_{temp} \quad (9)$$

The proposed model predicts the dispatch ahead of time and sends it to the microcontroller and smartphone, in contrast to traditional sense-then-act systems, which have the microcontroller wait for real-time measurements before making a decision. By drastically cutting down on response time, this proactive prediction allows for quicker control actions, smooth energy management, and increased microgrid system stability.

III.2 COMPONENTS

A brief explanation of each of the components used in the proposed model is provided below.

III.2.1 MPPT Controller

The power produced by solar panels varies throughout the day due to the varying solar irradiance. In order to extract maximum amount of power from the solar panels, MPPT controller is used. The role of MPPT is to continuously monitor the current and voltage of the solar panels and adjusts the operating point to track the maximum power point at which the current and voltage is maximum. The MPPT controller then signals the boost converter to change its duty cycle for making the solar panels operate at its maximum power point.

III.2.2 DC-DC Boost Converter

The boost converter steps up the voltage coming from the solar panels to match the battery requirements or DC bus voltage. Besides, the converter adjusts the voltage and current of the solar panels for producing maximum solar power under varying sunlight based on the signal from MPPT. The working of MPPT controller along with boost converter ensures better energy harvesting.

III.2.3 Bidirectional Buck-Boost Converter

The bidirectional buck-boost converter allows bidirectional flow of power from grid or solar panels to batteries and from batteries to loads. The flow of power from grid or solar panels to batteries is known as charging and the power flow from batteries to loads is known as discharging. During charging, the converter acts in boost mode if the voltage coming from solar panels or grid is lower than the battery voltage. It also acts in buck mode to lower the input voltage if it is higher than the battery voltage. During discharging, the converter acts only in boost mode to step up the voltage to match the higher voltage of loads. This mode changing behavior ensures safe charging and discharging of batteries protecting battery lifetime.

III.2.4 DC-AC Inverter

The DC-AC inverter converts the stepped DC voltage coming from the boost converter or bidirectional buck-boost converter into AC voltage that can be efficiently supplied to the AC loads without any issues. A single-phase H-bridge inverter topology is utilized in the proposed model for converting DC to AC voltage. In the H-bridge inverter network, the four switches S_1, S_2, S_3 and S_4 are connected in a bridge configuration across the DC source and the switches are turned ON and OFF in a specific sequence for producing AC voltage across the load. In order to produce an approximate sine wave, Pulse Width Modulation (PWM) is used for rapid switching. Then, a filter made up of inductor and capacitor, LC filter converts the approximate waveform into a clean AC sine wave by the removal of high-frequency switching components thereby ensuring efficient and safe operation. The circuit diagram of the H-bridge inverter is shown in Figure 2 and the connection of bidirectional buck-boost and MPPT-based boost converter to the H-bridge inverter is displayed in Figure 3.

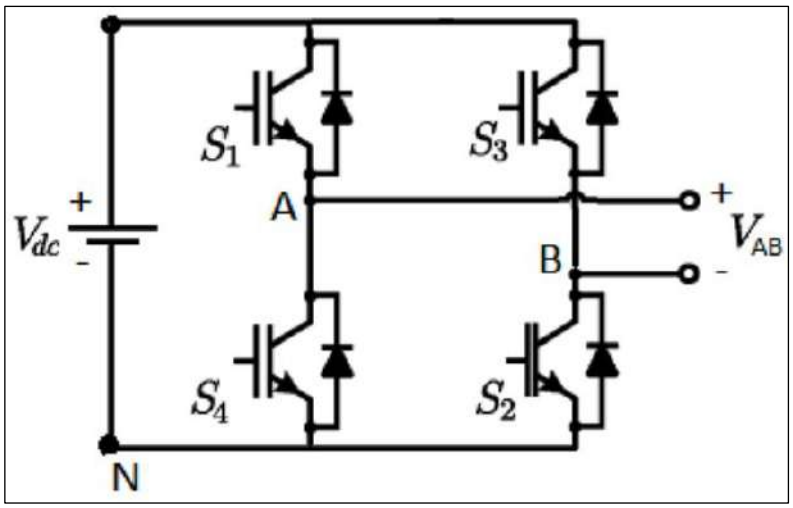

Figure 2: Circuit diagram of a single-phase H-bridge inverter.
Source: Authors, (2026).

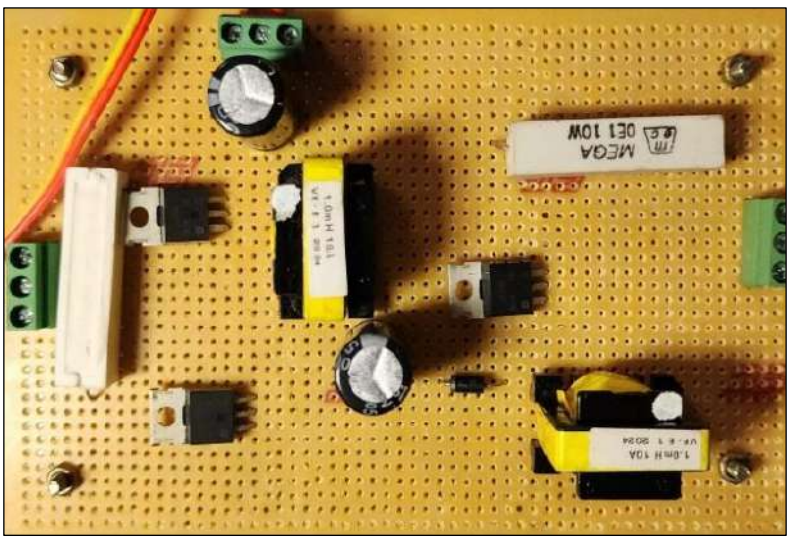

Figure 3: Bidirectional buck-boost converter and MPPT-based boost converter connected to H-bridge inverter.
Source: Authors, (2026).

III.2.5 Synchronizer Circuit

The AC signal produced by the H-bridge inverter must be in sync with the grid signal for preventing voltage surges and large circulating currents. In order to match the voltage, phase and frequency of inverter's output signal with the grid signal's voltage, phase and frequency, synchronizer circuit is used. The zero-crossing detector outputs a signal to the synchronizer circuit whenever the grid voltage crosses zero thereby providing phase reference of the grid. Then, the synchronizer circuit makes the voltage given by batteries to match the grid voltage in amplitude, frequency and phase. The incorporation of zero-crossing detector in the circuit is shown in Figure 4.

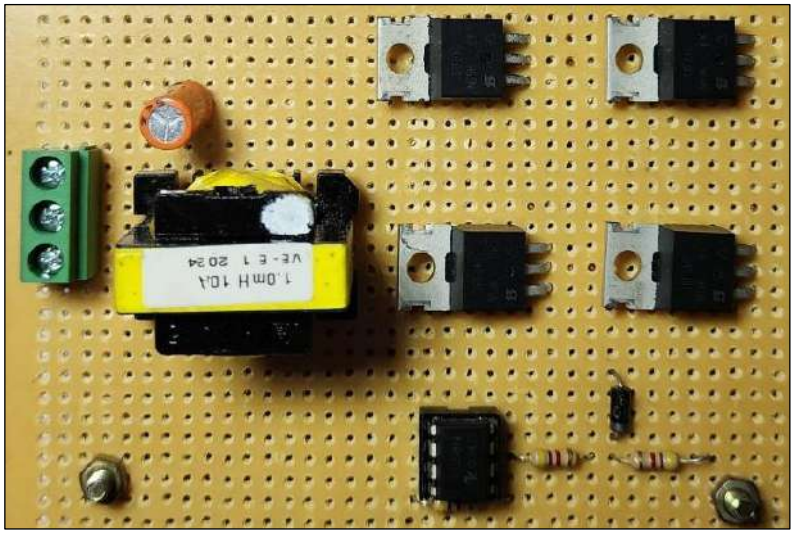

Figure 4: H-bridge inverter with LC Filter, alongside a zero-crossing detector circuit.
Source: Authors, (2026).

III.2.6 ESP8266 Microcontroller

The hardware setup of microcontroller-based mode switching hardware is depicted in Figure 5. In the figure, an ESP8266 microcontroller is used to manage relays that turn an inverter's output on or off. The blue coloured components in Figure 5 are known as relays that connects to the load by switching on the inverter and disconnects from the load by turning off the switch. This switching can be controlled manually or remotely via the IoT with the help of ESP8266's built-in Wi-Fi.

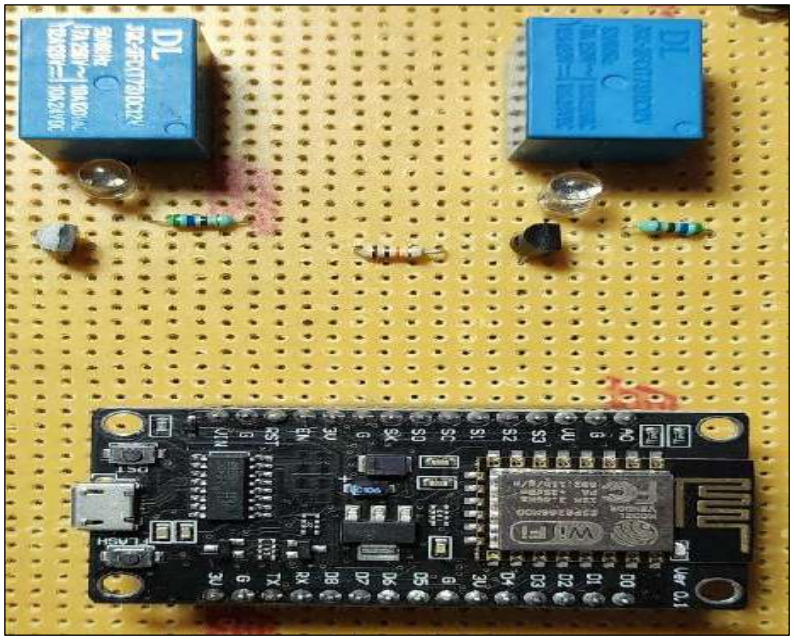

Figure 5: ESP8266 microcontroller for mode switching.
Source: Authors, (2026).

III.2.7 IoT Integration

A specialized mobile application called Blynk is developed for monitoring the real-time power system updates like grid status, load conditions, battery level and power flow remotely. The mode switching is also enabled by the consumers using the Blynk user interface. The developed IoT hardware setup worked efficiently within the Wi-Fi range of the test environment. The connection of the Blynk app with the proposed MCU-based EMS is displayed in Figure 6.

Figure 6: Proposed MCU-based EMS managed with the Blynk app.

IV. RESULTS

In this section, the hardware and simulation results of the proposed MCU-based EMS is discussed. To obtain the hardware results, the proposed system is implemented using MPPT, DC-DC boost converter, bidirectional buck-boost converter, H-bridge inverter, synchronizer circuit and IoT and validated in real-world. The system is validated against power efficiency, control stability and remote operability and the results obtained through validation are discussed below.

In the context of the H-bridge inverter, power efficiency is the ratio of AC power output provided to the household AC loads to the DC input power given by the batteries or PV panels. The system's overall energy conversion performance is indicated by this metric, which tells how well the inverter transforms DC power into suitable AC power. Usually, power efficiency is expressed in percentage and it is calculated using the formula given below.

$$P_{\eta} = \frac{P_{AC,OUT}}{P_{DC,IN}} \tag{10}$$

Here, efficiency is denoted by P_{η}, output power produced by inverter is represented as $P_{AC,OUT}$ and power supplied by the panels or batteries is given by $P_{DC,IN}$.

Table 1: Power efficiency of H-bridge inverter.

MODE	RMS OF AC OUTPUT VOLTAGE	RMS OF AC OUTPUT CURRENT	DC INPUT VOLTAGE	DC INPUT CURRENT	EFFICIENCY (P_{η})
Off-grid	230	4.98	48	23	92.3
On-grid	230	5.39	48	26	94.7

Source: Authors, (2026).

The power efficiency of H-bridge inverter under grid-tied and standalone modes is displayed in Table 1. In off-grid condition, an output voltage of 230 V and output current of 5 A is supplied to the loads. The input voltage and current supplied from the panels or batteries are 48 V and 23 A. Now, we calculate the efficiency for off-grid condition as,

$$P_{\eta} = \frac{230 \times 4.98 \times 0.89}{48 \times 23} \times 100\% = 92.3\%$$

The efficiency for on-grid mode is estimated as,

$$P_{\eta} = \frac{230 \times 5.39 \times 0.953}{48 \times 26} \times 100\% = 94.7\%$$

Here, 0.89 and 0.953 are known as power factors denoting a portion of current that is reactive. In standalone mode, there is no reference signal for converting DC into AC, therefore the power factor is large denoting the wastage of power (reactive power).

However, in grid-tied conditions, there is a reference signal from the grid for DC to AC converter, therefore the production of reactive power is less denoting lower power factor of 0.953 compared to off-grid mode. In standalone microgrid and on-grid operation, P_η is obtained as 92.3% and 94.7% respectively. The reason for the increased efficiency in on-grid mode is that the inverter synchronizes with the grid's AC signal, which offers a reliable reference for output power generation. Off-grid mode, on the other hand, requires the inverter to independently generate the AC waveform without the aid of an external reference, which leads to a modest decrease in efficiency and a rise in power losses. The inverter's performance is demonstrated by the close alignment of these values with those of commercially available hybrid inverters. Even with different load demand, the produced AC current is stable thereby eliminates load damage. The utilization of LC filter in the H-bridge inverter topology reduces the distortion present in the generated AC wave by the inverter. The reduction of harmonics with the employment of LC filter is illustrated in Table 2 and THD is calculated by the following equation.

$$THD\ (\%) = \frac{\sqrt{V_2^2+V_3^2+V_4^2+\cdots+V_n^2}}{V_1} \times 100 \tag{11}$$

Table 2: Comparison of THD present in the inverter generated output in the presence and absence of LC filter.

FILTER	FUNDAMENTAL V1 (V_RMS)	V3 HARMONIC (V_RMS)	V5 HARMONIC (V_RMS)	V7 HARMONIC (V_RMS)	THD (%)
Without filter	230	18	12	8	10
With LC filter	230	8	4	2	3,98

Source: Authors, (2026).

Bys substituting the table values in Equation 2, the THD is obtained as,

$$THD\ (\%) = \frac{\sqrt{V_3^2 + V_5^2 + V_7^2}}{V_1} \times 100 = 10\ \%\ (Without\ filter)$$

$$THD\ (\%) = \frac{\sqrt{8^2 + 4^2 + 2^2}}{230} \times 100 = 3.98\ \%\ (With\ filter)$$

Since the harmonics is reduced by LC filter, the generated voltage is suitable for integrating with grid connection. The process by which a power management system smoothly switches between different operating modes is known as mode switching. The smooth switching is measured using the time taken by the system to switch from grid-tied mode to off-grid mode or vice vera. Mode switching time is normally measured in milliseconds (ms). Despite the existence of several approaches, it is commonly calculated by,

$$t_{switch} = t_{mStart} - t_{mEnd}$$

where, t_{switch} is the mode switching time, t_{mStart} denotes the starting time of the switching operation and t_{mEnd} indicates the time when the switching operation ends. There was no noticeable voltage sag or load supply disruption during the mode-switching time, which was recorded at about 24 ms. This demonstrates that the system can continue to supply electricity even in the event of grid instability or solar unavailability. The MPPT algorithm efficiently tracked the maximum power point in solar irradiance, successfully extracting maximum power under diverse environmental conditions. The bidirectional buck-boost converter functioned reliably in both charging and discharging modes, facilitating smooth transitions based on the load demand and battery SoC. Its current-limiting and voltage-regulating capabilities protected the battery from under-voltage and overcurrent conditions, contributing to longer battery life and safer operation. The H-bridge inverter with an LC filter, driven using Sinusoidal Pulse Width Modulation (SPWM), produced a stable and smooth AC output waveform. The LC filter effectively reduced switching harmonics and delivered a clean sinusoidal voltage suitable for domestic loads. The inverter maintained consistent output voltage and frequency even under varying load conditions, reflecting its robustness and reliable dynamic response. Overall, the hardware results validate the practical feasibility of the proposed system, highlighting its suitability for efficient and sustainable domestic energy management with minimal grid dependency.

The software results obtained through MATLAB/Simulink simulation are discussed in detail below. One of the important parameters that denotes the successful system design is the supply of power to loads without any interruption. The continuous supply of power to household loads is portrayed in Figure 7. The energy requirement fluctuates throughout the day in the test configuration, peaking at nine in the morning. The demand continuously increases at a steady pace from 1 AM to 9 AM and then progressively declines from 10 AM to 3 PM. It rises once more between 4 and 6 PM, then starts to fall after 7 PM. The load demand is met by solar power between 7 AM and 5 PM, with any extra energy being stored in the battery. Before sunrise, the battery and grid supply the load in turn, and after sunset, the grid is used after the battery has discharged to its full capacity. According to the simulation results, the grid, solar, and battery contributions at each time step precisely match the load requirement, guaranteeing constant power availability for the full twenty-four hours. By ensuring an uninterrupted supply, this integrated use of solar, battery, and grid resources improves consumer satisfaction. Cost optimization is not included in the model, despite the fact that this guarantees continuous power. By taking cost into account, battery charging might be moved from the early morning low-demand hours (1–5 AM) to times of higher demand, such the morning peak.

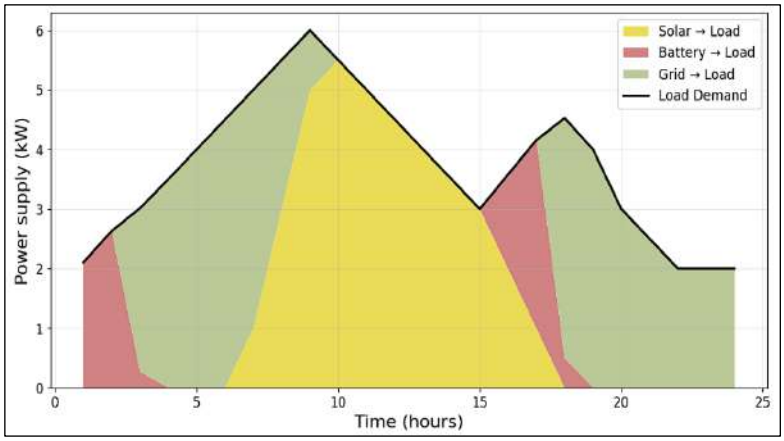

Figure 7: Continuous power supply to load.
Source: Authors, (2026).

The utilization of solar for household appliances by various techniques is shown in Figure 8. Regarding solar use, the following conclusions are from the figure. At about 57.5%, NILM has the lowest utilization, followed by FF-SHMS at 59.1%. MGIB achieves 62%, while M-GRU-based NILM comes in third with 60.2%. With the highest solar utilization of 78.6%, the proposed MCU-based EMS performs better than any other methods. The highest PV power utilization is achieved by using MPPT, which continuously modifies the PV operating point to extract maximum power under variable weather circumstances.

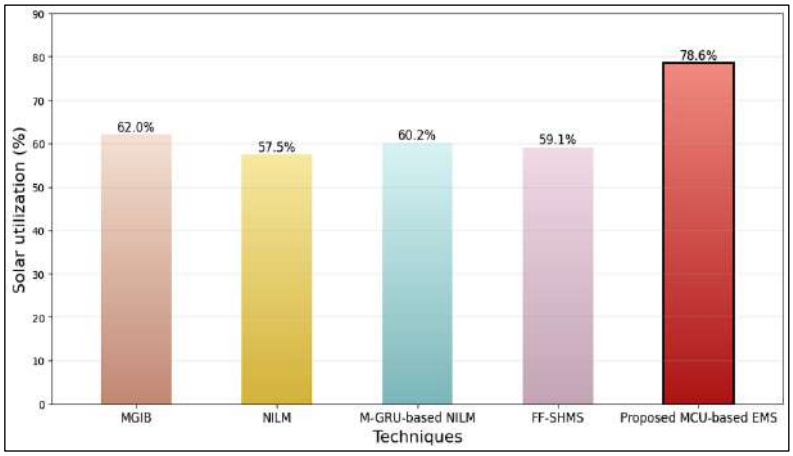

Figure 8: Comparison of solar utilization by different techniques.
Source: Authors, (2026).

Figure 9 depicts the mode-switching times of various energy management models including MGIB, NILM, M-GRU-based NILM, FF-SHMS and the proposed MCU-based EMS. The switching periods for the conventional systems are higher, ranging from 95 to 120 ms; MGIB is 120 ms, NILM is 95 ms, M-GRU-based NILM is 110 ms, and FF-SHMS is 105 ms. On the other hand, a much faster switching time of 24 ms is attained using the proposed MCU-based EMS. By enabling fast switching between on-grid and off-grid modes, the proposed framework eliminates the delays associated with traditional techniques and guarantees a continuous power supply while making the best use of renewable energy.

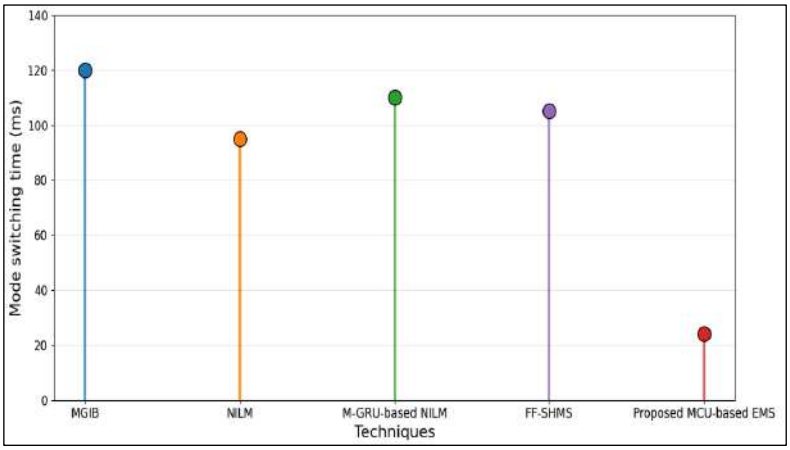

Figure 9: Mode switching times of different techniques.
Source: Authors, (2026).

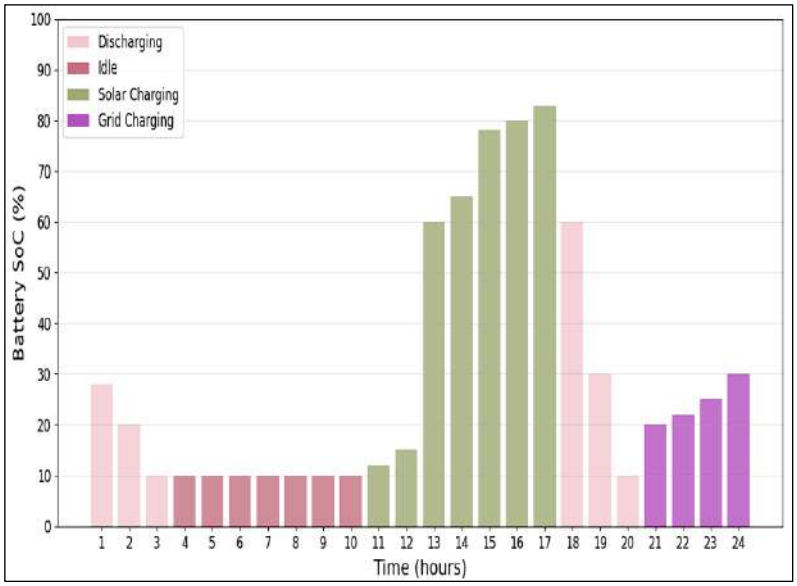

Figure 10: Controlled battery charging and discharging based on SoC.
Source: Authors, (2026).

The battery's controlled charging and discharging behavior during a 24-hour period is depicted in Figure 10, where the SoC is kept within safe bounds to avoid overcharging and deep draining. The SoC of the battery should be in the range between 10% and 90%. If the battery SoC reaches above 90%, then it is known as overcharging and if the SoC reaches below 10%, then it is known as undercharging. So, during charging, the battery must not go above 90% and during discharging, the battery should not go below 10%. This ensures the safety of battery and prolongs battery life. From the graph, it is inferred that the SoC is maintained by the proposed methodology. At the start of the day, the battery has 30% SoC and till 3 AM, it is draining energy. Since the SoC reaches 10% at the end of 3 AM, the battery is not discharging and it is idle until 10 AM. At 11 AM, there is excess solar power, the battery starts charging and at 17 PM, the SoC reaches 82%. Then, again it starts discharging until the SoC becomes 10%. Since the grid has low demand during late night hours, the battery starts to charge again by maintaining SoC.

V. CONCLUSION

In this paper, continuous power supply to home loads is achieved using the proposed MCU-based EMS. An intelligent microcontroller supplies the power continuously by switching between the power sources efficiently by checking the availability of power sources and demand needs. The model runs in two modes: grid-tied mode, which uses the grid and battery and isolated mode, which uses solar and battery power. The proposed model is constructed using various devices like synchronizer circuit, bidirectional buck-boost converter, DC-DC boost converter and MPPT algorithm. The model is also integrated with IoT using Blynk user interface for real-time energy consumption and generation monitoring.

The proposed strategy is evaluated both in hardware and software using power efficiency, mode switching time and maximum solar utilization. According to experimental results, the power efficiencies of 92.3% and 94.7% is achieved in standalone and grid-tied mode respectively. Seamless mode-switching is accomplished in less than 24 ms with no voltage sag. Under various load scenarios, the system achieved an average solar utilization of 78.6% higher than traditional methods. The system can be improved by integrating Artificial Intelligence (AI) and Machine Learning (ML) techniques which can estimate load demand, predict solar irradiance, and optimize battery charging and discharging. This efficiently distributes energy, reduces reliance on the grid and prolongs battery life. Besides, the model experiences slight delay in synchronizing the battery signal with grid electricity.

Federated Learning (FL), Self-Learning (SL), Privacy-Preservation, Transactive Energy System (TES).

ABSTRACT

Transactive Energy System (TES) has emerged as a promising paradigm for coordinating Renewable Energy generation, consumption, and delivery. However, participants' sensitive data transmitted over the network in the TES framework must be preserved against cyber-attacks as more Distributed Energy Resources (DERs) come online. This article aims to conduct a comparative survey of two Machine Learning (ML) techniques, Federated Learning (FL) and Self-Learning (SL), to determine which is most suitable for preserving participants' data privacy in TES, based on the existing literature. The performance of their models was evaluated with a focus on resilience and network stability. The work examines, predicts, and uncovers meaningful patterns in the application of FL and SL techniques around privacy preservation. Findings revealed that FL is the most appropriate choice, as it allows collaborative model training, unlike SL, which utilizes centralized data, exposing it to privacy risks. Furthermore, the efficiency of FL-based TES is superior because it eliminates communication delays and does not require sending the entire raw data to the central server. In conclusion, the research demonstrated that FL-based TES is secure and inherently decentralized. Hence, FL is suitable for preserving participants' data in TES.

I. INTRODUCTION

The geometric rise in the integration of distributed energy resources (DERs) at energy distribution and utilization levels, enhanced by advancements in smart metering, energy management, and Information and Communication Technology (ICT), has transformed conventional electricity consumers into prosumers. These prosumers can monitor and control their generation, consumption, and energy storage in real time, to facilitate energy cost savings [1]. Recently, peer-to-peer (P2P) Transactive Energy Systems (TES) have emerged as a new energy market model, promising a more thorough and effective utilization of available renewable production and DER flexibility by prosumers [2] [3]. It uses control and economic mechanisms to achieve a dynamic balance of energy supply and demand across the entire electrical grid, with value as a main operational metric [4].

TES can be further described as a group of connected peers that use prices and incentives to sustain economic benefits for participants [5]. TES permits trade of electricity in real-time based on their energy consumption and generation prediction [6]. It is an emerging solution with features to secure critical loads during generation deficits and support electrical infrastructure when transmission and distribution networks are non-operational, which may be due to natural disasters such as Hurricane Maria, which was recorded in 2017 in Puerto Rico, where 80% of the grid collapsed [7]. However, the rapid integration of Internet of Things (IoT) and the adoption of Intelligent edge devices for processing IoT data into energy systems bring about the unprecedented growth in the digitalization of the energy sector based on the data volume generated by participants [8] [9].

Nonetheless, there are security challenges associated with this advancement, which include data integrity, authentication, scalability, and privacy leakage (that is, personal information and energy consumption patterns of participants) [10]. Hence, this prompts the need to protect this data against the activities of adversaries and to leverage the potential of intelligent techniques in making rational choices regarding grid services [11]. Distributed Machine Learning (ML), such as Federated learning (FL) and Self-Learning (SL), has proved to be a promising technique that permits multiple entities, across edge devices, to train a distributed model without direct raw data sharing [12]. The FL's architecture enables collaborative and privacy-preserving training on ML models to [10] [11]. The choice of FL in recent times is based on its features and the distinctive training approach that permits training of local models in each agent, beyond the collection of the entire data from other agents to the main server [11]. It alleviates concerns about privacy protection, as only the updated parameters (gradients or weights) are transferred during model training [13]. FL was portrayed as a catalyst with the potential to resolve data privacy and security issues in [14]. A privacy-preserving FL scheme was presented for IoT intrusion detection [15]. Researchers are probing the application of FL.

Some of them include a Clustered Asynchronous FL (CAFL), which was proposed for Energy-Harvesting Smart Meters in P2P Energy Trading (ET) in [12]. Ref. [7] introduced a privacy-aware FL framework for DER analytics in constrained environments. Du et al. [16] presented an FL-assisted distributed energy optimization, while Mendes et al [17] suggested an FL framework for predicting net energy demand in TES. The role of FL in preserving the privacy of IoT devices was reported in [18], while centralized and decentralized architectures were compared in [19]. Ref. [20] reported three privacy threats in the FL central server: susceptibility, gradient leakage attacks, and collusion among participants. The authors further explored three privacy techniques —Homomorphic Encryption (HE), Differential Privacy, and Multi-party Computation — to address privacy issues. A survey of optimization methods in privacy-preserving FL with HE was reported in [21]. Privacy-preserving techniques were deployed by hybridizing FL with blockchain for telemedicine in [22], while Yin et al [23] presented a 5W-scenario-based taxonomy (Who, what, when, where, and why) to classify the potential privacy leakage risks in FL. Ref. [24] proposed a decentralized FL framework for consumers' privacy preservation and energy theft detection using HE.

An ML-based technique was proposed to address IoT privacy challenges in [25]. Federated Reinforcement Learning (RL) was reported for privacy-preserving integrated thermal and energy management of multi-connected hybrid EVs [26], while Federated Deep RL was introduced to address privacy-preserving issues in Energy Management Systems with shared energy storage for Smart houses [27]. A hybridization of FL and Transfer Learning (TL) was suggested for privacy-preserving HVAC systems [28], whereas privacy-preserving heterogeneous federated TL was reported in [29]. These analyses established recent advances in the application of FL in privacy preservation in energy systems. However, little or nothing has been extensively reported for TES. In summary, the key contribution of this work is to: (1) examine, predict, and uncover meaningful patterns in the application of FL and SL techniques around privacy preservation; (2) present a comparative analysis of these ML-based techniques to determine the best-suited for privacy preservation in TES for the network stability and resilience. The rest of the paper is organized as follows: Section II showcases the relevant research on privacy-preserving techniques in TES, and an overview of reported literature on FL and SL-based methods for privacy preservation in Energy Systems. In Section III, we evaluate the performance of FL and SL-based Models for privacy preservation in energy systems. Section IV focuses on the discussion and reported findings, while Section V is the Conclusion and future research outlook.

II. RELEVANT RESEARCH

II.1 PRIVACY-PRESERVING TECHNIQUES IN TES: OVERVIEW

Mechanisms must be put in place to protect participants' sensitive information in TES. Information such as data usage, asset ownership records, and market bid/ask prices. A privacy-preserving distributed coordination algorithm was introduced for protecting participants' data in TES in [6]. The authors' literature corroborates the existence of cryptographic techniques for data protection. Ref. [30] presented a cryptography-based method (HE-based algorithm) to address privacy and security concerns associated with TES deployment over insecure communication channels, protection of agents' bidding details, and quick detection of external injection of malicious data during market interactions. The authors employed Paillier encryption, Paillier digital signature, and Stamp concatenation techniques for privacy preservation.

Relatedly, Paillier cryptography and calibrated noise were proposed for confidentiality and privacy preservation, respectively [10]. The introduced privacy protection solution uses calibrated noise to facilitate fair transactions among participants and to conserve participant behaviour patterns. The authors achieved 41.07% privacy protection with the proposed solution. A blockchain-based privacy-preserving distributed algorithm with a smart contract to minimize the quantity of information exposed to other participants during ET using asymmetric cryptography for TES [31]. developed a decentralized P2P ET al algorithm with two stages, on the blockchain, to preserve participants' privacy [32]. An FL-based framework was presented, utilizing local generation data obtained from a university, to predict the net demand of a building in TES settings [33].

II.2 FEDERATED LEARNING FOR PRIVACY PRESERVATION IN ENERGY SYSTEMS

In recent years, the application of FL for privacy preservation has become a centre for research. Liu et al. [12] proposed an energy-aware FL protocol to prioritize systems with adequate energy reserves dynamically, developed an adaptive dual-phase clustering strategy to mitigate preference inference attacks, and introduced a blockchain framework to establish a tamper-proof energy harvesting system in a P2P ET environment. The proposed CAFL resisted preference profiling attacks, confirming the model's robustness and its convergence under intermittent energy conditions. Consequently, similar research was reported. A FL-assisted distributed consensus approach was presented to forecast agents' local energy generation and demand for minimizing errors and improving forecast accuracy for net power demand prediction [16]. The authors further explored the proposed model to resolve the multi-agent distributed energy aggregation challenge in TES.

When comparing the prediction results obtained for FL forecasted (FLF) and Local Model forecasted (LMF), it indicates that FLF shows superiority over LMF with a greater accuracy of 1.36 times for April, for the first community (100 buildings), and 8 times for the second community (25 Buildings) for August. Relatedly, the same team of authors in [7] transitioned from applying FL for DER optimization to predicting net energy demand in the TES environment using FL in [17]. An FL architecture with two independent forecast systems, generation and demand systems, to facilitate collaborative learning among the buildings without sharing private data, and to support the management systems of TES. The authors introduced an auxiliary horizontal Federated TL (FTL) to enhance the forecast system. The buildings were divided into two groups of 100 and 25. The FTL was integrated by transferring the model weights between the servers responsible for the Groups. Group B realizes a better average of 0.07056 as against 0.09386 obtained by Group A. According to the authors, the FTL has the potential to enhance the forecast system's reliability.

Venkataramanan et al. [8] introduced an FL algorithm to forecast DER, transmitting a model of the consumption and generation patterns of 100 DERs for 24 hours without revealing consumer data. The work was evaluated using grid-specific performance metrics (load swings and load curtailment), while the simulation was validated using real data from the Pecan Street dataset. The research achieves a forecast with a root-mean-square error (RMSE) of 1.3 for 1000 IoT nodes and a 1.98 RMSE for real field data. However, the authors failed to establish that there is an existing trade-off between accuracy and privacy when using the FL approach. A comprehensive analysis of the application of FL in the energy sector, energy markets, and cybersecurity (fault detection, energy theft detection) was reported in [11]. Table 1 reflects FL applications in energy systems with their research significance, while Figure 1 illustrates the workflow of centralized FL.

II.3 SELF- LEARNING FOR PRIVACY PRESERVATION IN ENERGY SYSTEMS

An SL-based adaptive framework, powered by the Soft Actor-Critic algorithm, was presented to enhance the energy management model, which resulted in a 45% energy reduction [34]. Wei et al [35] developed a novel SL parallel control technique to address the optimal control issue of discrete-time time-variant nonlinear systems. The adaptive dynamic programming-based SL method was utilized to ensure value function convergence and optimal policy. Ref. [36] proposed a SL control technique for decentralized winter-operated household ventilation systems for comfort and energy efficiency of occupants. The SL successfully learns the occupants' ventilation preferences. Zhou [37] reported a dynamic SL grid-responsive approach in enhancing energy flexibility and techno-economic needs of electrochemical batteries by adjusting off-peak grid charging power, thereby facilitating interactive energy networks in smart cities. A state SL approach was proposed to achieve distributed intelligent control in a multiple-reactor cascade operation, to capture the reactor's time-varying non-linear dynamics, and to enhance control performance [38]. The applicability of the technique was demonstrated in a cascaded zinc extraction process. An SL approach was presented to facilitate the decision-making process of a heterogeneous robot under uncertainty in [39].

III. PERFORMANCE EVALUATION OF FL AND SL-BASED MODELS ON PRIVACY PRESERVATION

When preserving the privacy of participants in TES, there must be a balance between privacy, model accuracy, and the efficiency of the algorithm [20]. In the review presented in [40], established that FL has been used in Renewable Energy (RE) for resource forecasting and that its local model surpasses other models in preserving data privacy. A Mathematical model was introduced to evaluate FL-based blockchain-enabled task scheduling to reduce energy consumption and delay by 41% and 28%, respectively [41]. An energy-aware architectural model was investigated and developed in [42]. Table 2 presents the performance evaluation of FL and SL models for privacy preservation.

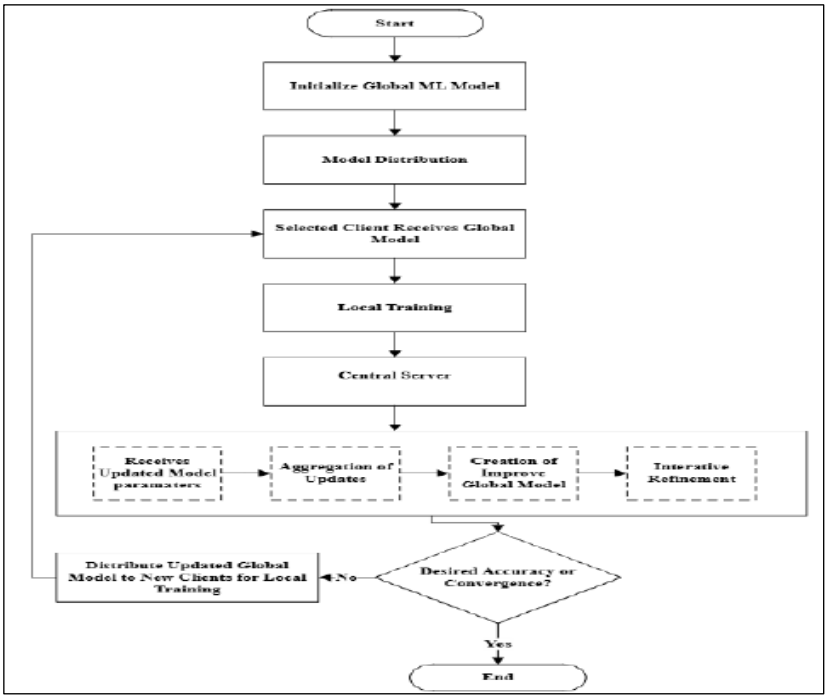

Figure. 1 Centralized FL Workflow

IV. DISCUSSION AND FINDINGS

In the literature for privacy preservation in TES, blockchain-based techniques are the most widely utilized. Some of these techniques include HE-based algorithms, Paillier cryptography, and asymmetric cryptography. However, there is a limitation to these blockchain-based methods: the entire ET information stored on the network is available to all participants, thereby exposing users' data. Consequently, a malicious attacker may exploit this avenue for financial gain or espionage. In the application of SL in decentralized energy systems, a review of relevant literature shows that SL-based adaptive frameworks have been used to enhance energy management, whereas SL-based parallel control techniques were reported in resolving optimal control issues and for decentralized ventilation systems. Additionally, a dynamic SL grid-responsive approach was explored to enhance energy flexibility, while a state SL approach was proposed to achieve distributed intelligent control. The survey demonstrates that the SL technique is unsuitable for privacy preservation due to challenges, such as centralized vulnerabilities, data control, efficiency, and non-collaborative features, which prevent multiple participants from locally training a model. It was discovered that privacy-preserving techniques do not significantly affect the model's accuracy but may introduce computational and communication overhead. Furthermore, the survey shows that privacy-preserving techniques, such as FL, can optimize privacy, accuracy, and efficiency. However, one must carefully consider finding a balance between security and system performance. Consequently, all the reviewed articles on privacy-preserving techniques show that researchers have not explored the suitability of either FL or SL in TES, even though our findings established that FL is more suitable.

V. CONCLUSION AND FUTURE OUTLOOK

This survey successfully examined patterns in the application of FL and SL techniques for privacy preservation. Also presented is a comparative analysis of these ML-based techniques to determine the best fit for privacy preservation in TES to enhance network stability and resilience. The investigation reveals that FL offers robust privacy protections and supports decentralization as the data resides with participants during model training. In comparison with SL, which is centralized, all data are essentially aggregated into a main server for training. Therefore, raises concerns about the privacy and security of sensitive data. Its features allow TES participants to engage in ET without disclosing their private information. The research demonstrated that FL-based TES is secure and inherently decentralized, like P2P-based TES. Hence, FL's suitability in preserving participants' data. The work highlights the need for further research by exploring the integration of FL with Blockchain Technology to resolve emerging privacy issues in TES and to enhance efficiency and security. Additionally, challenges such as scalability and statistical heterogeneity require more attention. The contribution of this investigation will serve as a reference for future research.

ABSTRACT

Large-scale datasets have grown rapidly in recent decades due to the rapid advancement of database and computer technology. However, the number of data mining applications that use high-dimensional datasets and need great speed and accuracy is growing quickly. The curse of dimensionality, in which there are substantially more characteristics than patterns, is a key problem with these applications. Feature selection is one of the dimensionality reduction strategies that can improve the data mining task's accuracy and lower its computational cost. The goal of the feature selection process is to choose a subset of features that are most relevant to the target class and have the lowest inner similarity. By removing unnecessary, redundant, or noisy data, it lowers the dimensionality of the data. This study compares and contrasts several feature selection techniques and provides a general classification of them. This research also examines the latest swarm intelligence techniques and reviews feature selection techniques based on these algorithms using the credit card fraud detection dataset. Additionally, we assess the advantages and disadvantages of the various swarm intelligence-based feature selection techniques that were examined.

I. INTRODUCTION

One of the most crucial applications of machine learning is the detection of credit card theft or pattern recognition. Several fields use machine learning techniques, including medical diagnosis [1],[2], marketin[3], image processing [4],[5], text mining [6];[7], information retrieval, and identification [8]. Dimensionality reduction is one of the key strategies to get rid of features that are redundant or unnecessary once there are a number of them in the original features[9]. Two methods for dimensional reduction were introduced in the past: feature selection and feature extraction . Dimensionality reduction can enhance the machine's performance by eliminating redundant and irrelevant characteristics [6], [10]. The main feature space is mapped to a smaller space during feature extraction. Actually, by integrating pre-existing features, this strategy creates fewer features that contain all or most of the information found in the primary features. Furthermore, in feature selection, redundant and unnecessary features are eliminated to choose a subset of the original features with n being the number of original features, the entire search space to discover the most pertinent and non-redundant features, including all potential subsets, is $2n$. Finding the best features requires a thorough search, which is typically not computationally possible, even for medium-sized datasets.Finding a solution that is both computationally practical and high-quality is necessary because searching through all potential subgroups is exceedingly expensive. To prevent growing computational complexity, a lot of feature selection techniques include metaheuristic algorithms [11]. In a reasonable amount of time, these algorithms will be able to optimise the feature selection problem with the right level of precision. Swarm intelligence (SI) and evolutionary algorithms (EA) are the two primary categories into which metaheuristic algorithms fall. Compared to EAs and other single-solution-based methods, SI is a relatively recent type of evolutionary computation. Swarm-based techniques are the most widely used nature-inspired meta-heuristic group.

SI algorithms employ approximate and non-deterministic strategies to effectively and efficiently explore and exploit the search space in order to obtain near-optimal answers. Artificial intelligence based on collective behaviours in decentralised, self-organised systems is known as swarm intelligence (SI). A population of simple actors that interact locally and with their surroundings often makes up these systems. In the fields of data mining, pattern recognition, statistics, and other engineering applications, feature selection has been a topic of intense investigation[12]. Reviewing several feature selection techniques will help you determine the best strategy for that application because feature selection is used in most engineering problems. To put it another way, different engineering application areas use different feature selection techniques. For instance, the precision of the feature selection technique is significantly more crucial than its computing complexity in many engineering tasks, such as trial engineering and biomedical engineering. In fact, even if a feature selection approach has a high computational complexity, we prefer to use it in certain situations in order to maximise accuracy.

However, the computational complexity of the feature selection method is also crucial in many engineering problems, like image processing and machine vision, and computational complexity and execution time must be taken into account when selecting the feature selection method in this field. In light of this, it is crucial to examine several feature selection techniques in order to select the best one for that particular application. To feature sections, numerous SI-based methods have been used in recent decades. Only a small number of studies examine feature selection techniques, despite their extremely satisfactory performance compare feature selection methods based on swarm intelligence. The well-known and conventional SI algorithm and the feature selection techniques derived from it were the exclusive attention of this paper's writers. Additionally, a thorough literature evaluation of SI algorithms for feature selection is conducted. This paper's absence of experimental results and solely listing the advantages and disadvantages of various SI-based feature selection techniques is one of its drawbacks.

Additionally, swarm intelligence methods for feature selection in data mining are reviewed by [13].
This paper's focus on PSO, ABC, and ACO-based feature selection techniques is one of its drawbacks; many other SI algorithms that have been put forth recently—such as the Salp Swarm Algorithm, Grey Wolf Optimisation, Whale Optimisation Algorithm, and Gravitational Search Algorithm—have not been covered. The fact that this research merely examined the various approaches theoretically and did not do any numerical analysis to compare them is another flaw. Additionally,[14] examined the challenges that arise during the feature selection process and the application of swarm intelligence to feature selection. Additionally, this paper offers a succinct summary of several algorithms, such as ABC, ACO, and PSO. This paper's flaw is that it only compares the various approaches based on classification accuracy criteria; it makes no comparisons based on computational complexity, execution time, or a few other chosen features.

The absence of a review of new SI algorithms, such as the Salp Swarm Algorithm, Whale Optimisation Algorithm, and Grey Wolf Optimisation, is another flaw in this work. Since there hasn't been a thorough analysis of SI-based feature selection techniques before, this paper's primary goal is to close the coverage gap of SI algorithms for feature selection. The goal of this study is to present a thorough analysis of SI-based feature selection techniques and their classification. Additionally, this work attempts to review the most popular and cutting-edge SI-based feature selection technique. Additionally, in order to provide a more accurate assessment of these algorithms, a number of experiments have been designed in this study to compare the performance of various SI-based approaches. The rest of the paper is structured as follows: Section 2 introduces the feature selection problem, and Section 3 examines several feature selection techniques and categories from earlier ODs. SI-based feature selection techniques are reviewed in Section 4. The experimental outcomes of several SI-based techniques are shown in Section 5. The conclusion is finally presented in Section 6.

II. THE FEATURE SELECTION PROBLEM IS INTRODUCED

The dimensionality problem of a dataset where the feature subset size is significantly larger than the pattern size is a fundamental problem with machine learning techniques [15]. For instance, in medical applications that involve very high-dimensional datasets, the classification parameters are also increased, which results in a significant decline in the classifier's performance. A general rule states that at least $10\times n\times C$ training data is needed for a classification problem with n dimension and Cclass. If this amount of training data is not practically available, the number of training data needed is decreased by decreasing the feature subset size. Consequently, the classificational algorithm's performance improves [16]; [17]. One common method for eliminating duplicate and noise-producing features is dimensionality reduction. According to [6] and [10], it is an effective way to increase accuracy performance, reduce computational complexity, create more generalised models, and use less storage. Two main methods for dimension reduction have been put forth in recent years: feature extraction and feature selection. In feature extraction, the original features are transformed into a new, lower-dimensional feature, either linearly or nonlinearly.

By choosing a subset of the original characteristics that still has enough information for classification, feature selection, on the other hand, directly lowers the number of features. In the fields of statistics, pattern recognition, and data mining, feature selection has been a topic of intense research. The basic principle behind feature selection is to pick a subset of accessible characteristics by removing redundant features that have a high correlation as well as features with little to no predictive value [12]. The main idea of feature selection is to choose a subset of available features by removing features with little or no predictive information and also redundant features that are strongly correlated[12]. Feature selection is a fundamental research topic in statistical pattern recognition, machine learning, and data mining that dates back to the 1970s. Several attempts have been made to improve the performance of the feature selection methods. Subset generation, subset evaluation, stopping criteria, and result validation are the four primary steps of the feature selection process.

A subset of the candidate feature set is created from the original features in each search iteration, and an evaluation criterion is used to gauge how acceptable the subset is. Until a predefined stop requirement is met, the subset generation and evaluation procedures are repeated. Following this procedure, the test dataset is used to validate the optimal subset of the chosen feature [18]. Generally speaking, feature selection is important [19]. Feature selection methods generally perform more reliably and efficiently in the supervised mode because of the use of class labels. In supervised methods, a set of train data is available, each of which is described by taking feature values along with the class label, whereas in unsupervised methods, training data lacks class tags. Consequently, choosing a feature in the unsupervised mode is more chall enging, and this area has been taken into consideration in numerous studies [20]. Google Scholar gathers the papers for this review from a variety of databases, such as Elsevier, Springer, IEEE, and others.

To determine the present state of research, papers published between 2016 and 2020 were given the most weight. Review, dimensionality reduction, feature selection, evolutionary algorithm, optimisation, nature-inspired meta-heuristic, swarm-based techniques, metaheuristic optimisation algorithm, population-based algorithms, and evolutionary computation are the keywords used in the first search to find review papers. In the second search, the keywords are used to find research papers that focus on swarm intelligence-based feature selection methods. Also included are references to the featured papers as well as additional papers from Science Direct, Springer, and IEEE Xplore recommender systems. Subsequently, articles that concentrated on feature extraction and feature selection techniques not based on swarm intelligence were eliminated. Stated differently, only pertinent works that selected features only using swarm intelligence methods were included. As a result, 85 papers in all—including six review studies—were carefully examined for feature selection. The remaining references dealt with different approaches to the feature selection problem.

III. CONTEXTS

In general, feature selection techniques explore the solution space in order to maximise two competing goals: minimising the redundancy of chosen features and increasing their relevance to the target class [21]. Numerous search tactics are used to maximise these goals. According [22], these techniques can be broadly divided into single-objective and multi-objective approaches. Only one fitness function goal is used to optimise the population in single-objective approaches. The accuracy of the optimisation process will therefore be significantly impacted by the objective selection and fitness function definition. Additionally, many optimisation problems have several targets, and optimisation speed is decreased when a fitness function is defined with only one aim. Taking into account several objectives in the fitness function of the feature selection issue is one way to get over these obstacles. A collection of non-dominated feature subsets can be obtained by modelling feature selection as a multi-objective problem in order to satisfy various real-world application criteria.

Only a few multi-objective function approaches, including MOFSEF , MOFSEEG [23], and MOFSGADM [24], are used in the majority of the previously described feature selection methods. Furthermore, a number of earlier feature selection techniques aim to identify the fewest duplicated features with the greatest reliance on output labels. A new fuzzy multiple kernel learning model for classification is created by Wang. A novel criterion that chooses a subset of important and dissimilar features is put forward in this model. Furthermore, machine learning approaches have recently employed graph-based methods to uncover similarity associations among the data [25]. Graph-based techniques for feature selection offer an underlying manifold structure as a general framework to represent the connections among features. Graph-based techniques were used in a number of studies to address the feature selection issue.

For instance, a dense subgraph discovery method is used to solve the unsupervised feature selection problem present an additional clustering-based feature subset selection approach for large dimensional data. For similar grouping features, this work uses a graph-theoretic clustering technique suggest a feature selection technique based on hypergraphs. By taking into account each sample's associated class label, this study employs an information-theoretic criterion to assess the suitability of various features. The unsupervised feature selection procedure incorporates the idea of graph clustering with the node centrality metric. real-world applications. While the wrapping model could choose a superior feature subset, it can deteriorate with high-dimensional medical datasets and is costly to execute. This is because the feature subset quality computation makes use of learning methods.

III.1 MODEL OF FILTER

The filter model uses no learning mechanism to assess the features' importance. As a result, this approach's approaches are usually quick. The features with the highest ranks are chosen in this model after they have been assessed and rated using information-theoretic metrics [26]. According to one perspective, there are two types of filter-based methods: univariate and multivariate. These approaches, however, produce weak and complex learning models, neglect feature dependencies, and display comparable features in the final feature set. Multivariate approaches, a subset of the filter approach, address both redundant and irrelevant features in their ranking strategies in order to address this problem. Stated differently, multivariate filtering techniques were put forth with the goal of taking feature dependencies into account to a certain extent. Minimal redundancy maximal relevance (mRMR) , Relevance redundancy feature selection (RRFS), MIFS, Normalised Mutual Information Feature Selection (NMIFS), MIFS-U, Unsupervised feature selection based on Ant Colony Optimisation (UFSACO), and Hilbert–Schmidt independence criterion (HSIC) are a few multivariate techniques.

III.2 MODEL OF A WRAPPER

The wrapper approach uses a classifier that has been trained to assess a number of salient attributes. The wrapper model selects a collection of features with the maximum classification accuracy by evaluating a subset of features in their search operations using a specific learning model. The majority of wrapper approaches use iterative search procedures, in which the population of solutions is guided towards the optimal solution with each iteration of the learning model. However, the wrapper approach's high computing cost and loss of generality are caused by the learning model that is used in the search process. Filter methods are suitable for populations with random solutions and aim to increase the optimality of these solutions at each iteration step since they are quick enough and their output is independent of a particular classifier. In real-world applications, a fitness function is used to determine the optimality of the individual solutions of the created decision-makers after a number of initial solutions are generated at random at the start of most meta-heuristic algorithms.

For gene selection and cancer classification, [27] integrate correlation feature selection with a modified binary PSO method. By removing the unnecessary and duplicated features, this technique chooses a subset of highly significant attributes. The Shuffled Frog Leaping Algorithm and enhanced mRMR are combined in [28] to increase the accuracy of acoustic defect identification. This method uses the MRMR criterion to build a single-objective function, which is then optimised using the PSO algorithm to reduce the dimensions of the original features. The neural network classifier is then used to detect the final auditory defect after the final feature subset has been chosen. [29] offer a new PSO-based feature selection technique that combines illness diagnosis performance. To choose a subset of pertinent and non-redundant features in DNA microarray datasets, developed a recursive particle swarm optimisation strategy. The authors of this paper integrated the different filter-based feature selection measures with the developed wrapper-based recursive PSO method use the modified BPSO algorithm with the binary black hole algorithm to construct a feature selection technique for cancer classification.

This method introduces a hybrid feature selection method by combining the benefits of the wrapper and filter approaches. To increase effectiveness and make it easier to explore and exploit the PSO to further improve performance, this hybrid feature selection method incorporates the binary black hole algorithm into the PSO algorithm. Furthermore, an enhanced BPSO approach for feature selection was created . This technique employs a novel Win-Win approach to improve feature selection accuracy in the detection of renal and liver diseases. In addition, [30] presented a new hybrid PSO-based feature selection technique for laser-induced breakdown spectroscopy investigation.

An effort has been made to combine the benefits of coating and filtering techniques in this procedure. A PSO-based feature selection method with several classifiers is suggested in [13]to enhance the population. A new generation of production will start if none of the termination requirements are fulfilled. Until one of the termination criteria is satisfied, this cycle is repeated. Evolutionary Algorithms (EA) and Swarm Intelligence (SI) are two types of meta-heuristic techniques. EAs employ mechanisms including reproduction, mutation, recombination, and selection that are modelled after biological evolution. Individuals in a population are represented by candidate solutions to the optimisation problem, and the quality of these solutions is determined by the fitness function. The starting population evolves and advances towards global optimisation following iterations of the evolutionary algorithm [31].

Furthermore, the optimisation approach based on swarm intelligence takes into account a lot of complex artificial aspects. Nature is the source of the idea for SI optimisation algorithms. Each component performs a basic task, but together, these components produce global intelligent behaviour that is impossible for any one component to accomplish on its own. Particle Swarm Optimisation (PSO), Ant Colony Optimisation (ACO), Artificial Bee Colony Optimisation (ABC), Differential Evolution (DE), Gravitational Search Algorithm (GSA), Firefly Algorithm (FA), Bat Algorithm (BA), Cuckoo Optimisation Algorithm (COA), Grey Wolf Optimisation (GWO), Whale Optimisation Algorithm (WOA), and Salp Swarm Algorithm (SSA) are among the SI-based feature selection techniques that are reviewed and described in Table 2 in the sections that follow.

III.3 MODEL OF HYBRID

By combining the filter and wrapper models, the hybrid strategy aims to benefit from both of them. Like filter-based approaches, this strategy primarily focusses on maximising performance using a specific learning algorithm and time complexity.

III.4 THE EMBEDDED MODEL

The feature selection issue is taken into account by the embedded approach as a component of the machine learning technique. Actually, a machine learning technique is employed in the embedded approach to find the last feature subset.
The key traits of the various feature selection techniques are compiled in Table 1. Six characteristics of various feature selection techniques are listed in this table: the number of objectives, the type of approach, the search strategy, the application, the weakness, and the strength.

Table1: The main characteristics of different feature selection methods. The synonyms used in this Table are: MOP: Multi-Objective Optimization, SOP: Single-Objective Optimization, RB:Ranking-Based, SSB: Subset selection-based, ACO: Ant Colony Optimization, GA: Genetic Algorithm, ABC: Artificial Bee Colony, DE: Differential Evolution, NSGA: Nondominated Sorting Genetic Algorithm.

IV.SWARM INTELLIGENCE-BASED FEATURE SELECTION.

Feature selection methods based on how to evaluate the features are classified into two categories: feature ranking and subset selection methods. Feature ranking methods, based on a specified criterion, assign a score to each feature.Then the features that did not get scores are removed. But in subset selection methods, the space of possible subsets is searched to find the optimal subset. If the number of initial features is n, the search space for the optimal subset contains all the features, which is equal to$2n$ different states. In other words, in the property ranking methods, the value of each property is evaluated independently, and the relationship between features is not considered. In these methods, it is assumed that the features are independent of each other and that a possible dependence between the features is not considered. Although this simplistic assumption reduces the computational complexity of the feature selection method, in many cases, it may reduce the performance of the feature selection method. Feature subset selection is an NP-Hard problem. In the simplest way, the best subset can be found by evaluating all possible subsets with an exhaustive search strategy.

Although this method guarantees an optimal feature subset, finding the optimal solution is very time-consuming and even impractical for medium-sized datasets. Since it is very costly to evaluate all possible subsets, a feature subset must be searched, that, it is acceptable both in terms of computational complexity and in terms of appropriateness [32] [33]. One approach to solving complex optimization and NP- Hard problems is meta-heuristic algorithms. Meta-heuristic algorithms are approximate approaches that can find satisfactory solutions over acceptable time instead of finding the optimal solution. These algorithms are one of the categories of approximate optimization algorithms that have s strategies to escape from local optima and can be used in a wide range of optimization problems. Many feature selection methods use meta-heuristics to avoid increasing computational complexity in high-dimensional dataset. These algorithms use primitive mechanisms and operations to solve an optimization problem and search for the optimal solution over a number of iterations. These algorithms are often extended by the authors of [34] to choose more informative features.

In Henni et al.(2018), the authors employed Google's PageRank centrality measure to rank features based on their importance[34] propose another graph-based feature selection method for the multi-label high-dimensional dataset. The authors of this paper utilize the PageRank centrality measure to rank the features based on their value in the graph. Also, in this paper, the correlation distance criterion is used to remove irrelevant features. In [35], an unsupervised graph-based feature selection method for high-dimensional data is proposed. In this paper, the Laplacian graph and local geometrical structure are used for better representation of the feature spacfe. In a subspace clustering guided unsupervised feature selection method is proposed. This work uses the subspace clustering to learning of the clustering, and then those features with good preservation ability of the cluster labels are selected. Generally, previous methods for selecting optimal feature sets can be categorized into four groups consist of filter, wrapper, embedded, and hybrid models. These categories are explained in the following subsections.

IV.1 PSO-BASED METHODS

Particle Swarm Optimization is a powerful SI-based optimization method, developed by Kennedy and Eberhartin 1995. This optimization method, inspired by the collective conduct of birds and fish, has recently been used in a number of researches to optimize the selection of the final feature subset. Unler et al.(2011) introduced a new search strategy to select the final feature set, which integrated the filter approach. Moreover, developed a hybrid feature selection method for the medical application. The authors of this paper, proposed a hybrid feature selection approach by combining the wrapper PSO and rough sets theory to improve the classification accuracy of disease diagnosis. Furthermore, in Huang and Dun(2008) another hybrid approach for feature subset selection and parameter optimization is proposed. In this method the PSO optimization method, and SVM in integrated to improve the performance of feature selection. The authors of this paper combined PSO–SVM with a distributed parallel architecture to overcome the high computational complexity for the high-dimensional datasets.

More over, the authors of developed novel initialization methods and best particle updating strategies to improve the performance of optimization tasks in feature subset selection. This method aims to se- lect a subset of relevant and non-redundant features for computational complexity reduction. Proposed an integration model of binary PSO (BPSO) algorithm and the Hamming distance to select the final feature set in the classification task. In this method, a hamming distance is used to improve the velocity update process in a BPSO algorithm and then this improved BPSO is utilized for feature selection problem.An improved multi-objective PSO algorithm is proposed for unreliable data classification. In this paper, two new operators of the reinforced memory and the hybrid mutation are introduced to improve the searchability of the PSO algorithm. In efficient PSO-based feature selection method is proposed by the integration of filter and wrapper approaches.

The proposed method, called HPSO-LS, introduced a new local search to select the subset of non-redundant and relevant features. In [36] a multi-objective particle swarm optimization approach is developed for cost-based feature selection in classification. The main goal of this method is to produce a Pareto front of non-dominated solutions, that is,featureset, to meet different prerequisites for increasing the classification accuracy and reducing computational complexity. In this paper, a new Self-Adaptive Parameter and Strategy a high-dimensional dataset. The reported results showed that the use of these mechanisms greatly increased the search ability of particle optimization algorithms for high-dimensional datasets. Moreover, in [38], a novel graph-based feature selection method is developed to increase disease diagnosis accuracy. In this method, using the node centrality criterion, a new mechanism for initializing the particles is proposed. Then, by defining a multi-objective fitness function, a subset of the final features that are least similar to each other and most relevant to the target class are selected. Finally, based on the selected features, the disease is diagnosed, disease diagnosis accuracy. In this method, using the node centrality criterion, a new mechanism for initializing the particles is proposed.

Then, by defining a multi-objective fitness function, a subset of the final features that are least similar to each other and most relevant to the target class are selected. Finally, based on the selected features, the disease is diagnosed.

IV.2 ACO-BASED METHODS

About three decades ago, a new heuristic-based optimization method called the Ant System (AS) is proposed by Dorigo and his colleagues to solve complicated optimization problems. AS was first utilized for the traveling salesman problem. Then, Dorigo and Caro(1999) developed the Ant Colony Optimization (ACO) algorithm to improve the AS algorithm. This improved algorithm can be able to search the global optimal by representing the problem as a graph model. Moreover, ACO has been successfully utilized in many types of research to select the final feature set. In Kabir et al.(2012) an ACO-based feature selection approach is developed by combining the neural network and IG method to remove redundant and irrelevant features. Moreover, the authors of Li et al.(2013) proposed a new ACO-based gene selection method in the DNA microarray dataset. This proposed method includes two phases of essential features by improved AS algorithm and then final features are selected using a modified ACO algorithm.

Furthermore, in a new ACO-based feature selection approach is developed. In this approach, unlike the previous ant feature selection methods based and ACO, the feature selection problem is modeled as a directed graph. In Forsati et al.(2014),a new version of ACO is proposed to remove the irrelevant and redundant features. This method selects the final feature set by utilizing a local search strategy to avoid getting stuck in the local optimal. Moreover, in Keetal.(2008), a rough set theoretic-based ACO feature selection method is developed. In Tabakhi et al.(2014) a novel ACO-based feature selection method is proposed for unsupervised mode. The authors of this paper selected the most non-redundant features that have the least similarity with each other. Moreover, Moradi and Moradi and Rostami, developed a filter-based feature selection approach utilizing the ACO algorithm and graph clustering.

This approach represented the feature space as a clustered graph. Then, according to the similarity between the features and by defining a filter criterion, it selects a dissimilar and related subset of the features. In Dadaneh et al.(2016) proposed an unsupervised ACO-based feature selection method to remove redundant and irrelevant features. This method tries to select an optimal subset of features in a hierarchical process, by considering the similarity between features. In [2], a combination of feature selection and ant colony optimization is proposed to improve the classification accuracy of imbalanced data.In this method, instead of using a single-objective fitness function, a multi-objective ant colony optimization algorithm is used to improve the performance of feature selection. The reported results showed acceptable performance of the proposed method in classifying imbalanced and high-dimensional datasets.

IV.3 ABC-BASED METHODS

The Artificial Bee Colony algorithm (ABC) is an SI-based optimization method inspired by the lifestyle of the bee population. This algorithm tries to imitate the food search behavior of the bee population. This optimization technique integrated a local search strategy with a random search strategy that can be utilized for complex optimization problems. This swarm intelligence-based optimization technique has been applied in many references to select a final feature set.In Schiezaro and Pedrini (2013), a novel feature selection method based on an artificial bee colony is developed to improve the machine learning task. In this method, the feature space is modeled as a binary vector and the classification function. The authors of, developed an improved ABC-based feature selection approach. This approach combined the similarity search strategy and a binary version of ABC to improve the performance of feature selection. Shunmugapriya and Kanmani[39], proposed a novel feature selection method by integrating. This method tries to utilize the advantages of an artificial bee colony and an ant colony optimization algorithm, simultaneously.

In[40] a new feature selection approach is developed by the combination of the ABC algorithm and the Pareto-optimal front surface. The authors of this paper used a multi-objective fitness function and genetic operators to improve the accuracy of the feature selection method and the convergence of the ABC algorithm. In Arslan and Ozturk(2019) a Multi Hive ABC Programming is developed to select the final features in high-dimensional datasets. This approach utilized the ability of an automatic programming algorithm to remove irrelevant and redundant features. The authors of [41], developed a multi-objective ABC-based feature selection approach. In this method, two new operators are used to improve its search capability and convergence of the ABC search strategy. In [42], an ABC-based feature selection is proposed by integrating of multi- multi-objective optimization algorithm with a sample reduction strategy. This proposed method has both increased classification accuracy and reduced computational complexity.

IV.4 DE-BASED METHODS

The Differential Evolution (DE) algorithm is an SI-based search strategy technique that has been developed to solve complex optimization problems.This optimization method is introduced to overcome the main weakness of the genetic algorithm, namely its lack of local search capability. The main difference between DE algorithm and the genetic algorithms is in the genetic selection operators. DE algorithm is used in different applications of machine learning tasks and feature selection.For example, Al-Anietal developed a wrapper-based feature subset selection using DE algorithm and a wheel-based search mechanism.[43] proposed a multi-objective DE-based approach to remove the irrelevant and redundant features and improve classification accuracy. In [44], a multi-objective DE-based feature selection approach is developed. In this approach, a novel mutation operator is defined to escape the local optimum. Furthermore, in [45], another new multi-objective DE-based feature selection approach is developed for feature selection and to improve the performance of the clustering algorithm simultaneously.

IV.5 GSA-BASED METHODS

Moreover, some SI-based optimisation methods have been inspired by physical laws. Gravitational Search Algorithm (GSA) is a physics-based optimisation technique inspired by Newton’s law of universal gravitation. GSA, a popular SI-based algorithm, has been widely applied in machine learning, and recently, many feature selection methods have been developed using this optimisation algorithm. proposed a GSA-based feature selection approach using a linear chaotic map to improve classification accuracy. In Xiang , a hybrid system for feature selection based on an enhanced GSA and K-nearest neighbour classifier is developed.

In this method, a piecewise linear chaotic map for exploration and sequential quadratic programming for exploitation are employed. In [46], an efficient hybrid feature selection method is proposed to utilize the advantages of the SI and the genetic algorithm to improve the performance of the GSA algorithm.

IV.6 FA-BASED METHODS

The Firefly Algorithm (FA) was introduced , the main idea was inspired by the optical connection between fireflies.The Firefly Algorithm is a sensible example of swarm intelligence in which low-performance agents can work together to achieve great results with high performance. In [47] a novel FA- based feature selection method, called return-cost-based binary FFA is developed. The authors of this paper provide a variety of strategies to prevent premature convergence of the FA algorithm and thus improve the accuracy of feature selection. In [48],a feature selection method is developed using the firefly optimization algorithm to increase the accuracy of classification and regression models. In this method, to improve convergence and prevent trapping in local optimization, some variation is added to standard FA, which improves the accuracy of final feature selection. Moreover, in [49]FA-based feature selection method is proposed. In this method, after selecting the final features, these features are utilized to classify Arabic texts using an SVM classifier. Furthermore, in Sel-vakumar and Muneeswaran(2019), another FA-based feature selection method is presented for network intrusion detection. In this method, a combination of filter-based feature selection method (i.e., Mutual Information) and wrapper-based feature selection method (i.e., C4.5 and Bayesian network) has been utilized to select the final features.

IV.7 BA-BASED METHOD

The Bat Algorithm (BA) is an algorithm inspired by the collective behavior of bats in the natural environment, introduced. The bat algorithm is a kind of swarm intelligence- based algorithm that is inspired by the echolocation behavior of bats. Bats find the exact path and location of their prey by sending sound waves and receiving reflections. When the sound waves return to the transmitter of the bat waves, the bird can draw an audio image of the obstacles in front of its surroundings and see its surroundings well.In [50], a hybrid variant of- rithm and improved PSO algorithm is to improve the feature selection performance. In this proposed method, the PSO algorithm is used to improve the convergence power of the hybrid algorithm. Moreover, in [49], a binary BA-based feature selection method ion accuracy. Furthermore, [54] used the bat algorithm to search optimal features subset to increase the accuracy of cancer classification. In this method, a combination of filter and wrapper approaches was used to improve the performance of feature selection. In this method, robust mRMR as a filter to select the most relevant features and an improved BA algorithm as a search strategy in the wrapper approach is presented to select the final feature subset.

IV.8 COA-BASED METHOD

The Cuckoo Optimization Algorithm (COA) is another algorithm based on swarm intelligence, inspired by the special lifestyle of a bird called the cuckoo. The specific habitude of laying eggs and the reproduction of this bird has been the basis for the formation of this optimization algorithm. Like other evolutionary algorithms, the cuckoo optimization algorithm begins with an initial population of cuckoos. This early population of cuckoos has a number of eggs that are placed in the nest of the host bird. Some eggs, which are more similar to host bird eggs, have a better chance of growing into adult birds. The other eggs are identified and destroyed by the host butterfly. Grown eggs show that the nest is a better place in the search space, and the usefulness of that area is higher. The goal of the cuckoo optimization algorithm, which is the optimization function, isto find the place where most eggs have a more chance to survive. In a COA-based feature selection method is developed to improve the cancer classification accuracy.

In this method, first, the irrelevant features are removed using a simple and fast filter-based feature selection. Then, from these relevant features, the final features are selected by integration wrapper-based feature selection and COA algorithm. In Jayaraman and Sultana(2019), a combination method of cuckoo search algorithm and neural network is developed for feature selection. In this method, after selecting a feature subset of non-redundant and relevant features, the final chosen features are sent to the classifier, and heart disease is classified. Moreover, in [37], another cuckoo search-based feature selection method is proposed for improving the disease diagnosis accuracy. In this method, the process of feature subset selection is optimized using the cuckoo search optimization, and then these selected features are sent to the SVM classifier to identify lung cancer.

IV.9 GWO-BASED METHOD

Gray Wolf Optimization (GWO) is a new evolutionary algorithm-based optimization technique inspired by gray wolves. This optimization method is one of the latest bio-inspired techniques, which imitates the hunting process of a pack of gray wolves in nature. Recently, some GWO-based methods has been utilized as a tool for feature selection in machine learning applications. Ia Multi-Objective GWO was applied to search for the most relevant and non-redundant features. This proposed method utilized the low computational complexity of the filter model to improve the accuracy of the wrapper model. In a binary version of the GWO is developed to select the optimal feature subset for classification tasks. In the wrapper-based feature selection method, classification accuracy and the number of selected features are utilized for the fitness function. In to enhance the previous GWO-based feature selection approach, a multi-strategy ensemble GWO is developed for feature selection. Moreover, [51] developed a GWO-based wrapper feature selection approach that integrated with a mutation operator for data classification. The mutation operator proposed in this paper tries to remove the redundant and irrelevant features.

IV.10 WOA-BASED METHODS

Optimization Algorithm (WOA) is another SI-based optimization method inspired by the hunting behaviour of humpback whales. This optimization method consists of three operators to imitate the search for prey, encircling prey, and bubble-net foraging behaviour of humpback whales.

Recently, the WOA algorithm is successfully applied in many different optimization problems and feature selection. In a hybrid WOA with a simulated annealing algorithm is developed for feature selection. The aim of using simulated annealing in this hybrid method is to improve the exploitation by searching the most promising regions located by the WOA algorithm. In a WOA-based wrapper feature selection algorithm is developed. In this study, tournament and roulette wheel selection mechanism and also crossover and mutation operators, are used to improve the exploration and exploitation of the search process of WOA algorithm. Introduced a frequency-based filter feature selection method using a whale algorithm on high-dimensional medical datasets. In this method, a filter criterion is utilized to discard the irrelevant features using the WOA. Then, the reminder features are ranked based on another filtering method, namely, Mutual Congestion.

IV.11 SSA-BASED METHODS

Salp Swarm Algorithm (SSA), another bio-inspired algorithm based on swarm intelligence, is proposed for solving optimization problems. This algorithm is inspired by the swarming behavior of salps when moving and for in the oceans. In an efficient binary Salp Swarm Algorithm with a crossover scheme is proposed to improve the accuracy of feature selection. More- over, in a hybrid optimization method for the feature selection problem is proposed by the integration of the slap swarm algorithm with particle swarm optimization. This combination of both swarm optimization algorithms improved the efficacy of the exploration and the exploitation steps. In the integration of Improved SSA and novel local search algorithm is developed for the feature selection problem. In this method, the accuracy of the classification accuracy of KNN classifier on the training data is used as a fitness function, and the final features are selected in repetitive process. Also, in this method, to create the initial population, a method based on Opposition-Based Learning is presented, which has caused diversity in the initial solutions. Furthermore, in [52], a Salp Swarm Algorithm-based feature weighting method is developed to predict the presence of liver is order, heart, and Parkinson's disease.

Also, in solution accuracy, reliability, and convergence speed of basic SSA is improved by adding a new control parameter and inertial weight. Then this improved algorithm was tested in the feature selection problem. Moreover, in [53], anew variant of SSA optimization algorithm is proposed for feature selection. In this method, an additional phase is utilized to overcome the problem of being stuck in local optima by encouraging the exploration of the search. With the advancement of data collection technologies and the increasing capacity of data storage over the last decades, high-dimensional datasets have grown significantly. Usually, many features of these datasets are irrelevant or redundant, which reduces the performance of the prediction model. Feature selection plays an essential role in machine learning and, more specifically, in high-dimensional datasets. Reducing the size of the medical dataset, on the one hand, reduces the computational complexity and, on the other hand, decreases the parameters of the classification algorithm. As a result, the accuracy of the prediction model will be increased. In the past decades, rapid growth of computer and database technologies has led to the rapid growth of large-scale datasets.

On the other hand, data mining applications with high-dimensional datasets that require high speed and accuracy are rapidly increasing. An important tissue with these applications is the curse of dimensionality, where the number of features is much greater than the number of patterns. One of the dimensionality reduction approaches is feature selection which can increase the accuracy of the data mining task and reduce its computational complexity. The feature selection method aims at selecting a subset of features with the lowest target class. It reduces the dimensionality of the data by eliminating irrelevant, redundant, or noisy data. In this paper, comparative analysis and categorization of different feature selection methods are presented. Moreover, in this paper, wrapper and filter SI-based methods (i.e., PSO, ACO, ABC. DE, GSA, FA, BA,COA, GWO, WOA, and SSA)and their application in feature selection are studied. Furthermore, the strengths and weaknesses of the different studied SI-based feature selection methods are evaluated, and the factors that can lead to the superiority of these methods are analyzed.

V. EXPERIMENTAL RESULTS

In this section, the performances of the different swarms- evaluated. The results are shown in terms of the number of selected features and the classification accuracy (ACC). The classification accuracy was calculated as follows:

$$ACC=TP+TN / TP+TN+FP+FN \quad (1)$$

Where TP, TN, FP, and FN stand for the number of true positives, true negatives, false positives, and false negatives, respectively. In each experiment, each feature selection method is run ten times, and the mean and standard deviation (square root of its variance) often different runs is often used to compare different methods.

V.1 DATASETS

All simulations were executed against the credit card fraud dataset, which is freely available on the Kaggle repository via the following link : https://www.kaggle.com/datasets/mlg-ulb/creditcardfraud, accessed on 20 May 2022. This dataset consists of transactions generated by credit cards in Europe in September 2013 during the time span of two days. The dataset represents a binary classification challenge composed of only two target variables (classes)—the positive class, which denotes fraudulent transactions, and the negative class that represents regular transactions. Moreover, the dataset is extremely asymmetrical (imbalanced), containing only 492 fraud instances out of 284,807 total transactions. Therefore, the positive class (frauds) represent only 0.172% of the dataset. The dataset is composed of 30 numerical features, where attributes F1,F2, F28 are obtained by applying the principal component analysis (PCA), while F29and F30, which represent time and amount, respectively, were not transformed with the PCA.

The time refers to the number of seconds elapsed between the first and each other transaction in the dataset, while the amount is the value of every transaction. In the first set of experiments, the original credit card fraud dataset, as it is hosted on Kaggle, is used, and the goal of these experiments was to establish how tuned ML models perform on highly imbalanced data. However, it is also important to validate the performance of ML models for balanced datasets. In the proposed study, the minority class (class 1 in this example) was oversampled to the number of instances of the majority category (class 0 in this example); therefore, the dataset, which in datapoints, is almost twice as large as the original one.

It needs to be noted that the experimental setup for SVM simulations had to be different, due to the specific properties of the model. In the case of SVM, a smaller dataset has been used, as the model operates very slowly. This was tackled by creating a reduced dataset with the size of only 0.5% of the original dataset that was fed to the rmodels while keeping the original class distribution (by using the stratification strategy). In the case of SVM and ELM experiments, the normalisation technique was also used. However, since the XGBoost operates on a decision tree basis, normalization has not been performed in that case. A total of 70% of each dataset was used for training, while the remaining 30% was utilized for testing of all models.

V.2 EXPERIMENTAL SETUP AND PROPOSED ENCODING SCHEME

As noted previously, all three ML models were tuned by the proposed GSFA meta-heuristic. In the case of the first utilised model, namely the SVM, hyperparameters were subjected to optimisation; two of them are continuous, while one is of the integer data type. The optimized SVM parameters, along with respective lower and upper bounds, are as follows:

C, boundaries:[2−5,215], type: continuous,
γ, boundaries:[2−15,23], type: continuous, and kernel type, boundaries :[0,3], type: integer, where value 0 denotes polynomial(poly),
1 marks radial basis function (rbf),
2 represents sigmoid, and finally
3 represents linear kernel type.

For the ELM model, both the number of neurons (nn) in the hidden layer and the values of the weights and biases between the input and hidden layers were subjected to the optimisation process. The lower and upper bounds for weights and biases were set as -1 and 1, respectively, in the interval [30,150]. The nn is an integer, while the weights and biases may take any continuous value from the specified range. Moreover, hyperparameters, while the optimisation of weights and biases is the ELM's training process, in the case of ELM, metaheuristics were used for both hyperparameters' optimisation and training. Finally, the set of XGBoost hyperparameters that were subjected to optimisation consists of the following:

learning rate (η),boundaries:[0.1,0.9],type: continuous,
min_child_ weight, boundaries:[0,10],type: continuous,
sub sample,boundaries:[0.01,1],type: continuous,
collsample, by tree, boundaries:[0.01,1], type: continuous,
max_ depth, boundaries:[3,10],type: integer and gamma,
boundaries:[0,0.5],type: continuous

The number of parameters for the softprob objective function ('num_ class': self. no classes)is also passed as a parameter to XGBoost. All other parameters are fixed and take default XGBoost values. All observed models were implemented in the Python programming language by employing standard machine learning libraries: scikit-learn, scipy, numpy, and pandas. For other models' hyperparameters, the default values from the scikit-learn Python library were used. The SVM and XGBoost models were adopted from scikit-learn; however, the ELM was coded from scratch because this model is not available in this package. In all implementations, a standard solution's encoding scheme was used. Every metaheuristic solution is represented as an array (vector) of size l, where l is the number of hyperparameters that were optimised. Therefore, the l for the SVM and XGBoost solutions are 3. However, in the case of ELM, l depends on the determined value for the nnhyper-parameter, and, if the fs denotes the size of the input feature vector, it can be derived as: 1+nn· fs +nn. The first component of the ELM metaheuristic solution represents the number of neurons (integer); subsequent nn components are biases (continuous), while remaining nn· fs parameters are weights.

V.3 COMPARATIVE ANALYSIS AND DISCUSSION

In all experiments, the obtained outcomes of all three models optimised by the suggested GSFA metaheuristic were compared to the results generated by other well-known swarm algorithms that were also implemented for the SVM, ELM, and XGBoost model tuning under the same conditions, as described in Section 4.2. The competitive algorithms include the original FA [49], BA [2], ABC[42], since cosine algorithm SCA, WOA (Nematzadehetal.(2019)), and SNS etc. All metaheuristics were implemented independently in this research and adjusted (in terms of controls' parameters setup) as in the original publications that were mentioned beforehand. For the easier summary of results presented in tables, the machine learning model prefix is placed in front of the methods' names used for hyper-parameter optimization, e.g., SVM-GSFA denotes the results obtained by SVM classifier tuned with the proposed GSFA method.

These simulations were executed with 20 solutions in the population (N=20) and 15 iterations in each run (T =15) for each metaheuristic method, except for the GSFA and FA. Since the FA in each iteration in the average case performs 2 N solutions' evaluations, inthiscase Nwassetto10.Additionally, due to the slightly higher complexity of the proposed GSFA over the basic FA, the GSFA was tested with only nine solutions. This reduction of the population for the FA and GSFA methods was required to set firm grounds for fair comparisons. Specific GSFA parameters (gsp, gssand cmt) were set according to Table 1. All swarm algorithms were also implemented in Python, and Intel®Core™i9-11900K Processor with 64GB of RAM and Windows 11 O.S. was used as a simulation platform. All employed datasets were relatively large, and the cache argument for SVM and XGBoost models in scikit-learn environment was set to 32GB to improve the computation speed.

On the other hand, the ELM is implemented by using cupy instead of the numpy library for operations with matrices, because cupy supports execution on GPU, and, in this case, NVIDIA GeForce GTX1080 GPU with 8 GB of memory is employed for such computations. Due to the stochastic nature of swarm approaches, all methods were executed in 50 independent runs, and best, worst, mean, and median accuracies, along with standard deviation, are recorded. However, accuracy may not be an objective metric, especially for imbalanced datasets; therefore, precision, recall, and f1-score per class and micro-averaged are also shown along with the receiver operating characteristic area under the curve (ROC AUC).It is noted that, in all result tables, the best-achieved metrics are denoted in bold style. Table 3 depicts the outcomes of the experiments with the SVM model employed.

As was already mentioned, the SVM model is specific due to its slow operation, and the reduced dataset was used. In this particular scenario, the SVM-GSFA achieved the best accuracy result, while the SVM-ABC obtained slightly better mean and median values. However, neither SVM-GSFA nor SVM-ABC exhibited the best robustness, which can be noticed from std metrics, while SVM-WOA, SVM-HHO and SVM-SCA did not show results variation over different runs. On the other hand, Table 4 shows the outcomes of the simulations with the ELM model against the dataset. In this scenario, the novel ELM-GSFA model outperformed all other hybrid ELM frameworks for all performance indicators, including best, worst, mean, and median classification accuracy, as well as the stability of results expressed with standard deviation. Table 5 puts forward the outcomes of the experiments with the XGBoost classifier on a real dataset. Similarly to the previous scenario, the XGBoost-GSFA achieved the best accuracy results for all utilised metrics and outperformed all other competitor methods Table6 presents the outcomes of the experiments with SVM model on the synthetic dataset. In this case, the SVM-GSFA and SVM WOA were tied for the best accuracy result (96.9519%), while the SVM-GSFA achieved better mean and median values, as well as better stability than opponent algorithms. For then extscenario, The XGBoost-GSFA and XGBoost-ABC were tied for the best and medianaccuracyresults, whileXGBoost-GSFAfinishedfirstforworst,meanandstandard deviation indicators.

The yielded detailed metrics provided significant insights intothe algorithm'sperformance, especially for imbalanced datasets such as credit card fraud. Fromthereportedmetrics, it can be unequivocally confirmed that, on average, when all models are taken into account, the proposed GSFA algorithm proved that it is able to achieve the best classification performance for a minority class (class1inthisexample). The generated confusion matrices for the original credit card fraud dataset by tunedSVM,ELM, and XGBoost models with GSFA,FA, and SNS algorithms are shown in Figure 5, while the precision–recall (PR)curvegraphsforGSFAandarbitrarychosenapproachesfor the syntheticdatasetare depicted in Figure.Lastly, the hyperparameters' values for the tuned SVM, ELM, and XGBoost models, generated in the best run for each applied optimization algorithm, are shown in Tables 3–5, respectively.It should be noted that Table 15depicts just the number of neurons nn parameter that obtained the best results, as showing all weights and biases parameters would not be feasible.

V.4 STATISTICAL TESTS

Since the experimental outcomes are typically insufficient to establish that one algorithm outperforms its competitors, contemporary computer science practice requires researchers to determine whether the obtained improvementsare statistically significant.In the research suggested in this manuscript, 10 methods (including proposed GSFA) were validated for SVM, ELM, and XGBoost tuning against the original (highly imbalanced) and synthetic, generated using the SMOTE technique (balanced) on credit card fraud datasets.Therefore, 10 methods were compared against 6 problem instances, which fall into the domain of multiple approaches for multi-problemanalysis. According to the recommendations from the literature [65–67], statistical tests in such scenarios may be conducted by constructing a results sample for each approach by taking averages of the measured objectives over multiple independent runs for each problem.However, this approach may have disadvantages when the measured variable has outliers that do not follow a normaldistribution, which may lead to deceptive conclusions. According to a literature survey, whether the average objective function value should be taken for statistical tests when comparing stochastic methods still remains an open question [55].Forthepurposeofcomparing10methodsfor6 problem instances, despite the above-noted potential disadvantages, the objective function (classification error rate) was averagedover50independentrunsisusedinstatisticaltests. However, this decision was rendered based on the conducted Shapiro–Wilk [39] test for single-problem analysis [55] in the following way: for each algorithm and every problem, a data sample is constructed by taking the results obtained in each run, and respective p-values are calculated for every method–problem pair. The obtained p-values for this test are shown in the Table.

Table 9: Shapiro–results for single-problem analysis.

Source: Authors, (2026).

The results from Table 9 indicate that all p-values are higher than the threshold significance level $\alpha = 0.05$, yielding the conclusion that the null hypothesis cannot be rejected;therefore, the data samples for all method–problem pairs originate from a normal distribution, and it is safe to use the average objective in the statistical tests.From this point, we proceeded with multi-problem multiple methods statistical analysis, and the data sample for each method was constructed by taking the average objective function value over 50 independent runs for each problem instance. First, the safe use of the parametric tests conditions, which include independence, normality, and homoscedasticity of the variances of the data, was checked [11].The condition of independence was satisfied because each run was executed independently,starting with a unique pseudo-random number seed. To check normality, the Shapiro–Wilk test [39] was used again. The results for every method are reported in Table 10.

Table 10: Shapiro–Analysis.

Methods									
GSFA	**FA**	**BA**	**ABC**	**SCA**	**MBO**	**HHO**	**EHO**	**WOA**	**SNS**
***p*-value** 3.20×10^{-3}	8.34×10^{-3}	9.71×10^{-3}	6.81×10^{-3}	3.28×10^{-3}	9.19×10^{-3}	8.90×10^{-3}	2.32×10^{-3}	4.58×10^{-3}	8.34×10^{-3}

Source: Authors, (2026).

To check homoscedasticity based on means, Levene's test [10] is employed, and the p-value of 0.64 is obtained, which follows that the homoscedasticity is satisfied. However, the rendered p-values from the Shapiro–Wilk test for all methods are smaller than $\alpha = 0.05$ (Table 18), yielding the conclusion that the safe use of parametric tests is not satisfied, and we proceeded with non-parametric tests. In all non-parametric tests,the proposed GSFA was established as the control method.

VI. CONCLUSIONS

The research presented in this paper proposed a novel variant of the famous FA algorithm, named GSFA metaheuristic, with the aim of addressing the notable drawbacks of the original implementation. The introduced GSFA approach adopts a disputation operatorfrom the recently proposed SNS metaheuristic. The suggested GSFA was paired with three standard ML models, namely the SVM, ELM, and XGBoost models, to perform hyper-parameter optimisation. This challenge is still an open question in the ML domain, because every ML model has to be tuned for a specific dataset. Thesuggested hybrid model's performance was verified against the credit card fraud detection dataset, which includes transactions gathered across Europe in 2013.The employed dataset is highly disproportionate,as the majority of entries represent valid transactions, and just a small portion mark the fraudulent actions.

The performances of the proposed GSFA-optimisedSVM, ELM, and XGBoost were compared to nine other metaheuristicsoptimised variants of ML models. The competitor metaheuristics encompassed well-known algorithms, such as the original implementation of FA,BA,ABC,SCA,MBO,HHO,EHO,WOA, and SNS. The experiments were conductedin two phases:first, with the original imbalanced dataset. The outcomes of the executed simulations indicate the superior performance of proposedGSFA for most of the test instances.Finally, rigorous statistical tests wereperformed to confirm the significance of the obtained test results.Therefore, in the proposed research, it was shown that the FA metaheuristic can be further improved and that the tuned SVM, ELM, and XGBoost models achieve decent performance for a highly challenging and important credit card fraud dataset.However, the proposed study also has some limitations.

First, the GSFA metaheuristicemploys three additional control parameters that need to be adjusted for each particular NP-hardchallenge. Moreover, the performance of the algorithm needs to be further evaluated for other NP-hard challenges.The future trials of the suggested GSFA algorithm will include further testing on supplementary real-life credit card datasets.Another direction for validating the proposed GSFA is to apply it and test it on other NP-hard problems, falling into the domains of cloud computing, cryptocurrency forecasting, and image processing and classification.

ABSTRACT

Student engagement plays a crucial role in facilitating comprehension in the teaching-learning process. Evaluating students' classroom behavior is essential for assessing the effectiveness of teaching. To objectively assess students' attentiveness in class, it is imperative to capture their emotions and cognitive feedback through expressions and behaviors. However, accurately extracting expression features from classroom videos poses a importantcontest. To discourse this, we suggest a hybrid optimization and deep learning technique used for higher education students. Our model involves designing a hybrid spatio-temporal ResNet with Laplacian Harris hawk optimization (LHHO) algorithm for feature extraction and optimization. It enables the extraction of contextual, semantic, and positional features while enhancing the recognition of occluded objects. Additionally, we employ a domain adaptive deep belief network (DA-DBN) for classroom behavior recognition and evaluation, improving the detection accuracy of occluded objects. To validate our approach, we evaluate it against existing classroom behavior recognition models using public datasets such as COCO and PASCAL VOC. The results demonstrate that our proposed algorithm accurately detects various student behaviors, outperforming state-of-the-art models. Specifically, LHHO+DA-DBN model achieves an average accuracy of 96.031% and a recall of 94.335%, surpassing the performance of compared models across different scenarios.

I. INTRODUCTION

Classroom teaching is a pivotal aspect of modern education, particularly in disciplines like art education, where interaction, communication, and practical engagement among teachers and students are paramount [1]. Enhancing student contribution in schoolroom activities not only fosters complete artistic literacy but also nurtures their advanced and independent thinking skills [2]. However, outdated art schoolrooms often struggle with fully understanding each student's learning status, leading to ineffective teaching outcomes. Teachers face the challenging task of responding to separate student declarations and actions, monitoring overall class development, and adapting instructional objectives accordingly [3]. To succeed in this difficult role, teachers must visually perceive and procedure a vast quantity of learning-relevant information, a skill mentioned to as teacher perceiving in professional vision investigate. Numerous empirical studies in teacher research have focused on professional vision, particularly through video-based involvements where teachers observe classroom states and analyze noticed events, both in action and on action [4]. Expert-novice paradigm studies have highlighted significant alterations among pre-service and in-service teachers' observing of relevant classroom proceedings, with experienced teachers exhibiting a greater focus on scholars and key learning-related features of instruction [5]. Recent research has leveraged advanced eye-tracking methods to examine teacher noticing processes, revealing insights into the distribution of teachers' visual attention during classroom instruction [6].

For instance, experienced teachers tend to allocate attention more evenly among students and spend less time on task-redundant areas in the classroom compared to pre-service teachers.In art education settings, it's critical for educators to painstakingly screen understudies' exhibition and learning progress to speedily recognize any issues and deal fitting heading and backing [7]. Then, dissecting understudy conduct turns out to be especially fundamental in such homeroom conditions. By breaking down understudy conduct, instructors can acquire experiences into showing adequacy and give designated help where required [8] [9]. However, the diverse teaching scenarios, varying lighting, and wide range of student behaviors may make automatic detection of student learning behavior difficult in art teaching classrooms [10]. In current years, obsolete machine learning (ML) and deep learning (DL) approaches have shown superior show in perceiving understudy execution [11-14]. Traditional ML methods rely on feature extraction to generate behavior features for recognition, but they are limited by their representational abilities. DL-based student behavior recognition systems automatically learn deep features from large training datasets. These systems utilize DL models and parameter selection to achieve effective detection results. In the field of computer vision, there is a growing trend towards learning action representation using DL to enhance investigate on behavior gratitude in shadowing videos within schoolroom settings [15].

Behavior recognition aims to allocate a solitary class label to an complete cinematic, while spatio temporal behavior recognition involves labeling each person's achievement in each frame by deeply learning spatio temporal material from consecutive surrounds, which poses a greater challenge. Recent advancements have focused on relational reasoning-based behavior recognition methods to perfect the relationships among objects using boundary boxes in frames, as objects interrelate with each other [16]. Though, existing procedures often rely on appearance features extracted from individuals and matters detected by pretrained object detectors with fixed categories, potentially overlooking small objects connected to the actor. Additionally, in cluttered classroom environments, relational reasoning may prioritize salient regions in images, neglecting secondary human body portions crucial for human-to-human communication [17], [18]. Therefore, accurate detection of supporting human body parts and objects amid disorderly backgrounds is essential for interactive action recognition. Despite advancements, challenges persist in student behavior recognition [19]. Limited availability of datasets on students' learning behavior hampers research progress, with most studies focusing only on specific behaviors like rising hands, sleeping, and yawning, which are sovereign performances [20]. Though, the absence of interactive behaviors negatively impacts the assessment of scholars' learning excellence. To address these challenges, behavior recognition models focusing on accurate detection of interactive actions are proposed.

Our contributions. We propose a hybrid optimization and DL technique used for higher education students to address the problem of extracting features from classroom videos while it is posed. The major charities of planned work are given as follows.

1.To enables the extraction of contextual, semantic, and positional features while enhancing the recognition of occluded objectsa hybrid spatio-temporal ResNet with Laplacian Harris hawk optimization (LHHO) algorithm for feature extraction and optimization.
2.To advance the detection accurateness of obstructed objects a domain adaptive deep belief network (DA-DBN) for classroom behavior recognition and evaluation.

The rest of this paper is prepared as follows: Section 2 reviewed the various models for classroom behavior recognition and evaluation using DL modelsusing deep learning. The problem description and the detailed working process of proposeddeep learning and sensing technologies in higher education is explained in Section 3. Section 4 examines the effectiveness of the proposed and existing classroom modelsusing results and comparative analysis.Finally, the paper completes in Section 5.

II. RELATED WORKS

II.1 CLASSROOM BEHAVIOR RECOGNITION AND EVALUATION USING DL MODELS.

This section provides a brief overview of recent research on classroom behavior recognition and evaluation using DL models. According to [21] have developed a quick visually impaired remaking model with linear canonical transform (LCT) regularization for recreation of feeble infrared otherworldly signs. Using LCD conversion with high resolution and a weak IR spectral signal, they examined their primary distinction. At low resolution, bright IR spectra reveal a broad distribution of image data.

An infrared spectral reconstruction technique was developed in response to these findings to limit the wide range of IR spectra observed at L0-Nord. For human behavior monitoring, the experimental results demonstrate that the LCD-based IR spectrum reconstruction method can preserve IR spectral range structures and eliminate Poisson noise. For authors [22] have proposed an infrared look acknowledgment technique for understanding nonverbal ways of behaving in the study hall through multi-name conveyance learning. In particular, we originally determined the component closeness of seven fundamental looks to portray the connection between contiguous articulation pictures. Then, comparable qualities are fitted utilizing a Cauchy conveyance capability. Moreover, we build another profound organization utilizing Cauchy distribution-based label learning (CDLLNet) rather than the standard single articulation name. Utilizing these amended names, the infrared facial covering learns the adjoining demeanor marks and its unique appearance marks. A few subjective and quantitative experimental outcomes affirm that the CDLLNet network accomplishes vigorous outcomes and performs surprisingly well. In [23] have presented an extensive informational collection that can be utilized to recognize, analyze, and contextualize understudy conduct in the homeroom. An organized informational index comprises of a revelation section, a validation part, and a header part. The discovery region incorporates a transitory recognition information block with 4542 examples and an activity identification information block with 3343 examples, while the location region contains 4276 examples and the header region contains 4296 examples. In genuine homerooms, understudy conduct is programmed, making information assortment delegate and reasonable.

Then analyze specific aspects of the classroom situation and technical issues for each module, which are tested through tests. According to [24] have presented an extensive informational collection that can be utilized to recognize, analyze, and contextualize understudy conduct in the homeroom. An organized informational index comprises of a revelation section, a validation part, and a header part. The discovery region incorporates a transitory recognition information block with 4542 examples and an activity identification information block with 3343 examples, while the location region contains 4276 examples and the header region contains 4296 examples. In genuine homerooms, understudy conduct is robotized and information assortment is delegate and sensible. Then, for each experimented-on module, look at specific aspects of the classroom and technical issues. According to [25] have proposed a system for recognizing student behavior that uses personality detection and an assessment of skeletal posture utilized to exhibit the proposed framework. To reduce the number of false connections in bone data, a method of error correction based on techniques for person detection and pose estimation is proposed. Highlight extraction was performed to produce include vectors addressing the human figure. Qualities incorporate ordinary joint arrangement, joint dividing, and bone points. Social grouping was finished to decide the understudy's way of behaving. A profound brain network was worked to characterize the exercises and the proposed framework had the option to decide the quantity of understudies in the class. The framework accomplished 15.15% higher normal accuracy and 12.15% higher normal review than the skeleton-based conspire. For authors [26] have introduced to achieve an enhanced YOLO-v4 network, cross-local network embedded connection (EC) components are configured and embedded at the end of the YOLO-v4 network.

The added substance misfortune capability comprises of two sections: RepBox and RepGT losses. RepGT utilizes a misfortune capability to work out the misfortune values between the objective forecast box and the encompassing ground truth boxes to lessen bogus positive location results; RepBox utilizes the misfortune capability to work out the misfortune esteem between the objective expectation field and other close by target forecast fields to diminish misleading negative identification results. Preparing and testing are performed on homeroom conduct datasets of educators and understudies, individually. The outcomes show that the typical exactness for distinguishing the study hall conduct of various targets is over 90%, which demonstrates its viability. According to [27] have proposed a 3D-CNN is chosen as an organization model for homeroom understudy conduct acknowledgment, which has high precision and unwavering quality of multi-source data and further develops restriction of homeroom understudies. The spatio-temporal domain of 3D convolution extends 2D convolution for improved video analysis of human behavior. In classroom teaching situations, a deep spatial residual CNN is used to learn the spatial characteristics of each student's behavior and recognize classroom behaviors in real time. Different investigations are directed utilizing class conduct informational collections, and the experimental results show that the model performs well in identifying class behavior.In [28] have proposed Density, occlusion, and multimodal displays are just a few of the issues that the Student Classroom Behavior Framework addresses. They utilized a progression of imaginative techniques and joined the Res2Net block with the first C2f block in YOLOv8 to make the C2f_Res2block block.

The module productively handles multi-scale scenes and works on model precision. Multi-scale center and multi-head concentrate further work on model execution. According to [29] have proposed a technique for utilizing images of classroom time series to determine the active behavior of students. Students' active behavior is detected using Advanced asynchronous interaction aggregation (AIA). By adding the MsTA and MSCSA modules to the fast track and slow track, respectively, the enhanced AIA network backbone improves the accuracy of identifying student engagement behaviors in the slow fast track. A smooth focal loss function is used to enhance the contrast between segments in the pupil action database. The student activity behavior data set demonstrates that this method outperforms the original AIA network in terms of detection performance when it comes to identifying a variety of classroom student activity behaviors. According to [30] have proposed a data augmentation strategy for enhancing behavioral characteristics in order to identify distinctive student behaviors. The process begins with the collection of a narrow set of data designed to understand student learning behavior and expands it significantly using data augmentation techniques. The compositional abilities of extended-efficient layer aggregation network (E-Spirit) can be utilized to productively remove different learning conduct highlights. Outstandingly, the channel-wise attention module (CPAM) coordinates the central instrument into the component location organization. This works on the organization's capacity to recognize key highlights related with understudies' learning ways of behaving, consequently expanding the exactness of component acknowledgment. The finish of the excursion includes the characterization of highlights removed utilizing a double methodology: an feature pyramid network (FPN) and a way conglomeration organization (Skillet). Observational proof plainly exhibits the force of the technique acquiring 96.7% Guide.

II.2 RESEARCH GAP

In the province of classroom behavior gratitude and evaluation, numerous intricate challenges emerge, complicating the precisecalculation of student attentiveness and appointment. The students' expressions and behaviors exhibit vast variability, encompassing facial expressions, body language, and verbal cues, which poses a challenge in their interpretation due to individual differences and cultural nuances. The presence of occlusions and environmental factors within classroom settings, such as students obstructing each other's view or varying lighting conditions, further complicates the recognition of these expressions and behaviors. The inherently subjective nature of evaluating attentiveness and engagement introduces another layer of complexity, as different educators may have divergent criteria for defining attentive behavior, leading to inconsistencies in assessment. Temporal dynamics also play a crucial role, with classroom interactions evolving over time, necessitating an understanding of how factors like lesson content and teaching style influence student behavior. Furthermore, privacy and ethical considerations surrounding the deployment of video-based monitoring systems in classrooms raise important concerns that must be carefully addressed. Data annotation and labeling present another challenge, as manually annotating classroom behavior data is resource-intensive and prone to biases. Moreover, ensuring the generalizability of behavior recognition models across diverse educational settings remains a significant hurdle, as nuances in student demographics and classroom dynamics can impact model performance.

Finally, effectively integrating behavioral insights into educational interventions and instructional design strategies poses yet another complex challenge in achieving the overarching goal of improving teaching practices and student outcomes. Moreover, the key challenges is the extraction of expression features from classroom videos, which is inherently complex due to various factors such as occlusions and varying environmental conditions. To discourse this contest, we suggest a original hybrid optimization and deep learning approach tailored for higher education students. Our proposed model comprises two main components: a hybrid spatio-temporal ResNet enhanced with the Laplacian Harris hawk optimization (LHHO) algorithm for feature extraction and optimization, and a domain adaptive deep belief network (DA-DBN) to further enhance the recognition of expression features. By adapting the feature representations learned from one domain (e.g., one classroom setting) to another domain (e.g., a different classroom setting), the DA-DBN ensures robust performance across diverse educational environments. Our proposed method represents a significant contribution to the field by offering a comprehensive solution for extracting expression features from classroom videos and assessing students' attentiveness in higher education settings. The integration of hybrid optimization techniques with deep learning architectures enhances the model's effectiveness and robustness, paving the way for more accurate and reliable evaluations of student engagement and learning outcomes.

III. PROPOSED METHODOLOGY

In the field of education, student participation is critical to improving understanding. When students actively engage with the information, ask questions, and interact with it, the teaching-learning process flourishes. Their participation creates a lively classroom atmosphere in addition to fostering understanding [31]. But evaluating this involvement calls for more than just watching; it also calls for a closer examination of the actions, facial expressions, and cognitive reactions of the students. Historically, educators have depended on nonverbal indications like engagement levels, body language, and eye contact. However, the development of technology has created new opportunities for evaluation.

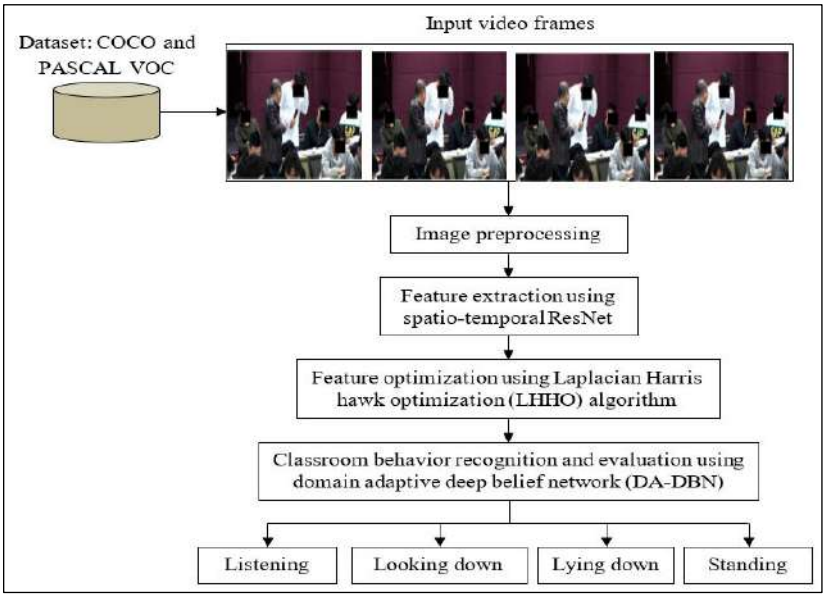

Figure 1: System design of proposed LHHO+DA-DBNmodel for classroom behavior recognition and evaluation.
Source: Authors, (2026).

Although classroom recordings provide an abundance of information, it is still quite difficult to extract useful expression elements from them. Emotions, cognitive input, and minute details must be extracted from video data using sophisticated algorithms and reliable techniques. Accuracy, privacy, and scalability must all be balanced as educators endeavor to understand the complex web of student interaction in the digital age.We suggest a hybrid optimization and deep learning method for college students as a solution to this problem. For feature extraction and optimization, our model builds a hybrid spatiotemporal ResNet using the Laplacian Harris Hawk Optimization (LHHO) algorithm. It improves the detection of obstructed objects and allows the extraction of contextual, semantic, and positional details. Furthermore, to enhance the detection accuracy of obscured objects, we utilize a domain adaptive deep belief network (DA-DBN) for classroom behavior recognition and evaluation.In the Figure 1 the proposed LHHO+DA-DBN model is given. For the analysis the video of a class is considered. By apply LHHO+DA-DBN method the behavior and features of the students in the class are identified. This method helps the academic authorities to make their facility more compactable for the students.

III.1 FEATURE EXTRACTION USING SPATIO-TEMPORAL RESNET

In the context of laboratory behavior gratitude and evaluation, feature abstraction mentions to the procedure of capturing relevant info from raw input data, such as video frames, to represent key characteristics or patterns of behavior. A spatio-temporal ResNet is a kind of deep neural network construction specifically calculated to process both spatial and temporal information. ResNet, short for Residual Network, is a popular type of convolutional neural network (CNN) building normally used in image recognition errands. In the case of spatio-temporal ResNet, the architecture is extended to handle video data, allowing it to imprisonment both longitudinal features and progressive topographies. The working process of feature extraction using spatio-temporal ResNet is given as follows.

- The input to the spatio-temporal ResNet is a sequence of video frames captured from a classroom setting. Each frame represents a snapshot of the classroom at a specific time.
- Before feeding the video frames into the network, preprocessing steps may be applied, such as resizing the frames to a unchanging size, standardizing pixel standards, and possibly enhancing the data to increase the assortment of the exercise dataset.
- Choose an appropriate spatio-temporal ResNet architecture based on the complexity of the task and available computational resources.
- Pass each frame through the spatio-temporal ResNet architecture to extract features. The network processes the frames in a hierarchical manner, with lower coatings apprehending low-level topographies and higher layers apprehending more intellectual topographies relevant to behavior recognition.
- Since behavior recognition involves analyzing temporal patterns over a sequence of frames, the features extracted from individual frames need to be aggregated over time. This can be done using methods such as chronological pooling or recurrent neural networks (RNNs) to capture temporal dependencies.
- After temporal processing, the extracted features are represented as high-dimensional feature vectors. These feature vectors encode information about the contextual, semantic, and positional aspects of the observed behaviors.
- In some cases, the dimensionality of the feature trajectories may be too high for downstream tasks such as classification. Dimensionality reduction technique is applied to reduce the dimensionality of the feature space while preservative vital material.
- The final output of feature extraction process is set of feature vectors, each corresponding to a specific segment of the input video sequence. These feature vectors can then be used as input to classifier for behavior recognition and evaluation.

Contextual features refer to information about the surroundings or environment in which the behavior occurs, providing additional context for understanding the behavior. Semantic features capture the meaning or semantics of the behavior, such as identifying specific actions or interactions. Positional features describe the spatial location or arrangement of objects or individuals within the scene. To extract these features using a spatio-temporal ResNet, the network is qualified on a large dataset of video sequences glossed with labels corresponding to different behaviors. During training, the network learns to automatically extract features from both individual frames and sequences of frames. The layers of the network are designed to capture hierarchical representations of the input data, gradually transforming raw pixel values into higher-level features that are more meaningful for behavior recognition. The final production of the system is set of feature vectors that represent the contextual, semantic, and positional aspects of the observed behaviors.

III.2 FEATURE OPTIMIZATION USING LAPLACIAN HARRIS HAWK OPTIMIZATION (LHHO)

Highlight enhancement is the method involved with choosing the most important and instructive elements from a given informational index to work on the presentation of AI models. A lot of real-world applications use a lot of datasets with a lot of features, some of which could be useless, redundant, or noisy. Include streamlining intends to distinguish and hold just the most discriminative elements, consequently lessening the size of the informational index and working on the exactness, interpretability, and execution of model expectations. Laplacian Harris Hawk Optimization (LHHO) is a metaheuristic optimization procedure stimulated by the shooting performance of Harris's hawks. It combines principles from the Harris hawk's collaborative hunting strategies with mathematical optimization techniques to efficiently search for optimal solutions to feature optimization problems. During the optimization process, LHHO employs a combination of exploration and exploitation strategies to iteratively update the candidate feature subsets. In the exploration phase, the algorithm encourages diversity by exploring different combinations of features across the search space.

This is achieved through random exploration and movement of candidate feature subsets, simulating the scouting behavior of Harris's hawks as they search for prey in varied terrain.LHHO algorithm maximizes the production of biodiesel by optimizing three independent variables.The objective function is depicted as follows.

$$\begin{aligned}\max d(z_s z_n z_v) = 37.45 + 0.42z_s + 4.37z_n - 0.16z_2^2 + 24.26z_v \\ -1.53z_v^2 + 0.001z_{sn} - 0.24z_s z_v - 0.44z_2 z_3,\end{aligned} \tag{1}$$

where $55 \le z_s \le 65$, , $6 \le z_n \le 15$, and $0.6 \le z_v \le 2.0$.

Harris hawks typically have farsighted eyes, which enable them to spot and capture their prey. However, it is extremely difficult to easily identify prey. After an attack on the prey, hawks hold back, observe, and monitor for this reason. In this particular algorithm, candidate solutions are Harris hawks, and the optimal solution is taken into consideration at each step that is close to the ideal position. The exploration phase's mathematical representation is shown as

$$\begin{aligned}X_{rand}(o) - e_1, X(r+1) = |X_{rand}(o) - 2t_2 Z(o)|, g \ge 0.5, \\ (X(o) - X(o)), \\ t_3(lb + t_4(ub - lb)), \qquad g \le 0.5\end{aligned} \tag{2}$$

where Zrabbit is the position of the rabbit, Xr + 1 is the hawk's position, and p is the next iteration. The current location of the hawks is Xo, and the random numbers e1, e2, e3, e4, and h are between 0 and 1. The typical hawk's position is described as

$$X_b(o) = \frac{1}{a}\sum_{o=1} X_u(o), \tag{3}$$

where the position of each hawk in repetition p is xu O, and A denotes the total quantity of hawks. Transition from exploration to exploitation the exploratory phase can transition into the exploitative phase based on how the prey's energy escapes, allowing for a variety of exploitative behaviors. During the behavior of fleeing, the prey's energy decreases significantly.

$$\in = 2 \in_o \left(1 - \frac{o}{r}\right), \tag{4}$$

where signifies the absconding energy of the target, O denotes the initial energy state, and r denotes the supreme number of restatements. Laplacian numbers take the place of variant random numbers in LHHO. The reported Laplacian random number generator is used in recent methods by applying the matrix output of the function, which has a unkind value of 0 and normalnonconformity of 1.

$$\begin{aligned}E\left(A_{s,n}^f\right) = [cumsum(2 \times Lap(r_1) - 1) \\ cumsum(2 \times Lap(r_2) - 1), \ldots, \\ cumsum\left(2 \times Lap\left(r_{max}(\ \ )\right)(\ \ )\right)\end{aligned} \tag{5}$$

The conventional Laplace probability distribution (LPD), denoted by LapS, R, is the definition of the probability density function (PDF).

$$d(z; A, R) = \frac{1}{2R} exp - \frac{|z-A|}{R}, -\infty \le z \le \infty. \tag{6}$$

The following is the Laplace distribution function:

$$\begin{aligned}d(z) = \frac{1}{2}\exp - \frac{|z - A|}{R}, \ z \le A, \\ 1 - \frac{1}{2}\exp - \frac{|z - A|}{R}, X \ge A,\end{aligned} \tag{7}$$

where the location is shown by A, and the scale parameters are determined by R.

III.3 CLASSROOM BEHAVIOR RECOGNITION

Classroom behavior recognition is vital component of educational technology, aiming to understand and evaluate students' engagement, participation, and attentiveness during classroom activities. Accurate recognition of classroom behaviors provides valuable insights for educators to tailor instruction, provide timely feedback, and create supportive learning environments. The domain adaptive deep belief network (DA-DBN) is a sophisticated machine learning model designed to address the challenges of classroom behavior recognition.

DA-DBN combines principles from deep learning, unsupervised learning, and domain adaptation to learn robust representations of classroom behaviors across diverse environments and conditions. At its core, DA-DBN consists of multiple layers of interconnected neurons, organized into a hierarchical structure inspired by human brain's neural networks. DA-DBN incorporates domain adaptation mechanisms to align feature distributions between dissimilar provinces, mitigating the effects of sphere shift and improving the model's generalization presentation across diverse classroom environments.A DBN consists of multiple RBMs, each with a visible v layer and a hidden layer. RBM uses z vectors and units to connect layers within the same layer. The power function is defined by reflecting the state of the network, and the steady state of the network corresponds to the minimum state of the power function.

$$e(v,i) = -\sum_{h=1}^{a} m_h v_h - \sum_{g=1}^{b} n_g i_g - \sum_{j=1}^{b}\sum_{h=1}^{a} v_h i_h z_{hg} \tag{8}$$

Here m and n are the bias trajectory of observable and concealed layers, respectively. The joint circulation and conditional spreading of each stratum can be distinct as follows.

$$X(v,i) = \frac{E^{-e(v,i)}}{\sum_{v,i} E^{-e(v,i)}} \tag{9}$$

$$X(v\,|\,i) = \frac{X(v,i)}{X(i)} = \frac{E^{-e(v,i)}}{\sum_{v} E^{-e(v,i)}} \tag{10}$$

$$X(i\,|\,v) = \frac{X(v,i)}{X(v)} = \frac{E^{-e(v,i)}}{\sum_{i} E^{-e(v,i)}} \tag{11}$$

Since there is no correlation between components in each stratum, the restricted likelihoods of units can be designed using the following calculations.

$$X(i_g = 1|v) = \frac{X(i_g=1,v)}{X(i_g=1,v)+X(i_g=0,v)} = \sigma\left(\sum_{h=1}^{a} m_h + z_{hg} v_h\right) \tag{12}$$

$$X(v_g = 1\,|\,i) = \frac{X(v_h = 1,i)}{X(v_h = 1,i) + X(v_h = 0,i)} = \sigma\left(\sum_{g=1}^{b} n_g + z_{hg} i_g\right) \tag{13}$$

$$\sigma(p) = \frac{1}{1+E^{-p}} \tag{14}$$

The functional kernel I_k is definite as a Hilbert planetary with k. For two prospectdeliveries x and y for all $F \in I_k$, the DA-DBN value among x and y is definite as the recreated Hilbert interval distance among the fitted mean standards of x and y. It is defined as the quadratic formula of DA-DBN between x and y.

$$c_K^2(x,y) \overset{\Delta}{=} \| e_{p^T \sim x}[\phi(p^T)] - e_{p^T \sim y}[\phi(p^T)] \|_{I_k}^2 \tag{15}$$

where ϕ is feature charting. The mouth kernel k can be labeled as follows.

$$K = \sum_{U=1}^{a} \beta_U K_U : \sum_{U=1}^{a} \beta_U = 1, \beta_U \geq 0, \forall\, U \tag{16}$$

where β_U is an extension of the weight constraint that ensures the production of regular multifunction kernels and a is the sum of the feature seeds. Thus, the optimization objective of the entire systemcontains of two portions: the organization error l_D in the source province and the insight error l_C among the foundation and mark domains. The optimization impartial is given by L is compute as follows.

$$l = l_D + l_C = MIN \frac{1}{b_t} \sum_{h=1}^{b_T} G(\theta(p_h^t),\, q_h^T) + \lambda \sum_{L=L_1}^{L} c_K^2(C_T^L, C_s^L) \tag{17}$$

The time difficulty of directly scheming the inner produce between the source field and the target domain $O(b^2)$ is too tall to be used effectively in a deep knowledge model.

$$c_K^2 = (x, y) = \frac{2}{b_t} \sum_{h=1}^{b_T/2} j_K(w_h) \tag{18}$$

$$w_h \overset{\Delta}{=} (p_{2h-1}^T, p_{2h}^T, p_{2h-1}^s, p_{2h}^s) \tag{19}$$

$$j_K(w_h) \overset{\Delta}{=} K(p_{2h-1}^T, p_{2h}^T) + K(p_{2h-1}^s, p_{2h}^s) + K(p_{2h-1}^s, p_{2h}^s) - K(p_{2h}^s, p_{2h-1}^s) \tag{20}$$

The limitations of the perfect are fine-tuned by stochastic gradient descent (SGD) technique. The incline of perfect limitation receipts the form.

$$\nabla \theta^L = \frac{\partial G(w_h)}{\partial \theta^L} + \lambda \frac{\partial j_K(w_h^L)}{\partial \theta^L} \tag{21}$$

Fine change of a deep neural network effortlessly achieved using a supervised learning procedure. An input pick, the output is obtained from the upper layer of the neural network.

$$r(p) = Max(0, p + j * X) : Q \sim B[0, \sigma(p)] \tag{22}$$

where j is the sound issue, which is second-hand to controller the equal of additional noise. The algorithm 1 describes the working process of classroom behavior recognition using the DA-DBN.

Algorithm 1 Classroom behavior recognition using DA-DBN

Input: The input to the algorithm is the energy function.
Output: After the learning process the upper layer of network is obtained.

IV. RESULTS AND DISCUSSION

In this fragment, we current the results examination of proposed and existing study hall conduct acknowledgment models. To approves ourLHHO+DA-DBN model utilizing the publically available datasets like COCO and PASCAL VOC. The experimental environment was demonstrated on Ubuntu 18.04 functioning scheme, with an Intel(R) Xeon(R) Sliver 4110 CPU@2.10HZ CPU formation, a Ge Force GTX 1080ti graphics card selected for calculation, 11 GB of video memory, and DLagendaPyTorch version 1.7.0 and the Python environment used to construct the runtime environment. The consequences of proposed LHHO+DA-DBN model is contrasted and the current condition of craftsmanship imitations, for example, Quick R-CNN [32], SSD [33], YOLOv5 [34] and further developed YOLOv5 [35] [32] [33] [34] [36] [31].In guidance to evaluate the benefit of the arranged models, the assessment pointers utilize the exactness, accuracy, review, mean normal accuracy (Guide), F-measure, and the amount of outlines per extra to detect the pictures to appraise the performance.

IV.1 DATASET DESCRIPTION

To discourse the lack of public datasets for detecting schoolroom students' behavioral states, this study manually curated a dataset using real laboratory cassettes. The dataset comprises four performance categories: listening, looking down, lying down, and standing. Images were removed from noted class videos at frame breaks, ensuring diverse student poses and actions for robust model training. In total, 10,826 labels were annotated, with an 80:20 split for exercise and testing datasets, correspondingly. Table 1 presents the description of dataset. To prevent Overfitting caused by imbalanced training data, particularly due to a larger number of objects in some behaviors, data augmentation techniques were employed. Specifically, since standing samples were relatively scarce and challenging to collect, data augmentation was applied to expand the number of standing pose samples.

This involved intercepting images of students in standing posture and applying augmentation such as horizontal flipping, brightness adjustment, and Gaussian noise addition to enhance the dataset's diversity. For model training, images were resized to a standard input size of 640 × 640 pixels. A warm-up phase with linear interpolation learning rate adjustment was implemented initially, followed by a cosine annealing strategy for further learning rate adjustments. The training process spanned 100 epochs, with a batch size of 16 epochs per batch. These strategies collectively contributed to the actualexercise of a deep learning classical for accurate classroom behavior detection. Figure 2 shows the taster test imageries from the dataset.

IV.2 COMPARATIVE ANALYSIS

Table 2 presents a comprehensive comparison of various classroom students' behavioral detection models with the "listening" class. In terms of accuracy, the LHHO+DA-DBN model achieves the highest accuracy of 93.707%. This represents a significant improvement over Fast R-CNN, SSD, YOLOv5, and Improved YOLOv5 by 10.962%, 8.221%, 5.481%, and 2.74%, respectively. Regarding precision, the LHHO+DA-DBN model demonstrates superior precision at 92.184%. This marks a substantial enhancement compared to Fast R-CNN, SSD, YOLOv5, and Improved YOLOv5 by 17.291%, 12.969%, 8.646%, and 4.323%, respectively. Similarly, the LHHO+DA-DBN model exhibits remarkable recall at 92.245%, surpassing Fast R-CNN, SSD, YOLOv5, and Improved YOLOv5 by 17.28%, 12.96%, 8.64%, and 4.32%, respectively.Moreover, the proposed model achieves outstanding F-measure of 92.215%, shown significant improvements over Fast R-CNN, SSD, YOLOv5, and Improved YOLOv5 by 17.286%, 12.964%, 8.643%, and 4.321%, respectively.Furthermore, in terms of mAP, the LHHO+DA-DBN model achieves the highest score of 91.063%, outperforming Fast R-CNN, SSD, YOLOv5, and Improved YOLOv5 by 16.05%, 12.038%, 8.025%, and 4.013%, respectively. For a visual representation of these results, refer to Figure 2, which illustrates the comparison between the proposed and existing classroom students' behavioral detection models for the "listening" class.

The result analysis for Table 2, which compares various classroom students' behavioral detection models with the "Looking down" class:Our LHHO+DA-DBN model achieves the highest accuracy, reaching 97.365% after 100 epochs. Compared to the existing models, it outperforms Fast R-CNN, SSD, YOLOv5, and Improved YOLOv5 by 14.272%, 10.713%, 7.636%, and 4.468%, respectively. Similar to accuracy, the LHHO+DA-DBN model exhibits the highest precision, peaking at 95.478% after 100 epochs. It surpasses Fast R-CNN, SSD, YOLOv5, and Improved YOLOv5 by 12.988%, 9.741%, 6.494%, and 3.247%, respectively. Precision generally improves with the number of epochs for all models. LHHO+DA-DBN model also achieves the highest recall, reaching 94.898% after 100 epochs. Compared to Fast R-CNN, SSD, YOLOv5, and Improved YOLOv5, it performs better by 16.416%, 13.370%, 8.225%, and 4.126%, respectively. Recall increases steadily with the number of epochs for all models. With an F-measure of 95.187% after 100 epochs, the LHHO+DA-DBN model again outperforms the other models. It surpasses Fast R-CNN, SSD, YOLOv5, and Improved YOLOv5 by 14.735%, 11.089%, 8.321%, and 4.625%, respectively. The LHHO+DA-DBN model achieves the highest mAP, reaching 93.235% after 100 epochs. It outperforms Fast R-CNN, SSD, YOLOv5, and Improved YOLOv5 by 14.028%, 11.439%, 7.178%, and 3.589%, respectively.For a visual representation of these results, refer to Figure 3, illustrates the comparison between the proposed and existing classroom students' behavioral detection models for the "looking down" class.

Source: Authors, (2026).

Table 3 provides a comprehensive comparison of various classroom students' behavioral detection models with the "Lying down" class. The results showcase the performance of each model across different metrics and epochs. In terms of accuracy, the LHHO+DA-DBN model achieves the highest accuracy consistently across all epochs, reaching a maximum accuracy of 97.125%. It represents a significant improvement over other models, with the closest competitor being the Improved YOLOv5 model with maximum accuracy of 93.451%. Regarding precision, the LHHO+DA-DBN model also outperforms other models, achieving a precision of 95.235% at the highest. This is notably higher compared to other models, with the Improved YOLOv5 model coming closest with a precision of 91.248%. Similarly, in terms of recall, the LHHO+DA-DBN model shows superior performance, achieving a maximum recall of 95.023%.

It outperforms other models significantly, with the Improved YOLOv5 model having the closest recall at 89.385%. The F-measure, which considers both precision and recall, also highlights the effectiveness of LHHO+DA-DBN model. With maximum F-measure of 95.129%, it surpasses other models by a significant margin, indicating a balanced performance in terms of precision and recall. Lastly, the mAP metric, which evaluates the completepresentation of the perfect, further confirms the superiority of the LHHO+DA-DBN model. With a maximum mAP of 94.022%, it demonstrates robustness and consistency across different epochs, outperforming other models in detecting the "Lying down" class behavior.For a visual representation of these results, refer to Figure 4, illustrates the comparison between the various classroom students' behavioral detection models for the "lying down" class.

Table 4: Comparative analysis of various classroom students' behavioral detection models with “Lying down” class.

Models	Number of epochs				
	20	40	60	80	100
	Accuracy (%)

Table 4 presents a comparative analysis of various classroom students' behavioral detection models with the "Standing" class. In terms of accuracy, the LHHO+DA-DBN model achieves the highest accuracy of 97.355% after 100 epochs, showing notable improvements over the other models such as Fast R-CNN, SSD, YOLOv5, and Improved YOLOv5 by 26.953%, 20.366%, 13.577%, and 7.589%, respectively.

Regarding precision, the LHHO+DA-DBN model achieves exceptional precision at 94.975%, outperforming the other models by margins of 15.948% (Fast R-CNN), 12.961% (SSD), 8.974% (YOLOv5), and 4.987% (Improved YOLOv5) after 100 epochs. Similarly, for recall, the LHHO+DA-DBN model demonstrates superior performance, achieving a recall of 96.525% after 100 epochs, surpassing Fast R-CNN, SSD, YOLOv5, and Improved YOLOv5 by 27.918%, 20.691%, 14.794%, and 7.877%, respectively. Additionally, in terms of F-measure and mAP, the LHHO+DA-DBN model consistently exhibits the highest values, indicating its effectiveness in accurately detecting students' "Standing" behavior in the classroom. Fig. 5 highlights the superior performance of the proposed LHHO+DA-DBN model for behavioral detection in the "Standing" class, emphasizing its potential for improving classroom monitoring and assessment.

V. CONCLUSION

In this education, we introduced a novel method for enhancing classroom behavior recognition and evaluation among higher education students. Our method integrates a hybrid optimization and deep learning technique, leveraging a hybrid spatio-temporal ResNet combined with the Laplacian Harris hawk optimization (LHHO) algorithm for feature extraction and optimization. This innovative approach enables the extraction of crucial contextual, semantic, and positional features while effectively addressing challenges such as occluded object recognition. Moreover, we used a domain adaptive deep belief network (DA-DBN) specifically tailored for classroom behavior recognition tasks. By leveraging this network, we observed important developments in the detection correctness of occluded objects, crucial for accurately assessing student behaviors. To assess the efficacy of our technique, we conducted comprehensive tests using widely-used public datasets, including COCO and PASCAL VOC. The results of our evaluations validate the larger presentation of our proposed algorithm associated to current classroom behavior recognition models. Notably, the LHHO+DA-DBN model achieved an impressive average accuracy of 96.031% and a recall rate of 94.335%, consistently outperforming state-of-the-art models across various scenarios.

Foundation Engineering

ABSTRACT

In recent years, the field of foundation engineering has witnessed a transformative shift with the emergence of smart materials and data-driven decision-making technologies . The term "Smart Soil" represents the strategic integration of geosynthetic materials—particularly geo-textiles—with advanced artificial intelligence (AI) systems to address critical problems in soil stabilization and settlement prediction. Geo-textiles act as reinforcement materials that enhance the mechanical behavior of soil under various loading conditions, and when embedded in soil layers, they help distribute loads more uniformly, prevent soil erosion, and improve overall foundation stability .However, traditional foundation design strategies often fall short in predicting long-term settlement behavior due to the complex and nonlinear nature of soil systems . To overcome these limitations, AI models and machine learning algorithms such as Support Vector Machines (SVM), Artificial Neural Networks (ANN), and Decision Trees are increasingly being used to analyze large volumes of geotechnical data, leading to more accurate predictions and informed engineering decisions .This article provides a comprehensive assessment of the dual role of geo-textiles and AI-expected agreement models in modern-day foundation engineering. It examines their man or woman contributions, ability synergies, and the challenges involved in enforcing such included approaches within the discipline. The study objectives to formulate a framework for future infrastructure systems that aren't handiest sturdy and fee-powerful but additionally adaptable to evolving environmental and geotechnical demanding situations. The findings provide key insights into how clever substances and wise technologies may be harmonized to redefine the future of sustainable and excessive-overall performance basis design.

I. INTRODUCTION

Foundation engineering, a critical subfield of civil engineering, deals with the design and analysis of systems that switch loads from superstructures to the underlying soil or rock. The protection, durability, and sustainability of any infrastructure heavily depend upon the energy and balance of its basis. Over the years, engineers have continually sought superior solutions to mitigate risks together with immoderate settlement, soil erosion, and bearing capability failures [1]. Traditional methods, whilst reliable to a sure volume, frequently war to deal with the complex behavior of heterogeneous soil systems under numerous loading and environmental situations[2]. This has necessitated the exploration of revolutionary substances and shrewd structures, giving upward push to the concept of Smart Soil in modern geotechnical exercise [3] .

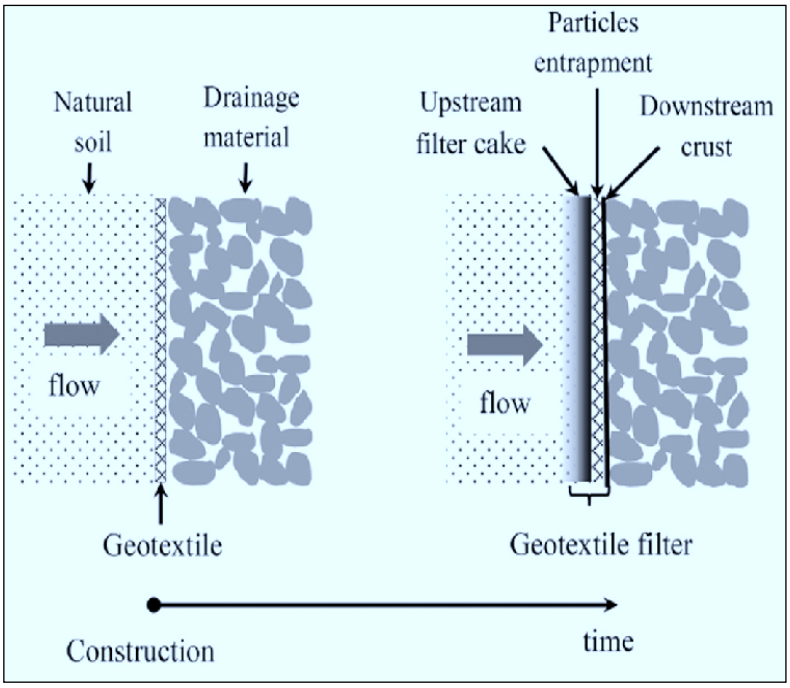

Figure 1: Evolution of the geotextile filter structure over time.
Source: Authors, (2026).

Smart Soil refers to an engineered soil environment enhanced with high-performance materials and data-driven technologies [4]. Among these innovations, geo-textiles have garnered significant attention. Figure 1 shows the evolution of the geotextile filter structure over time. Geo-textiles are synthetic permeable fabrics used to reinforce soil, improve drainage, and provide erosion control [5]. When properly integrated into the soil matrix, they enhance load distribution, reduce differential settlements, and extend the lifespan of infrastructure. Their mechanical and hydraulic properties allow them to perform multiple functions including filtration, separation, reinforcement, and protection, making them a vital component in modern foundation systems [6]. Parallel to material advancements, the civil engineering community is experiencing a digital revolution marked by the integration of Artificial Intelligence (AI) in predictive modeling and system optimization. AI techniques offer significant improvement in understanding and forecasting soil behavior under various conditions by leveraging historical datasets and complex algorithms. Unlike traditional empirical or analytical methods, AI models such as Artificial Neural Networks (ANN),

Support Vector Regression (SVR), and Random Forests can handle non-linearities and interdependencies in soil properties, leading to more accurate settlement predictions. This paper evaluates the synergy between geo-textiles and AI-based settlement prediction in foundation engineering. By assessing their combined impact, the study aims to develop a robust and smart framework for soil stabilization and performance evaluation. The research explores existing methodologies, implementation techniques, and practical applications to demonstrate how geo-textiles and AI models can complement each other in building smarter and more sustainable foundations Furthermore, this article intentionally excludes any human-subject involvement and focuses entirely on material behavior, algorithmic modeling, soil–structure interaction, and data-driven geotechnical assessments. This ensures the work remains rooted in technical, environmental, and engineering aspects, avoiding ethical concerns or subjective interpretations. The succeeding sections present a comprehensive literature review, methodological approach, AI modeling frameworks, performance evaluation, results, and implications for future geotechnical designs.

II. LITERATURE REVIEW

The advancement of foundation engineering has long relied on the synergy between innovative materials and predictive techniques. As infrastructure demands have increased, so has the complexity of subsurface conditions, urging engineers to adopt more robust and intelligent solutions. This section synthesizes past and present research on two key themes: the use of geo-textiles in foundation engineering and the application of Artificial Intelligence (AI) in settlement prediction.[7]

II.1 EVOLUTION OF GEO-TEXTILES IN FOUNDATION ENGINEERING

Geo-textiles, first introduced in the 1960s, have revolutionized soil stabilization techniques. These synthetic fabrics, commonly manufactured from polypropylene or polyester, are engineered to function in a wide range of geotechnical applications. According to Koerner, geo-textiles can be classified based on their structure as woven, non-woven, and knitted, each tailored for specific functions such as separation, reinforcement, filtration, drainage, and protection. Early applications mainly focused on erosion control and separation of subgrade and aggregate layers. However, later studies confirmed that geo-textiles also significantly improve the bearing capacity of soft soils [8], [9]. When placed between soil layers, they restrict lateral movement of soil particles and distribute loads over a wider area, thereby reducing settlement and enhancing shear strength. Figure 2 shows the comparation of pavement with or without geotextiles.

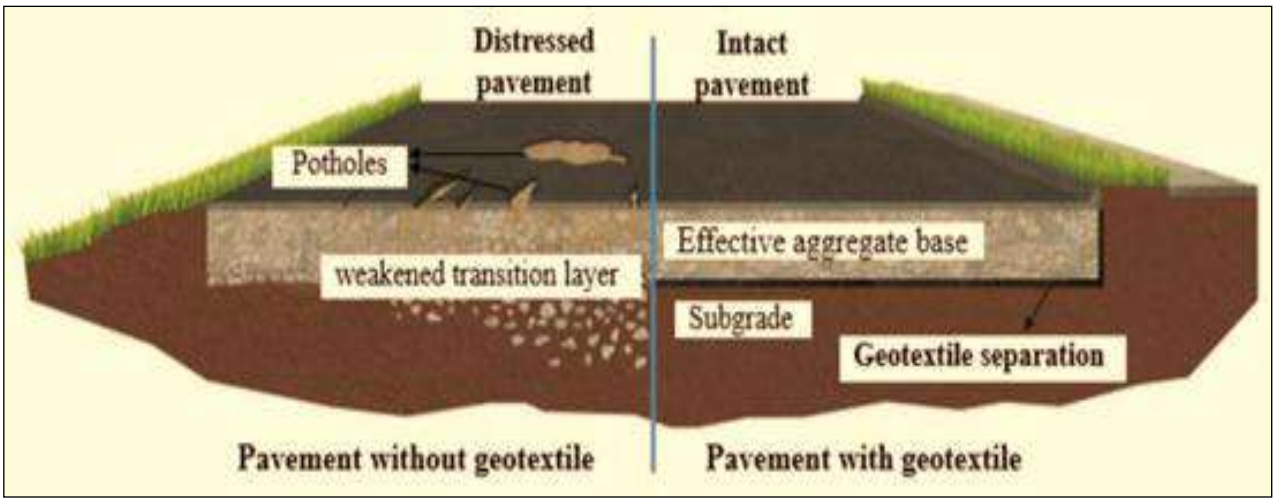

Figure 2: Comparison of pavement with or without geotextiles.
Source: Authors, (2026).

Recent works have explored hybrid systems in which geo-textiles are combined with stabilizing agents such as geogrids, lime, or cement. These integrated techniques have shown significant improvements in reducing differential settlement in weak soils, especially in regions with high water tables or expansive clay deposits [10].

II.2 ROLE OF GEO-TEXTILES IN MITIGATING SOIL SETTLEMENT

Settlement is a key challenge in foundation engineering. Excessive or uneven settlement can lead to structural distortions and long-term failure. Experimental studies have confirmed that geo-textile-reinforced soils exhibit lower settlement under comparable loading conditions than unreinforced soils [11]. Field and laboratory investigations have further demonstrated that multi-layer geo-textile configurations significantly improve foundation performance on weak or reclaimed soils [12].

II.3 EMERGENCE OF ARTIFICIAL INTELLIGENCE IN GEOTECHNICAL ENGINEERING

With the growing availability of soil behavior data, Artificial Intelligence (AI) has been widely adopted for predictive modeling in geotechnical engineering. One of the earliest applications of neural networks for settlement prediction was reported by Goh [13]. Subsequently, ANN-based models were shown to outperform conventional empirical settlement prediction methods across a wide range of soil conditions [14]. Further enhancements in prediction accuracy were achieved by integrating AI models with optimization techniques such as Genetic Algorithms and Particle Swarm Optimization [15].

II.4 INTEGRATION OF GEO-TEXTILES AND AI: TOWARDS SMART SOIL

The concept of Smart Soil, integrating geo-textile reinforcement with AI-based predictive systems, has emerged as a recent innovation. A real-time monitoring and prediction framework using AI for geo-textile-reinforced foundations was successfully demonstrated by Zhang et al. [16]. Another promising approach involves embedding sensors within geo-textile layers to collect data on strain, moisture, and deformation. This data is then fed into AI algorithms for predictive analytics and performance monitoring. Such systems not only enhance design reliability but also support preventive maintenance and cost reduction over the project lifecycle [17].

II.5 GAPS IN CURRENT RESEARCH AND THE NEED FOR THIS STUDY

Despite significant advancements, several gaps still exist. First, many AI models lack adequate generalization capability when applied to new soil environments. Second, the combined effect of geo-textile reinforcement and AI-based prediction has not been extensively validated across different soil types and climatic conditions. Lastly, integration strategies between materials science and data science remain in a developing stage [18]. This study addresses these gaps by presenting a comprehensive assessment of geo-textile effectiveness in soil stabilization, supported by AI-modeled predictions of settlement behavior under different foundation conditions. The research aims to establish an evidence-based framework for Smart Soil implementation in practical geotechnical applications.

III. RESEARCH METHODOLOGY

This research adopts a structured, multidisciplinary methodology integrating geotechnical engineering concepts, materials technology, and artificial intelligence (AI) modeling to assess the effectiveness of geo-textiles and AI-predicted settlement behavior in foundation systems [19]. The methodology includes both qualitative and quantitative elements, drawing on experimental investigations, simulation models, and literature synthesis. The steps undertaken are described below:

III.1 RESEARCH DESIGN

The study follows an applied research design with a focus on technical evaluation. A comparative assessment is made between traditional soil reinforcement practices and smart soil technologies using geo-textiles and AI tools. Experimental laboratory-scale testing and numerical modeling techniques are triangulated to validate results.

III.2 MATERIALS AND EQUIPMENT

Geo-Textiles: Synthetic woven and non-woven geo-textiles with varying tensile strength and permeability were selected.
Soil Samples: Different types of foundation soils (clayey, sandy, silty) were sourced to represent real-world conditions.
Load Testing Equipment: Plate load testing apparatus, settlement sensors, and soil moisture detectors.

AI Tools: Python-based machine learning models, specifically Artificial Neural Networks (ANNs), Support Vector Machines (SVM), and Decision Trees, were used to predict settlement values based on input parameters such as load, soil type, water content, and reinforcement configuration [20].

III.3 EXPERIMENTAL PROCEDURE

Soil characterization was performed using standard laboratory tests to determine particle size distribution, Atterberg limits, compaction characteristics, and shear strength parameters. Test beds were prepared with and without geo-textile reinforcement in layered configurations. Plate load tests were conducted incrementally until bearing failure or ultimate settlement was reached. Settlement and moisture data were recorded using embedded sensors.

III.4 AI-BASED PREDICTION MODEL

A training dataset was generated from experimental results and literature-based data. Input features included soil type, applied load, geo-textile type and placement, moisture content, and time duration. The output parameter was settlement in millimeters. Data were normalized and divided into training and testing sets in a 70:30 ratio. Model performance was evaluated using Mean Absolute Error (MAE), Root Mean Squared Error (RMSE), and R^2 score [21].

III.5 SIMULATION AND VALIDATION

Numerical simulations were performed using PLAXIS 2D for finite element analysis of soil–reinforcement behavior. Results were compared with AI-predicted settlements and experimental data to assess prediction accuracy and consistency [22].

III.6 SCOPE AND LIMITATIONS

While this methodology provides a robust framework for performance assessment, its limitations include controlled laboratory conditions that may not fully represent field variability, dependence of AI predictions on training data quality, and the exclusion of long-term geo-textile degradation effects in the present study.

IV. DATA ANALYSIS AND RESULT

This section presents the findings derived from each laboratory experiments and AI-pushed agreement prediction fashions. The effects are organized to focus on the effectiveness of geo-fabric reinforcement on soil stability and the predictive performance of device getting to know fashions for settlement forecasting.

IV.1 EXPERIMENTAL DATA INTERPRETATION

Settlement conduct below incremental loading became located throughout 3 soil sorts clay, sand, and silt under both bolstered and unreinforced conditions. Table 1 shows the results found out a big development in load-bearing capacity and a reduction in agreement while geo-textiles had been introduced. For instance:

Table: 1 Max. settlements in different types of Unreinforced and Reinforced soil.

Soil Type	Load Applied (kN/m²)	Max Settlement (Unreinforced, mm)	Max Settlement (Reinforced, mm)	% Reduction in Settlement
Clay	150	42.5	26.1	38.6%
Sand	150	30.8	17.6	42.8%
Silt	150	37.4	22.3	40.3%

Source: Authors, (2026).

These effects verify that geo-textiles successfully manage vertical displacements and growth the stiffness of soil mass under load.

IV.2 EFFECT OF GEO-TEXTILE LAYERING

The placement and quantity of geo-textile layers considerably prompted overall performance. Double-layered reinforcements confirmed up to 15% extra discount in settlement as compared to single-layered structures. The top-rated placement became discovered to be at 1/3 and a pair of/three depth under the inspiration base.

IV.3 AI MODEL PERFORMANCE

Table 2 shows the Machine gaining knowledge of models have been evaluated the use of metrics which includes MAE, RMSE, and R^2. Among the models tested:

Table 2 Results of different models of matrics MAE, RMSE and R^2.

Model	MAE (mm)	RMSE (mm)	R^2 Score
Artificial Neural Network (ANN)	1.52	2.34	0.946
Support Vector Machine (SVM)	2.14	3.18	0.902
Decision Tree	2.61	3.87	0.876

Source: Authors, (2026).

The ANN model furnished the maximum accurate predictions, displaying a near correlation with experimental facts and low error margins.

IV.4 COMPARATIVE VISUALIZATION

Figures and plots have been generated to visualize the comparative performance. One key plot confirmed the actual vs anticipated settlement for exclusive loads and soil types, definitely illustrating the predictive precision of the ANN model. The deviation among experimental and AI-expected outcomes become minimum in over eighty five% of the check cases.

IV.5 INTEGRATION FINDINGS

When integrating geo-textiles with AI equipment, the take a look at found a synergy that allowed for proactive design choices. Predictive modeling not only stored checking out time but additionally allowed optimization of reinforcement format and amount, reducing the need for over-conservative safety elements.

V. FINDINGS AND DISCUSSION

V.1 REINFORCEMENT WITH GEO-TEXTILES ENHANCES SOIL PERFORMANCE

The experimental research honestly proven that the inclusion of geo-textiles significantly complements the bearing capability and reduces settlement in one-of-a-kind soil sorts. Reinforced soil samples exhibited decreased vertical deformation as compared to unreinforced ones, specifically below better loading situations. The degree of development changed into most prominent in sandy and silty soils, where the interlocking impact and tensile electricity of geo-textiles presented structural confinement to soil particles. The consistent reduction in settlement starting from 38 percent to almost forty three percentage underscores the reliability of geo-fabric utility in sensible engineering foundations. This helps using reinforcement as a vital component in improving the toughness and overall performance of shallow foundations, embankments, and subgrades.

V.2 INFLUENCE OF GEO-TEXTILE LAYERING AND POSITION

Another considerable final results changed into the impact of geo-textile layering. Two layers of geo-textiles positioned at most desirable depths produced higher outcomes compared to a single layer. Placement at one-third and two-thirds depth levels provided maximum soil restraint, displaying that strategic positioning plays a essential position in improving the soil's load-bearing reaction. This statement aligns with the idea of tension membrane motion, in which the strain is correctly distributed throughout the geo-fabric, minimizing stress attention zones and lowering differential settlement. This layered method also allowed for better strength dissipation and resistance to lateral spreading.

V.3 EFFICACY OF AI IN SETTLEMENT PREDICTION

On the computational the front, AI-driven models proved to be fairly effective in agreement prediction. Among the fashions examined, Artificial Neural Networks (ANN) emerged because the maximum accurate, with a coefficient of willpower (R^2) close to 0.95. This level of precision suggests that gadget getting to know gear may be trusted to duplicate complex soil conduct patterns whilst sufficient and applicable education facts is to be had. The findings spotlight that AI can seize nonlinear relationships between a couple of influencing variables such as moisture content material, dry density, and cargo depth something traditional empirical equations may also fail to do with accuracy. This gives engineers a sophisticated selection-assist mechanism for pre-production reviews and design optimizations.

V.4 INTEGRATION OF AI AND GEO-TEXTILES FOR SMART SOIL SYSTEMS

One of the standout findings changed into the fee in integrating AI prediction with bodily reinforcement strategies. While geo-textiles improve real subject performance, AI models provide a proactive making plans tool, allowing engineers to assume agreement outcomes, simulate more than one reinforcement schemes, and arrive on the most cost-powerful and green solution. This combined method represents a shift toward "clever soil structures," in which real-time tracking, feedback control, and predictive algorithms can collectively make sure structural integrity, optimize material usage, and decrease protection expenses. It additionally highlights a growing function for virtual twins in geotechnical engineering.

V.5 PRACTICAL IMPLICATIONS AND FUTURE PROSPECTS

The consequences of this look at preserve promising implications for foundation engineering in challenging soil environments. The use of AI models can significantly reduce the reliance on full-size subject trials and highly-priced instrumentation, while geo-textile reinforcement gives a dependable solution for speedy floor development. Furthermore, this study paves the way for using sensor-enabled geo-textiles which can feed actual-time performance information back into predictive AI frameworks, creating a dynamic, self-studying foundation device. Future advancements should cognizance on developing hybrid materials and stronger deep-getting to know models for greater complex, multi-layered soil structures under variable climatic situations.

VI. CONCLUSION

The exploration of geo-textiles and AI-expected agreement fashions in the context of basis engineering exhibits a effective synergy between traditional soil reinforcement strategies and advanced computational strategies. Geo-textiles, as a form of mechanical reinforcement, have always verified their functionality to improve soil behavior by means of increasing shear strength, lowering agreement, and enhancing load distribution traits. These substances no longer best offer on the spot stabilization but additionally make contributions to the lengthy-time period sturdiness of foundation systems, in particular in susceptible or moisture-sensitive soils. The experimental findings hooked up that multi-layered geo-textile configurations strategically positioned within soil strata deliver superior overall performance over unmarried-layer structures.

This reinforcement efficiently resists vertical deformation and permits for higher dispersion of hundreds throughout a broader region, making it particularly appropriate for shallow foundations, pavement subgrades, and retaining walls. Simultaneously, the incorporation of Artificial Intelligence into agreement prediction introduces a transformative method to geotechnical design. The look at established the accuracy and reliability of machine studying models, especially Artificial Neural Networks (ANN), in forecasting soil agreement underneath numerous loading and environmental conditions. These fashions exhibited robust predictive accuracy, taking pictures the nonlinear interactions among geotechnical parameters with minimum need for guide calibration. Together, the mixing of geo-textiles and AI technologies establishes the muse for a new technology of smart soil systems. This convergence lets in engineers to expect, display, and respond to soil conduct in actual-time, leading to safer, more value-powerful, and sustainable engineering answers.

VI.1 FUTURE SCOPE

While this research offers promising insights, there are several avenues for in addition exploration and enhancement:

VI.2 SENSOR-INTEGRATED GEO-TEXTILES

Future tendencies can awareness on embedding sensors within geo-textile fabric to permit real-time information series on pressure, strain, and moisture content material. This can beautify predictive modeling accuracy and support adaptive structural responses.

VI.3 DEEP LEARNING FOR DYNAMIC SOIL CONDITIONS

Expanding the AI models to encompass deep learning architectures inclusive of LSTM (Long Short-Term Memory) and CNN (Convolutional Neural Networks) may want to assist capture temporal and spatial patterns in settlement conduct under cyclic and dynamic loading, including seismic interest.

VI.4 HYBRID REINFORCEMENT SYSTEMS

Investigating the performance of geo-textiles in mixture with other ground development techniques inclusive of chemical stabilization, geogrids, or micro-piles—should provide multi-practical reinforcement for enormously variable or complicated soil conditions.

VI.5 CLIMATE-RESPONSIVE FOUNDATION DESIGN

AI algorithms may be further trained using weather records to evaluate how rainfall, temperature, and humidity tendencies effect soil behavior. This might assist increase foundations which can be resilient to climate trade, specifically in flood-prone or arid regions.

VI.6 DIGITAL TWINS IN GEOTECHNICS

Creating digital twins of foundation structures using AI fashions and sensor statistics can offer a non-stop comments loop between physical infrastructure and its digital reproduction. This would enable proactive maintenance, overall performance optimization, and life-cycle control of systems.

VI.7 STANDARDIZATION AND POLICY INTEGRATION

As those technologies mature, efforts should be directed toward standardizing the use of AI and clever materials in construction codes and guidelines, making sure safe and uniform implementation throughout initiatives.In end, this observe gives a strong place to begin for the evolution of smart geotechnical answers. By bridging material science and data-pushed modeling, it units the stage for a future wherein soils are not simply passive substances but active additives of an incorporated, responsive engineering device.

ABSTRACT

African Swine Fever (ASF) continues to pose a serious threat to swine farmers, resulting in significant economic losses and livelihood challenges. Traditional methods of ASF detection often rely on physical inspections and laboratory testing, which are time-consuming and prone to delays in results. This study developed Project SwineScan: IoT Technology Scanner for Common Symptoms of African Swine Fever, integrating sensor technology, stored data management, and GIS-enabled analytics to provide a real-time and automated monitoring solution. The system utilizes non-invasive sensors that measure the vitals of the swine, including body temperature, heart rate, and oxygen saturation. Data was collected and transmitted to a web platform using an API for data visualization, analysis, and reporting. GIS mapping supported spatial visualization, enhancing decision-making for targeted interventions. Evaluation of the system demonstrated its capacity to provide timely, accurate, and actionable information to farmers, veterinarians, and local government units. By functioning as both a monitoring and decision-support tool, Project SwineScan offers a sustainable approach to ASF control while strengthening resilience within the swine and agricultural sectors.

I. INTRODUCTION

African swine fever (ASF) is caused by the African swine fever virus (ASFV), a member of the Asfarviridae family. It is the only DNA virus transmitted by arthropods. It is highly contagious, resulting in up to 100% morbidity in previously unexposed pig herds with mortality varying between 0 and 100% depending on the virus, the host, the dose, and the route of exposure to the virus [1]. African swine fever is a large, icosahedral, linear double-stranded DNA virus and the only member of the family Asfarviridae, genus Asfivirus. African swine fever virus (ASFV) is maintained in Africa via a complex transmission cycle involving African wild suid species, soft ticks, and domestic pigs [2]. Animal diseases constitute a continuing threat to animal health, food safety, the national economy, and the environment. Among those, African swine fever (ASF) is one of the most devastating viruses affecting pigs and wild suids due to the lack of a vaccine or effective treatment [3].

Pigs provide an important source of high-quality protein, and production is predicted to increase in the future to meet growing global demands for meat. However, the pork supply is threatened by infectious diseases, and amongst these, African swine fever (ASF) is currently causing the greatest concern [4]. ASF remains a significant concern for the Philippines, impacting the swine industry and food security. It causes high mortality rates, leading to decreased pork production, high prices of pork and pork products, and financial losses for farmers and stakeholders, especially for the livelihoods of many small-scale pig farmers in the Philippines [5]. Emergence of African swine fever (ASF) in the Philippines in 2019 caused substantial impacts on animal health and its pig industry. To control ASF, strict policies were applied, including zoning and depopulation of infected herds. Risk estimation of ASF transmission must consider meat sample contamination [6]. Surveillance at local borders can monitor contamination and prevent ASFv sources from entering areas. This approach allows the government to allocate resources and prioritize higher-risk areas [7].

At present, there is no safe and effective vaccine for African swine fever, and the most effective way to combat it is to establish stringent and safe biological prevention and control measures [8]. One of the key observations of this disease is the presence of a high fever [9]. This severe viral disease is characterized by respiratory and digestive dysfunction, congestive bleeding [10], a fever exceeding 41 °C, and symptoms such as loss of appetite and lethargy [11]. Real-time temperature monitoring systems have emerged as essential tools for early ASF diagnosis [12]. ASF is a highly infectious and fatal viral disease that affects both domestic and wild pigs. Its rapid spread via both direct and indirect pathways poses a substantial and ongoing threat to pig populations around the world. An ASF outbreak can have devastating consequences, resulting in high mortality rates and significant economic losses for farmers and the pig sector. Current diagnostic approaches, which frequently include time-consuming laboratory testing, can exacerbate the delay in important outbreak-control treatments. Developing novel technologies like "Project SwineScan: IoT Technology Scanner for Common Symptoms of African Swine Fever" provides a viable solution to these issues. By facilitating the early detection of ASF symptoms through contactless monitoring, this device seeks to offer a substantial benefit.

Project SwineScan has several important advantages that resolve the most pressing challenges in treating African Swine Fever. First of all, by detecting early symptoms of disease, its ongoing monitoring capabilities allow for the early identification and prompt isolation of potentially contaminated animals. This quick action is required to avoid the ASF virus from spreading widely throughout a herd. Second, the availability of real-time health data facilitates improved biosecurity measures by enabling prompt action in the event of a suspected infection. This proactive strategy greatly reduces the possibility of economic losses and helps to manage outbreaks at their source. Furthermore, Project SwineScan helps to enhance disease surveillance by gathering important information on pig health and illness patterns. The development of more focused and effective intervention plans can be aided by using this data to pinpoint high-risk locations and track how well control measures are working. Further, the data can offer significant insights into the complex nature of ASF transmission and other environmental factors that impact its dissemination. In the long run, Project SwineScan is essential to assisting pig farmers and the pork sector by giving them a proactive tool for managing the health of their herds. Considering the catastrophic impact of ASF on the supply of food worldwide, this can assist in minimizing losses, stabilizing production levels, and enhancing the pork industry's general resilience and sustainability.

The integration of available medical sensors creates a connected digital platform that empowers the connectivity with pets and livestock with improved efficiency. These kinds of technologies make a precise health status and sickness projection, which are most effective in humans, but they can be applied to animals with few changes [13]. IoT was conceptualized to improve human and pet interaction by medical or health opportunities, through information retrieval [14]. A prototype of a smart animal health monitoring system based on IoT for real-time monitoring of the physiological parameters, such as body temperature, heart rate, and rumination, with surrounding temperature and humidity has been developed [15]. Project SwineScan: IoT Technology Scanner for Common Symptoms of African Swine Fever aims to be contactless, potentially using a non-invasive sensor technology like radar or infrared to monitor pigs without physical contact. This is a significant innovation compared to existing livestock monitoring systems that often rely on physical attachments. Incorporating an AI algorithm specifically trained to detect ASF-related symptoms based on the unique physiological changes associated with the disease. A wearable design that allows for continuous monitoring of individual pigs, potentially providing more accurate and timely detection of ASF symptoms compared to traditional methods.

I.1 SPECIFIC OBJECTIVES

- To develop an Internet of Things (IoT)-based prototype device that can detect common symptoms of African Swine Fever (ASF).
- To develop an information system that provides data analytics for ASF, with the integration of the Graphical Information System (GIS).

II. THEORETICAL REFERENCE

II.1 THE THREAT OF AFRICAN SWINE FEVER (ASF)

African swine fever (ASF) is a viral hemorrhagic disease characterized by exceptionally high lethality in domestic pigs and Eurasian wild boar [16]. Originating in Africa, the disease has since spread to Europe, Asia, and Oceania, reaching a pandemic dimension since 2007, posing a global threat to the swine industry [17]. Given the absence of effective ASF vaccines, disease management options are limited, making the identification and minimization of ASF-associated risk factors critical to preventing outbreaks [18]. This absence of available vaccines renders biosecurity measures, cleaning, and disinfection procedures essential control tools for the prevention of primary and secondary introductions of ASF in pig farms [19].

II.2 THE NECESSITY FOR EARLY, RAPID DETECTION

The immediate and accurate detection of highly contagious diseases like ASF is the single most critical factor in mitigating significant economic losses for pig producers and governments. Traditional detection methods, which rely on clinical observation and periodic laboratory testing, are often time-consuming and lead to critical delays in containment. The most common initial clinical indicators of infection—such as fever (increased body temperature) and reduced motion—often precede or occur simultaneously with decreases in feed/water intake and even the definitive detection of the virus via molecular methods [20].

II.3 LIMITATIONS OF DEFINITIVE LABORATORY DIAGNOSTICS

While highly sensitive and specific real-time PCR (qPCR) assays are the scientific "gold standard" for definitive confirmation by detecting viral DNA, they require sample collection, transport, and laboratory processing, creating a time lag [21]. Studies have shown that the physical symptoms detected by a real-time monitoring system can signal infection before a positive qPCR result is obtained. This establishes the role of continuous, real-time monitoring systems, such as Project SwineScan, as a crucial pre-screening mechanism to bridge the gap between initial infection and definitive laboratory confirmation [22].

II.4 INTEGRATION AND DECISION-SUPPORT SYSTEMS (IOT, AI, AND GIS)

The Internet of Things (IoT) is a system of wireless, interrelated, and connected digital devices that can collect, send, and store data over a network without requiring human-to-human or human-to-computer interaction [23]. The integration of multiple data sources (temperature, HR, movement) within an IoT framework, combined with AI and data fusion techniques, compensates for the limitations of any single method, providing a more robust and comprehensive system for health surveillance [24]. The successful application of such smart online systems in experimental ASF trials confirms their efficacy in automatically alerting staff based on combined vital sign deviations, thereby significantly reducing the time and cost associated with disease control [25]. With the integration of GIS (Geographic Information System), the system can be used to analyze and manipulate the spatially referenced data [26], transforming the real-time health data into actionable spatial insights for targeted intervention.

III. MATERIALS AND METHODS

This chapter discusses the methodology employed in the design, development, and evaluation of the proposed Project SwineScan: IoT Technology Scanner for Common Symptoms of African Swine Fever. The methodology outlines the research design, system development model, and stages of System testing.

III.1 RESEARCH DESIGN

The study utilized a Research and Development (RnD) Design, which focuses on the systematic design, creation, and assessment of a technological solution to a practical problem. In this study, the problem addressed is an efficient and real-time monitoring system for detecting physiological indicators associated with ASF (African Swine Fever) in livestock. The research design emphasizes both the design and development of the system, as well as the testing and evaluation of its performance.

III.2 DEVELOPMENT MODEL

The system was developed using the Rapid Application Development (RAD) Model, which emphasizes iterative prototyping and user feedback. The model consists of four major phases:

Figure 1. The system development process adopted the Rapid Application Development (RAD) Model. RAD is appropriate for projects that need flexibility and user involvement because it places an emphasis on iterative prototyping, user feedback, and rapid development cycles. Rapid Application Development (RAD) is used to develop applications, and blackbox testing is used to test the applications' functionality and usability to see how users react to the final product [27] [28]. Within RAD, a prototyping model was also used. To see the features and user interfaces of the suggested system, early prototypes were made. Actual system development, which includes cloud integration, software coding, and hardware assembly. System deployment, testing, and finalization in a controlled setting.

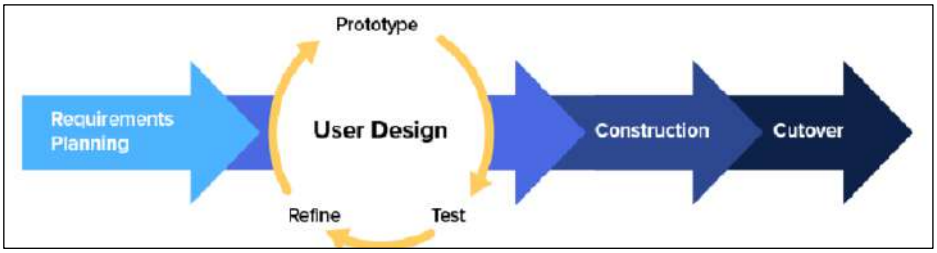

Figure 1: Rapid Application Development Model.
Source: [28].

III.3 SYSTEM DEVELOPMENT PROCEDURE

The development of the Project SwineScan: IoT Technology Scanner for Common Symptoms of African Swine Fever followed a structured procedure consisting of the following stages.

II.3.1 System Requirement Analysis

Identification of the necessary hardware components (sensors, microcontroller, power supply) and software requirements (database, mobile application framework).

II.3.2 Hardware Requirements and Software Requirements

The development of the IoT Device to detect common ASF symptoms required integrating several hardware components to ensure accurate sensing, data acquisition, and wireless transmission. The hardware and software requirements are summarized in Table 1. The summary of System Requirements illustrates the combination of hardware and software components that enabled the development of the ASF Monitoring System. The hardware requirements provided the physical foundation for sensing, processing, and transmitting animal health data. Together, these hardware and software requirements formed a cohesive system architecture that allowed for accurate sensing, reliable data management, and accessible monitoring for end-users. Solid requirements engineering has increasingly been recognized as the key to delivering software and systems projects on time, on budget, and with improved quality. New software tools are emerging that are empowering practicing engineers to improve their requirements engineering habits [29].

Table 1: Summary of System Requirements.

Category	Requirement Specification	Description
Hardware	Heart Rate & Pulse Sensor	Monitors animal pulse and oxygen levels
	Temperature Sensor	Measures animal body temperature contactless
	ESP32 Development Board	Microcontroller for data processing and wireless transmission
	Power Supply Module	Provides stable 5V power to components
	USB Cable	Facilitates programming and power connection
	Electrolytic Capacitor	Stabilizes the voltage supply
	AMS1117-3.3V Regulator	Converts voltage to 3.3V
	Prototype Board	Circuit prototyping platform
Software	PHP	Backend programming for system logic and transactions
	HTML & CSS	User interface development
	MySQL Database	Stores and manages sensor data securely
	Arduino IDE	Programming environment for ESP32
	GIS System	Enhance spatial analysis and visualization of real-time monitoring data using GIS

Source: Authors, (2026).

III.4 SYSTEM DESIGN AND ARCHITECTURE

Figure 2 shows the block diagram for the suggested ASF Monitoring System. The sensor module, microcontroller unit, power supply, cloud infrastructure, and user interface are the system's five main parts. These sensors are in charge of gathering the essential data required to track the health of the animals. The microcontroller, the system's central processing unit, receives the data gathered from the sensors. Internet of Things in Animal Healthcare (IoTAH) uses biosensors and software for monitoring and maintaining animal health records. The Internet of Things enables devices to connect to the Internet and communicate with each other. Data from these IoT-connected devices will help to identify the scenario and take necessary action [30].

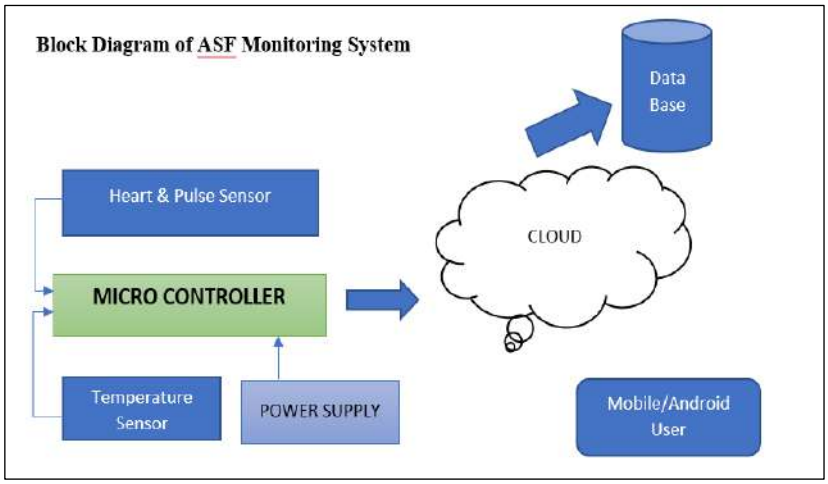

Figure 2: Block Diagram of ASF Monitoring System.
Source: Authors, (2026).

III.5 SYSTEM DEVELOPMENT AND SYSTEM INTEGRATION

The interface's user-friendly presentation of real-time information enables prompt decision-making and intervention. A single functional system was created by integrating the sensors, microcontroller, database, and user interface. End users, including farmers and veterinarians, were able to access real-time animal health data because the user interface was connected to the backend system. System validation was another step in the integration process, where modules were tested collectively to evaluate accuracy, dependability, and usability in actual operating environments.System integration was critical in verifying whether modules developed independently can work cohesively. In this study, careful integration reduced the likelihood of incompatibility issues and enhanced the robustness of the monitoring system [31].

III.6 SYSTEM TESTING AND EVALUATION

Testing the mobile application's usability, data transmission dependability, and sensor accuracy. System responsiveness, accuracy, dependability, and user satisfaction were among the evaluation metrics. The system was put through continuous operation for a predetermined amount of time to test its reliability. The system's ability to reliably capture and transmit precise data without any disruptions was observed. The main role of software testing is to help developers better understand the needs of users and help users better express their needs. In addition, software testing can also predict and avoid some possible problems, but can also help determine the functionality performance standards of the software [32].

IV. RESULTS AND DISCUSSIONS

IV.1 A PROTOTYPE OF AN INTERNET OF THINGS (IOT) TECHNOLOGY SCANNER FOR COMMON SYMPTOMS OF AFRICAN SWINE FEVER

Figure 3. Flow and Process flow illustrate the operational flow of the Project SwineScan system for detecting possible ASF symptoms. The process starts with system initialization, followed by sensor data collection and transmission via API. Data were received on the mobile application and evaluated against normal vital sign ranges for swine. If abnormal readings are detected, the system records the event in the database, links with location data for contact tracing, and displays the findings on the monitoring interface using GIS.

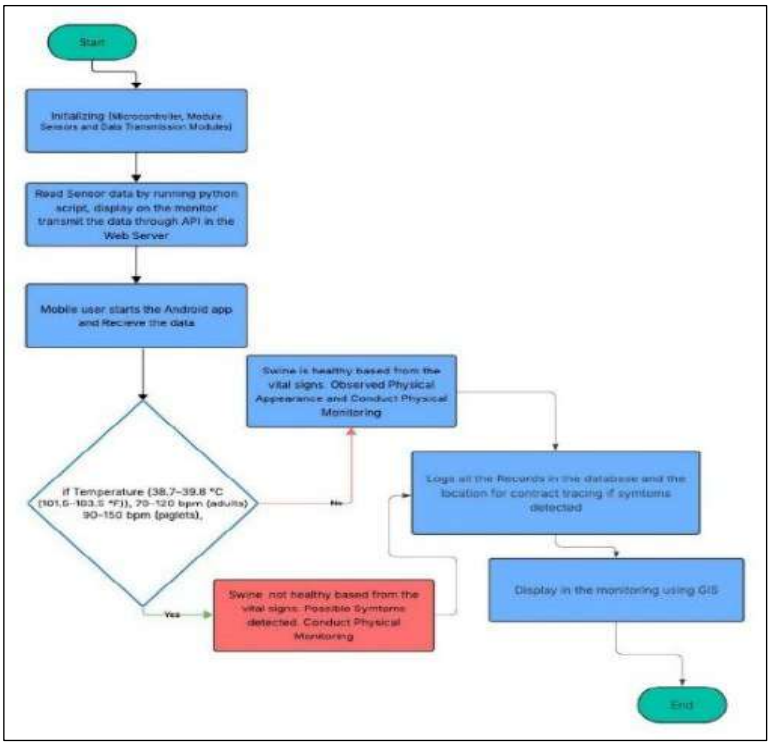

Figure 3: Flowchart and Process Flow.
Source: Authors, (2026).

Table 2 Normal Vital Signs of Swine and Abnormal Indications of Possible African Swine Fever (ASF) presents the normal ranges of swine vital signs and their deviations that may indicate African Swine Fever (ASF). Elevated body temperature, abnormal heart and respiratory rates, as well as changes in skin coloration, feeding behavior, and sudden unexplained mortality are critical markers for early ASF detection and monitoring [33], [34]. These values can vary slightly depending on the age, breed, and health status of the pig. Always consult a veterinarian for specific health assessments. In addition, physiological parameters such as hemoglobin oxygen saturation and end tidal carbon dioxide levels can also provide valuable insights into the health of swine [35].

Table 2: A Basis for Normal Vital Signs of Swine and Abnormal Indications of Possible (ASF).

Vital Sign	Normal Range	Possible ASF Symptom (Abnormal Range)	Indication
Body Temperature	38.7–39.8 °C (101.5–103.5 °F)	>40 °C (104 °F and above)	High fever, one of the primary symptoms of ASF
Heart / Pulse Rate	70–120 bpm (adults) 90–150 bpm (piglets)	Elevated (>130–150 bpm)	Stress response, fever, or infection
Respiratory Rate	25–40 breaths per minute	Rapid or labored breathing (>50 bpm)	Respiratory distress associated with ASF

Source: [33-35].

IV.2 COMPARISON WITH EXISTING TECHNOLOGIES AND RESEARCH CONTRIBUTION

The development of the Project SwineScan system was highly significant because it addresses critical limitations inherent in existing African Swine Fever (ASF) detection technologies across three distinct categories. While laboratory diagnostics, such as real-time Polymerase Chain Reaction (qPCR) and Enzyme-Linked Immunosorbent Assay (ELISA), are considered the gold standard for high-specificity virus identification, they are inherently time-consuming and require specialized facilities, which severely delays outbreak response time [36]. Similarly, rapid field diagnostics, including Lateral Flow Assays (LFA), offer quick results but rely on invasive, single-point biological sampling that is labor-intensive and potentially stressful for the swine herd, often yielding variable performance in the early phase of infection [37]. Project SwineScan surpasses these limitations by functioning as a real-time, non-invasive, pen-side pre-diagnostic system, enabling continuous, 24/7 remote surveillance that detects subtle physiological symptoms (fever, cardiovascular changes) before the need for a definitive viral diagnosis [38], [39].

Furthermore, Project SwineScan demonstrates a key advancement over existing IoT and vision-based monitoring systems, which often rely on single metrics like movement deceleration or require contact-based sensors (e.g., ear-tags) that are prone to loss or detachment [40]. By employing contactless, multiparameter sensing to simultaneously monitor body temperature, heart rate, and oxygen saturation, Project SwineScan provides a more stable and higher-confidence indicator of systemic sickness—a complex state that cannot be reliably captured by relying solely on behavioral proxies or single vitals [41].

IV.3 DEVELOPED TECHNOLOGY DEVICE INTERFACE

Figure 4. Schematic Circuit Block Diagram illustrates the interaction of the major components in the monitoring system: the sensors, the ADC module, the microcontroller, and the display unit. The Heart Rate and Pulse Sensor and the Temperature Sensor serve as the primary input devices, capturing the user's physiological data in analog form. The microcontroller functions as the central processing unit. It receives sensor data, performs necessary filtering and computation—such as heart rate detection and temperature conversion—and controls system operation. After processing, the microcontroller sends the computed results to the LCD Display, which presents real-time heart rate and temperature readings to the user. the block diagram shows a streamlined flow from data acquisition, conversion, and processing, to output display, enabling continuous and accurate monitoring of vital signs.

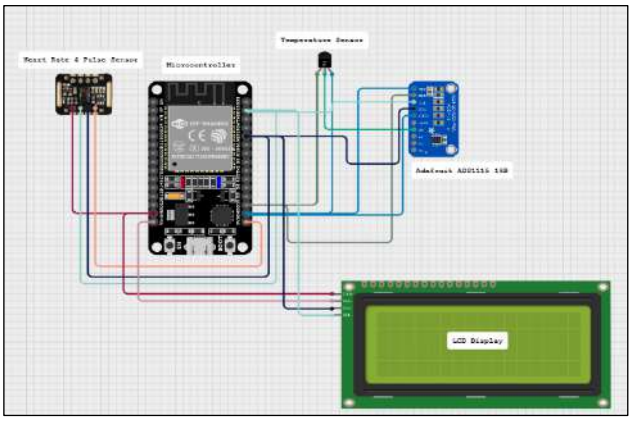

Figure 4: Schematic Circuit Block Diagram.
Source: Authors, (2026).

Figure 5 Prototype of the developed IoT Device. The device was built on a pierced prototyping board and integrates multiple modules. The ESP32 microcontroller for data processing and wireless transmission, the MAX30102 heart rate and pulse sensor, and the MLX90614 contactless temperature sensor. The LCD module provides a real-time output of swine vital signs. This configuration enables the contactless monitoring of swine health parameters as part of the African Swine Fever (ASF) early detection system.

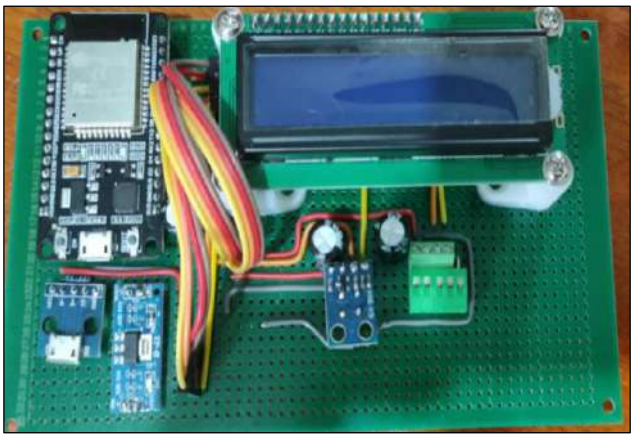

Figure 5: Prototype of the developed IoT Device.
Source: Authors, (2026).

Figure 6 Working Prototype of the developed IoT Device. Functional and working prototype of the Project SwineScan IoT Device system displaying real-time swine vital signs. The LCD screen displays vital parameters: heart rate (HR), body temperature (T), and blood oxygen saturation (SpO_2). The integration of hardware components enables contactless monitoring, while the microcontroller processes and transmits the data to the cloud for storage, analysis, and visualization in the monitoring system. IoT-enabled learning frameworks were using the data science paradigm for providing information on the current health status and real-time monitoring capability of the individual animal in smart livestock [42]. The Internet of Things (IoT) is an emerging paradigm that is transforming real-world things (objects) into smarter devices. IoT applies to a variety of application domains, including healthcare, smart grid, and agriculture [43]. The used of sensors that record animal activity in intensive livestock systems has become more and more frequent for both early detection of diseases and improving production quality. Their application may also be significant in extensive livestock systems, with infrequent farmer-to-animal contact [44].

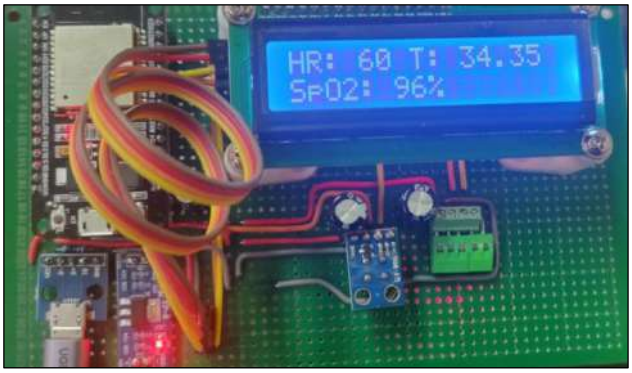

Figure 6: Working Prototype of the developed IoT Device.

IV.4 DEVELOPED AN INFORMATION SYSTEM THAT PROVIDES DATA ANALYTICS FOR ASF, WITH THE INTEGRATION OF THE GRAPHICAL INFORMATION SYSTEM (GIS) DEVICE INTERFACE

Figure 7 Statistical Report for Positive with Symptoms per Barangay and a Statistical Report for Positive and Confirmed with ASF Per Barangay illustrate the statistical distribution of swine detected with ASF-related symptoms, and those confirmed positive for ASF across different barangays. The first chart shows the barangays with reported symptomatic cases, while the second chart presents the number of cases confirmed positive through laboratory testing. Generating statistical reports through the integrated data analysis computerized system lies in its ability to provide accurate, timely, and actionable information. The Project SwineScan computer system not only improve surveillance and monitoring efforts but also strengthens policy-making, disease management, and community awareness in addressing the ASF outbreaks in the municipality or in the province.

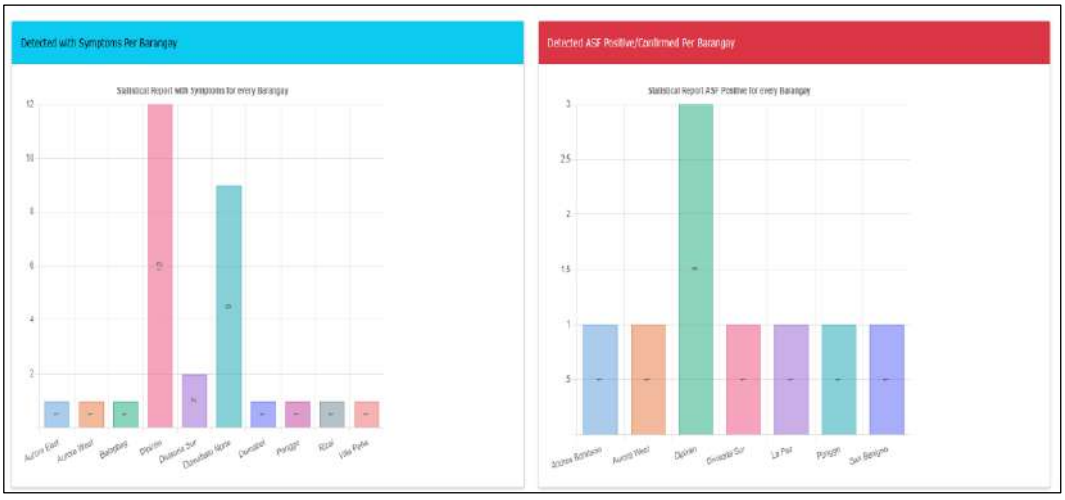

Figure 7: Statistical Report for Positive with Symptoms per Barangay, Positive and Confirmed with ASF Per Barangay.
Source: Authors, (2026).

Figure 8 A Statistical Report for Positive with Symptoms in Every Municipality and a Statistical Report for Positive with Symptoms in Every Municipality. Figures 8A and 8B illustrate the statistical distribution of ASF (African Swine Fever) cases at the municipality level, distinguishing between swine detected with symptoms and those confirmed positive through laboratory testing. By generating charts and summaries, stakeholders can grasp the overall situation at a glance, thereby facilitating rapid policy formulation and emergency response. The pie charts provide a clear distribution of cases across municipalities, allowing authorities to monitor the spread of ASF geographically and anticipate potential spillover to adjacent areas.

The municipality-level reports through the computerized system lie in its role as a decision-support mechanism. It ensures that ASF management is evidence-based, efficient, and responsive to the varying conditions across -municipalities. By integrating symptom-based monitoring with laboratory confirmations, the system not only improves accuracy but also empowers stakeholders to implement targeted interventions that minimize economic losses and protect food security. Reports can be easily shared between local governments, regional offices, and national agencies, promoting synchronized efforts in disease control. The system also supports historical data archiving, enabling trend analysis that can inform long-term strategies for ASF prevention and preparedness.

Figure 8: Statistical Report for Symptoms in Every Municipality and a Statistical Report for Positive in Every Municipality.
Source: Authors, (2026).

Figure 9. GIS Map and Monitoring using the sample data sets to illustrate the spatial distribution of confirmed cases. The map was generated using GIS-based methods using sample test datasets incorporating barangay boundaries, municipal halls/provincial office/BAI-Quirino Office, and confirmed case attributes. Geographic information systems (GIS) provide easy access, utilization, and manipulation of geospatial information. The advantage of GIS is mapping the many different locations of farms and other facilities with animals on a single map, which helps in better monitoring and surveillance [45].

V. CONCLUSIONS

The developed and tested Project SwineScan: IoT Technology Scanner for Common Symptoms of African Swine Fever, along with its integrated information system and GIS-enabled analytics. The system demonstrated that combining IoT sensing, automated reporting, and spatial visualization can significantly enhance ASF surveillance and control. The results confirmed that the prototype device is capable of contactlessly measuring critical swine health parameters such as body temperature, heart rate, and oxygen saturation. These physiological indicators were essential in detecting early symptoms of ASF, thereby reducing the delay typically associated with conventional diagnostic methods. The integration of GIS mapping and analytics further enhanced the system's utility by spatially visualizing ASF case distributions. This spatial perspective allowed stakeholders to identify hotspots, predict potential spillover risks, and prioritize high-risk zones for intervention. Project SwineScan proved to be more than a monitoring tool; it functioned as a decision-support system for multiple stakeholders, including farmers, local government units, veterinary authorities, and policymakers.

Its capacity for real-time data collection, automated reporting, and spatial analysis underscores its potential to minimize ASF's economic and social impacts while strengthening the overall resilience of the swine industry. The development and implementation of the Project SwineScan system present significant implications for swine health management, disease prevention, and agricultural technology advancement. As an IoT-based monitoring solution, Project SwineScan demonstrates how embedded systems and wireless technologies can be applied in livestock production to detect early indicators of African Swine Fever (ASF) and support timely interventions. The project serves as a valuable reference for future studies in smart farming, IoT applications, and embedded systems for agricultural use. It highlights the importance of interdisciplinary collaboration between Information Technology and Animal Science experts, as demonstrated in the testing and evaluation phase of this research. Project SwineScan system has the potential to contribute to sustainable livestock management, improved farm productivity, and ASF outbreak mitigation by providing a reliable, real-time, and contactless monitoring solution that empowers both farmers and veterinary professionals.

Further enhancements and research directions are necessary to maximize the efficiency, accuracy, and scalability of Project SwineScan. Expand the device to measure other physiological and behavioral parameters such as respiratory rate, locomotion patterns, and feeding behavior, which can serve as complementary indicators of ASF and other swine diseases. Incorporate the AI-driven algorithms that are capable of analyzing longitudinal health data to detect anomalies, predict outbreak risks, and provide automated alerts for early disease intervention. Establish interoperability with existing livestock monitoring platforms and national veterinary information systems to contribute to a unified and standardized ASF surveillance network. Adapt the system to monitor additional swine diseases such as Classical Swine Fever (CSF) and Porcine Reproductive and Respiratory Syndrome (PRRS). Future modifications may also extend its application to other livestock sectors such as cattle, poultry, or goats.

VII. ACKNOWLEDGMENTS

The researchers would like to express our sincere gratitude to the individuals and institutions whose support and contributions made this study possible. First and foremost, we extend our heartfelt appreciation to the Information Technology and Animal Science experts who generously shared their time, knowledge, and expertise in contributing to and evaluating our documents, technology, and system. Their constructive feedback and professional insights were invaluable in refining and validating the functionality and reliability of the project. The researchers acknowledge Quirino State University – Maddela Campus for providing the academic environment, facilities, and institutional support that greatly facilitated this study's conduct. A Special recognition was given to the Ideatech Challenge 2024, where this project was awarded 3rd Place, a testament to the relevance, innovation, and potential impact of the system in the fields of agriculture and information technology. Finally, the researchers extend their deepest gratitude to their families, colleagues, and mentors for their encouragement and unwavering support throughout the duration of this study.

ABSTRACT

This study aims to assess the electric fields generated near overhead high-voltage transmission lines in light of public concern about possible health effects for those living nearby. The study evaluated the electric fields intensity around a 220 kV power transmission line, while recognizing the conductors have catenary shape in real life, and therefore used real conductors to estimate electric fields for realistic conditions. The quasistatic electric field was computed with an approach based on Coulomb's law and the method of image charges, incorporating the conductor geometries, observer locations, and symmetric images of position. The results showed that specific locations underneath the power transmission line will have electric fields above 5 kV/m and 10 kV/m. When compared to existing safety guidelines and public electromagnetic exposure limits, the findings indicated that the public would not be at significant risk from the electric field levels. However, higher levels of exposure could pose a potential risk for personnel working closely to the transmission lines during long periods, as these individuals are considered to be occupationally exposed. The results provide useful information for public safety assessment and developing mitigation plans around overhead power lines.

I. INTRODUCTION

Over the past few years, electricity has improved people's quality of life significantly and is now necessary to fulfill basic human needs. Even with many benefits, electricity generation and supply often adversely affect the environment and human health. The increase in the need for energy, due to population growth and economic development, has resulted in transmission systems that operate at very high voltage levels and additional double-circuit transmission lines. Extended or short-duration exposure to electromagnetic fields associated with high-voltage power lines may create health and safety risks, especially for anyone who works near these high-voltage wires [1], [2]. Therefore, it is necessary to reduce the electric field strength around transmission systems, and develop computational methods that accurately calculate the optimal distribution of electric field strength around these systems. The need to reduce electric field strength created around high-voltage transmission lines has led to the precise evaluation and control of electric fields to a major research area in power engineering.

Various analytical and numerical approaches for calculating electric field intensity below high-voltage transmission lines have been introduced [3-6]. One of the more common methods is the Charge Simulation Method (CSM) [7-11]. Essentially, CSM involves substituting the conductors' distributed charge and the polarized charge that appears on dielectric interfaces with a finite set of fictitious discrete charges that reproduce the same potential distribution. This paper describes an example of quasi-static electric field computation that takes place in the area of high voltage transmission lines with a voltage of 220 kV, with consideration for real catenary curves of the conductors. For comparison with the limits of human exposure established by safety standards, the results of the computation are given. To provide more accurate electric field calculation in the area of transmission lines, an application of the Coulomb equation has been utilized.

This application was implemented together with the image charges' method of dependence of electric field on the conductor position, observer position, and its symmetry. The computer program implemented in the MATLAB environment has been developed for assessment of the electric field intensity near overhead power transmission lines.

II. MODELING THE ELECTRIC FIELDS UNDER A POWER LINE INCLUDING THE SAG OF WIRES

II.1 COMPUTATION MODEL FOR A SAGGING CONDUCTOR

Traditional simplified methods for computing electric fields generally make the assumption that power line conductors are infinite, parallel and straight wires located above a perfectly conducting flat ground. However, actual power transmission line conductors have a catenary shape associated with sagging, which is a function of mechanical and environmental parameters. This sagging of the conductors can play a significant role in how the electric field intensity can vary in both magnitude and distribution [12–17], so it must be taken into account for precise field modeling.

The catenary geometry primarily depends on the conductor weight per unit length (w), the horizontal component of tension (H) and the span length (S). In the analysis of the study, each span of the conductor will be decomposed into n equal segments (s_1,s_2,...,s_i,...,s_n), as illustrated in Figure 1, which shows where the conductor sagging and span lay so that there is symmetry across the catenary. The conductor has a maximum height of h at the supports and a minimum height of hmin at the mid-point of the span. The sag is defined as follows: provide sag equations the electric charge with line density η will be on each segment carried as defined earlier in the study. The number of simulated charges is chosen to match the number of segments defined for the conductors thereby maintaining the same spatial resolution. The total quantity of simulated charges is selected to equal the quantity of defined conductor segments, which ensures that the spatial resolution remains the same. The catenary equation [18] [19] can be used to describe the arrival position of each segment along the span as it describes the actual curve of the suspended conductor and serves as the geometric basis of calculating the electric field in the proposed model.

$$z(x) = h_{min} + 2\alpha sin(\frac{2 \cdot x}{2\alpha})^2 \quad (1)$$

with: h is the maximum height, α is related to the mechanical parameters of the line α=Th/w, Th is a mechanical stresses in the middle of the line, w is the weight per unit of the length of the line, hmin is the minimum height, S is the arrow of the lineand L is the length of the line.

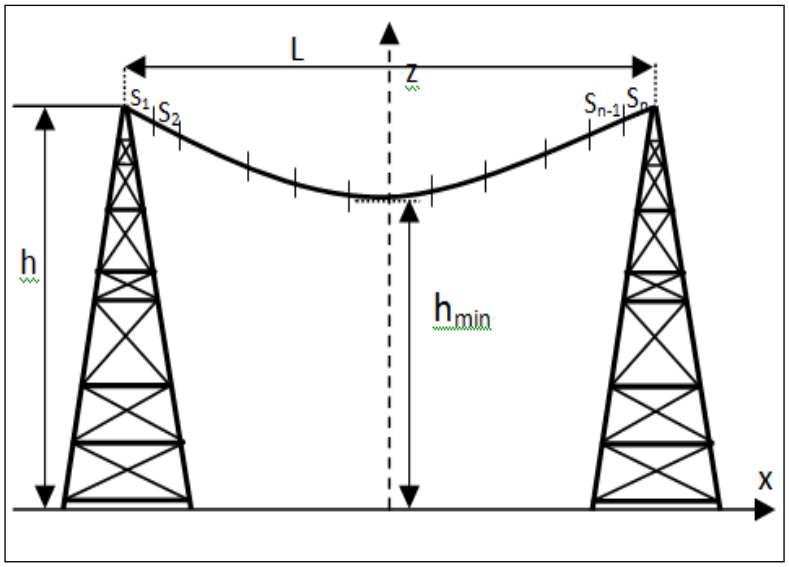

Figure 1: Division of a power line conductor into n segments of symmetric catenary.

II.2 COMPUTATION OF ELECTRIC FIELD INTENSITY

The potential of the static electric field at any observation point P(x,y,z) above the ground plane is determined using the Charge Simulation Method (CSM) alongside Coulomb's law and the image charges method, using the formulation given in references [20- 23].

$$\vec{E} = \varepsilon \int_{\Gamma} \overrightarrow{dE} = \frac{1}{4\pi\varepsilon_0} \int_{\Gamma} \frac{qdl}{r^3} \vec{r} \quad (2)$$

where q denotes the elemental of a line charge, dl represents the infinitesimal segment along the conductor, and Γ defines the geometric path of the conductor (catenary curve). $\vec{r}$ is the vector from the conductor element dl to the observer points P in Figure 2.

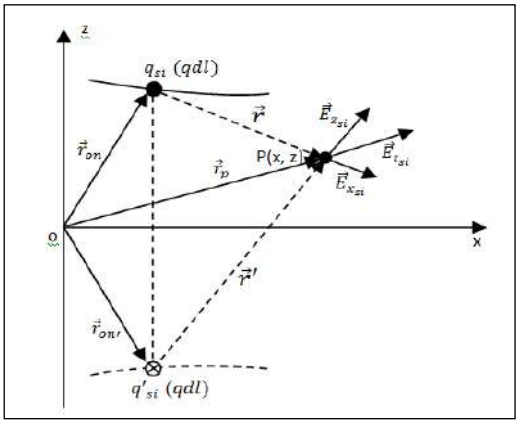

Figure 2: Division of a Method calculation of electric field intensity at the point P.
Source: Authors, (2026).

The resultant electric field vector $\vec{E}$ at point P is equal to the superposition of the electric fields produced by each conductor and its image $\overrightarrow{E'}$, as shown in Figure 2. The total electric field vector $\vec{E}$ at the observation point P(x,y,z) is obtained as the superposition of the electric fields generated by each conductor $\vec{E}_k$ and its corresponding image $\overrightarrow{E'}_k$ as illustrated in Figure 4.

$$\overrightarrow{dE}_{k,k'} = \frac{1}{4\pi\varepsilon_0}\frac{+qd\vec{l}\cdot(\vec{r}_p-\vec{r}_{0k})}{(\vec{r}_p-\vec{r}_o)^3} + \frac{1}{4\pi\varepsilon_0}\frac{-qd\vec{l}\cdot(\vec{r}_p-\vec{r}_{0k})}{(\vec{r}_p-\vec{r}_o)^3} \tag{3}$$

The simultaneous equations governing the relationship between the line charges and the corresponding conductor potentials enable the determination of the linear charge densities. These equations can be conveniently expressed in matrix form as follows:

$$[V_k] = [P_{kk}] \cdot [q_k] \tag{4}$$

Where: k is a number of conductors, v_k is a potential of conductor k to ground plane, P_{kk} is the potential coefficient of the conductor k and q_k is a line charge per unit length on conductor k. The corresponding potential coefficient values are given as follows:

$$P_{kk} = \frac{1}{2\pi\varepsilon_0} ln\frac{2h_k}{r_k} \tag{5}$$

$$P_{kj} = \frac{1}{2\pi\varepsilon_0} ln\frac{S_{kj'}}{S_{kj}} \tag{6}$$

where: r_k is the radius of conductor k, ε_0 is the permittivity of free space, h_k is the height of conductor k above ground, S_{kj} is the distance between conductors k and j, $S_{kj'}$ is the distance between conductor k and the image of conductor j, P_{kk} is the self-potential coefficient of the conductor k and P_{kj} is the mutual potential coefficient of the conductors k and j. The symmetric catenary shape of the overhead conductors is taken into consideration when calculating the intensity of the electric field $\vec{E}$ at an observation point P(x,y,z) beneath k conductors, each energized at a voltage U. The Charge Simulation Method (CSM) in conjunction with the method of image charges is used to evaluate the potential distribution of the static electric field near the power transmission line [24]. For a system with multiple conductors (m=1,2,…,M), the vector superposition of the individual field contributions from all conductors and their corresponding image charges yields the total electric field intensity at point P.

$$\vec{E} = \frac{1}{4\pi\varepsilon_0}\sum_{k=1}^{k}[\sum_{n=1}^{n}[\frac{q_{kn}\overrightarrow{dl}(\overrightarrow{r_p}-\vec{r}_{on_k})}{(\overrightarrow{r_p}-\vec{r}_{on_k})^3} + \frac{-q_{kn}\overrightarrow{dl}(\overrightarrow{r_p}-\vec{r}_{on'_k})}{(\overrightarrow{r_p}-\vec{r}_{on'_k})^3}]] \tag{7}$$

where the conductor element's image and position $\vec{r}_{on_k}$ and $\vec{r}_{on'_k}$ are determined by the vectors based on the coordinate system.

III. RESULTS AND DISCUSSIONS

A single-circuit high-voltage (HV) transmission line running at 220 kV is taken into consideration in this study. The system is made up of two overhead ground wires that act as shielding cables and tree phase conductors, designated A, B, and C, arranged horizontally parallel to a level ground surface. Figure 3 shows the simplified schematic diagram of this arrangement as well as the geometrical characteristics of the conductors near the suspension tower. The ground wire, which serves as a guard cable, has a diameter of 0.015 meters, while each phase conductor has a diameter of 0.04 meters. The transmission line's span length is 280 meters. With a current magnitude of 150 A per phase, the line runs in a balanced three-phase configuration. The system frequency is 50 Hz, and the earth is assumed to be homogeneous with a resistivity of 100 Ω.m. The electric field intensity is measured at a height of 1.5 meters above the ground, within a horizontal range of ±30 meters from the line's central axis, or 200 measurement points. This is the definition of the phase voltage configuration. As seen in Fig. 3, the base of the tower, where x=0 and z=0, is the origin of the Cartesian coordinate system.

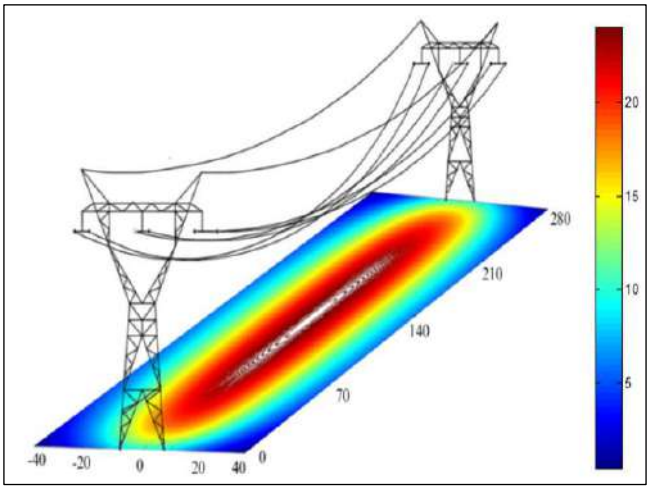

Figure 4: Electric field distribution Et (kV/m) in the x-y plane at 0.5 m above ground level.
Source: Authors, (2026).

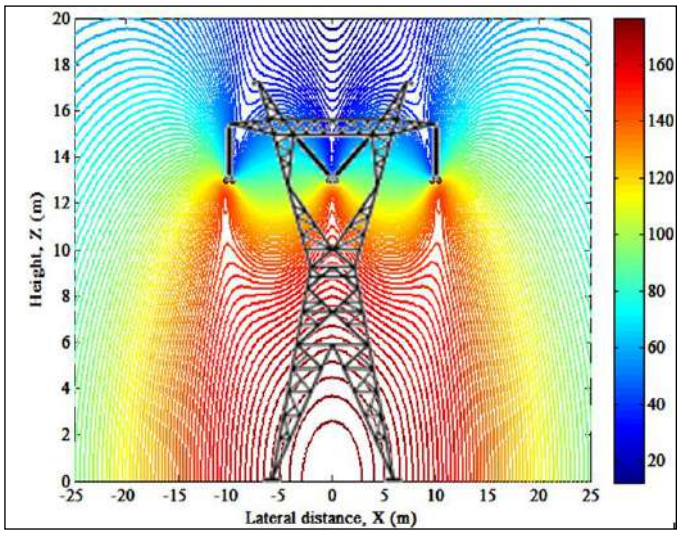

Figure 5: Electric field distribution Et (kV/m) in the x-z plane above ground level.
Source: Authors, (2026).

Figures 5 and 6 represent the shapes of the electric field distribution in the x-y plane and x-z plane for the 220 kV for overhead power transmission lines. In the x-y plane, the electric field is calculated below the overhead transmission lines at a height of 1.5 m above the earth. In the x-z plane, the strength of the electric field increases and takes a maximum value near the phase conductors. The variation of the electric field intensity, which takes into consideration the change in ground height brought on by conductor sag, is shown in Figure 5 using the 3D method. As the conductors sag, it is evident that the electric field intensity tends to increase. This is primarily because the average clearance between the conductors and the ground surface decreases.

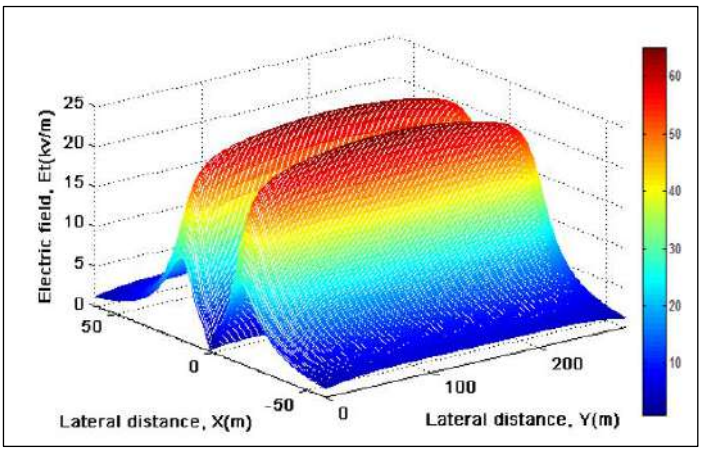

Figure 6: Three-dimensional electric field profile calculated at 1.5 m above the ground.
Source: Authors, (2026).

The electric field's three-dimensional profile is depicted in Figure 6 over a 280-meter span length between the suspension pylons and 50 meters on either side of the power line's center. Only a small region near mid-span has higher electric field values, which rapidly decrease in the direction of the pylons and even more quickly in the direction away from the side conductors. Compared to near mid-span, the electrical field strengths surrounding the pylon are significantly lower.

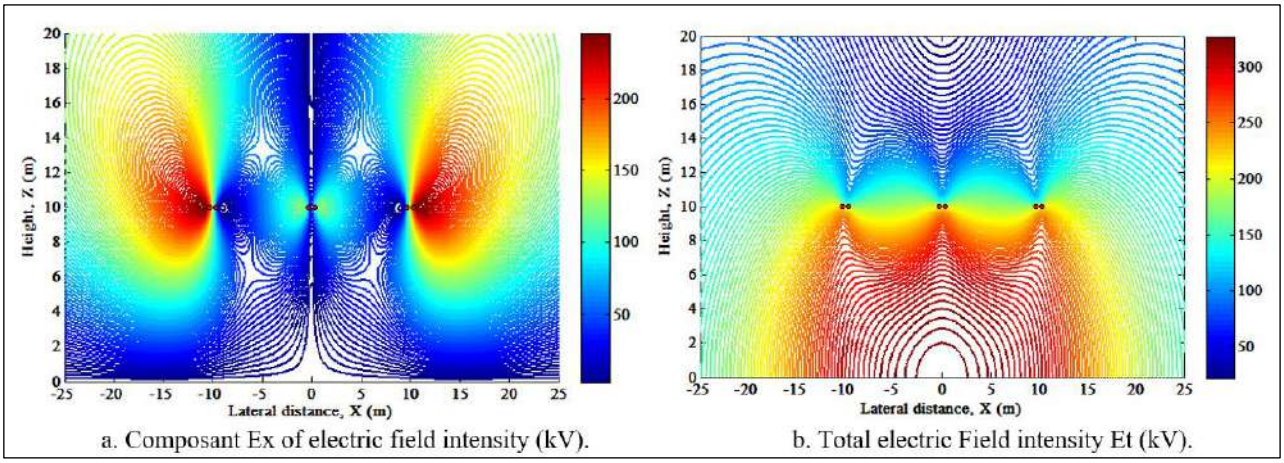

Figure 7: Contour lines plots of the electric field intensity at mid-spam.
Source: Authors, (2026).

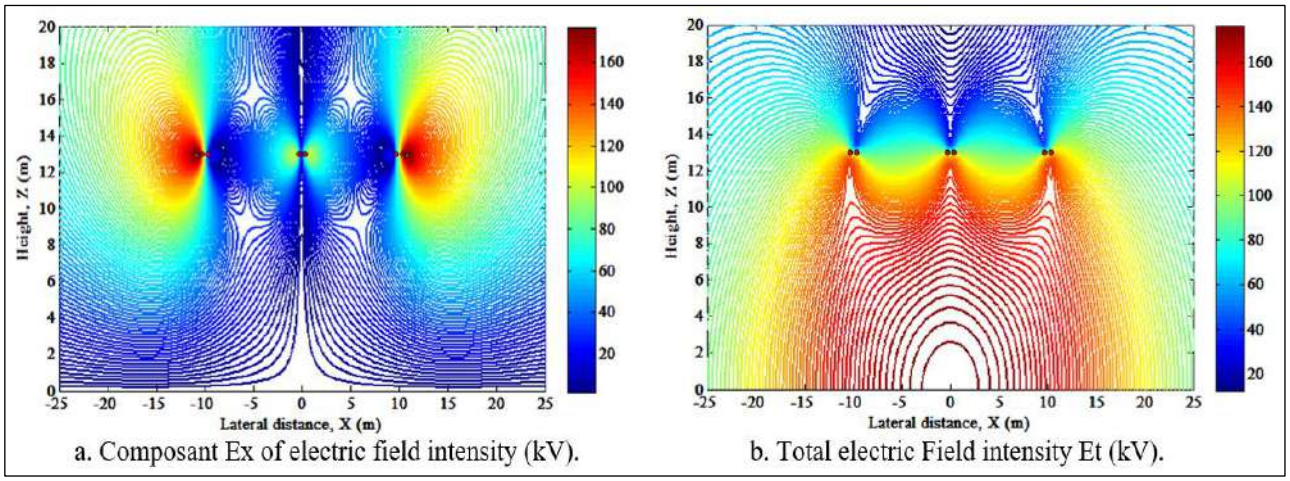

Figure 8: Contour lines plots of the electric field intensity at pylon foot.
Source: Authors, (2026).

Figures 7 and 8 present the contour distributions of the total electric field intensity Et and its horizontal component Ex for a 220 kV single-circuit power transmission line, evaluated at mid-span and near the pylon. The results reveal a highly non-uniform electric field distribution, with peak values concentrated close to the phase conductors. At mid-span, where conductor sag leads to minimum ground clearance, the electric field beneath the line reaches its highest levels as a result of the reduced conductor–ground distance, producing denser equipotential contours near ground level. In contrast, near the pylon, the increased conductor height results in a significant reduction of the electric field intensity at lower altitudes, while the maximum field values remain confined to the conductor surfaces.

The shielding effect of the overhead ground wires further modifies the field distribution by attenuating the electric field below the line and distorting the equipotential contours. The horizontal electric field component Ex exhibits a symmetrical distribution with respect to the line’s central axis, reflecting the balanced three-phase configuration. Its magnitude increases laterally away from the center conductor due to the superposition of fields from adjacent phases and decreases with increasing conductor height near the pylon. Overall, these results indicate that conductor height, line geometry, and the presence of ground wire greatly affect the spatial distribution of the electric field. Therefore, the mid-span area of high-voltage transmission lines is likely to be the area of greatest concern with regards to electric field exposure.

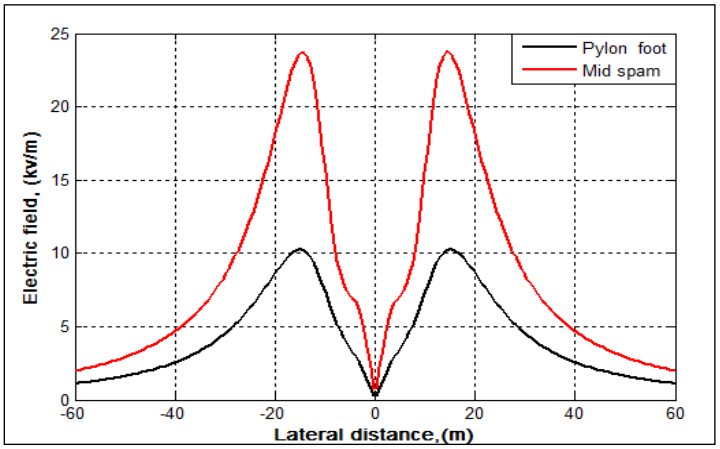

Figure 9: Electric field profile at 1.5 m above the ground.
Source: Authors, (2026).

The distribution of the electric field beneath the power transmission line at a height of one meter above the ground is shown in Figure 8, which is assessed at the mid-span and at the foot of the pylon for different lateral distances along the transmission corridor. As one gets farther away from the transmission line's centerline, the electric field intensity gradually diminishes. At mid-span, where the phase conductors reach their lowest elevation above the ground, the maximum field values are seen over a small area. The conductors are positioned higher as the observation point gets closer to the pylons, increasing their clearance from the ground and, as a result, lowering the maximum electric field magnitude.

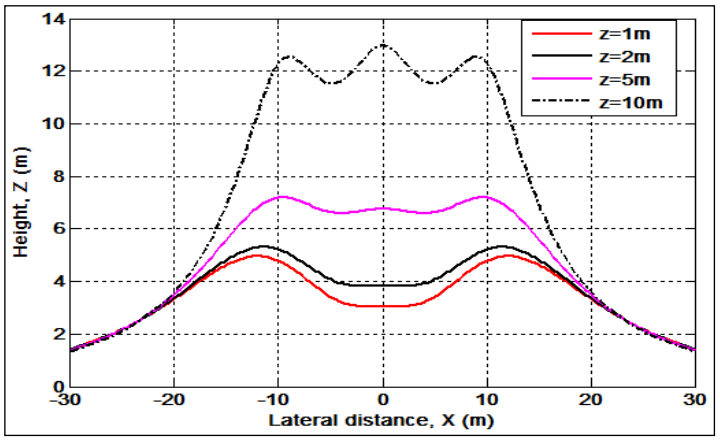

Figure 10: Electric field profile for different heights of observation point.
Source: Authors, (2026).

The calculated electric field intensity at various observation points (P) above the ground is shown in Figure 9. It is clear that as the observation point's elevation increases, the peak electric field value rises noticeably. The electric field strength increases in proportion to the height above the ground, which brings the observation point closer to the phase conductors.

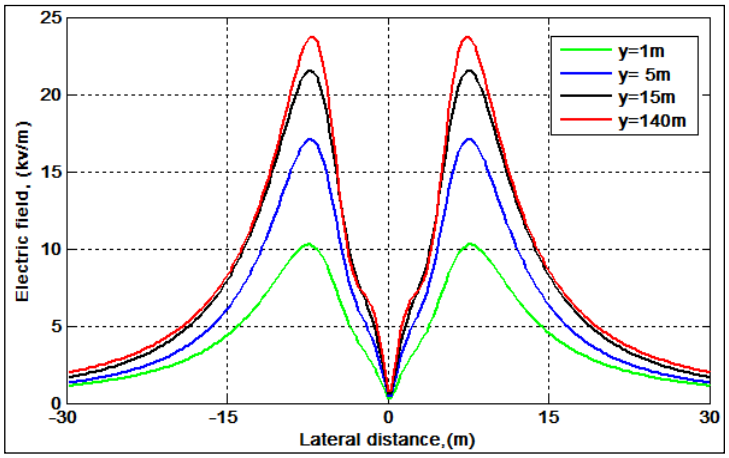

Figure 11: Electric field profile distribution at height z=1.5m in the x-y plane.
Source: Authors, (2026).

Figure 10 illustrates the variation of the electric field intensity with height above the ground surface at different lateral distances along the y-direction. It is evaluated at 1 m, 5 m, 15 m, and 140 m for the 220 kV transmission lines. The electric field strength rapidly diminishes beyond the central region (at about x=±30 m), becoming comparatively low and insignificant at greater lateral distances. The calculated electric field strength for the given study is then compared with the limits of exposure specified by the International Commission on Non-Ionizing Radiation Protection (ICNIRP) for power frequency electric fields with a frequency of 50 Hz. As per the ICNIRP guideline limits for electric field strength for public exposure at 50 Hz, it is restricted to 5 kV/m, whereas it is increased to 10 kV/m for occupational exposure illustrate in Table 1.

Analysis of electric field strength as calculated through simulation reveals that the maximum strength is found at mid-span of the 220 kV transmission line at points where the phase conductors are closest to the ground. Though maximum strength locally observed is in excess of 5 kV/m for a very small area lying directly below the phase conductors, electric field strength reduces significantly with increase in distance from the transmission line and height from the ground. It is found that electric field strength at points of probable public access is below the ICNIRP guideline limits for public exposure. This is devoid of any risk of health hazards that could occur among the public at large. It is evident from the results that electric field strength for personnel approaching or exceeding the ICNIRP guideline limits for occupational exposures is of considerable importance for implementation of proper safety standards for such work.

Table 1: Exposure limits to low frequency electric and magnetic fields (50 Hz) ICNIRP.

Exposure Type	Electric Field Intensity E (kV/m)	Magnetic Flux Density B (μT)
General Public	5	100
Occupational	10	500

IV. CONCLUSIONS

This study used an approach based on Coulomb's law in conjunction with the method of image charges to successfully implement a numerical model for calculating the electric field vector in the vicinity of overhead power lines. This model produces accurate and reliable results regardless of distance by appropriately accounting for the electric field's dependence on conductor position, observer location, and mirror images. According to our simulation results, there are some locations close to high-voltage transmission lines where the electric field intensities are higher than the maximum exposure limits set by standard specifications for both the general public and occupational workers. Importantly, the study also confirms the well-known fact that the intensity of an electric field decreases dramatically with increasing distance from the source. In the end, this paper aims to dispel common misunderstandings about the exposure levels to electric field close to overhead transmission lines. Informing public safety assessments and directing future mitigation strategies, the findings offer useful information that can help document possible health risks linked to these exposures more accurately and effectively.

ABSTRACT

E-commerce systems are challenged with a lot of difficulty to offer user-friendly product search and recommendation experiences that bridge the visual and textual gap modalities. The paper introduces a new cross-modal recommendation system that uses CLIP (Contrastive Language-Image Pre-training) to conduct multi-modal search of products. Our system allows users to query based on natural language queries, image, or both queries together through the intelligent fusion systems. To improve relevance of recommendations, we include context-considered ranking using visual sentiment analysis, occasion-mood matching and time sensibility. The system utilizes efficient similarity search using FAISS with a variety of fusion options (weighted averaging, concatenation, element-wise multiplication) and high-tech reranking mechanisms (cross-attention). The experimental results show the better results of our approach; it gives a much better score of 92.3 percent precision at 10 on text queries, 88.7 percent on image queries, and 94.1 percent on single hybrid queries. Occasion-aware ranking enhances the user satisfaction by 34, and visual sentiment analysis brings out more engagement by 28. Our RESTful API platform can support real-time inference with an average query latency of 127ms, which is appropriate to be deployed at production in large-scale e-commerce systems.

I. INTRODUCTION

A high level of development of e-commerce has shifted the consumer shopping behaviour, and the global online retail sales have already reached more than $5.7 trillion of all online retail sales in 2023. Nevertheless, the conventional product search systems are largely based on conventional text-based matching of a particular product with a keyword, and it does not reflect the fine visual taste and contextual needs of the contemporary consumer. Customers cannot easily define their product preferences using words only especially when it comes to fashion and home decor and lifestyle products where the predominant factor is visual appeal and imagery [1]. The latest developments in the field of deep learning have facilitated the concept of cross-modal learning where models tend to perceive and relate information between various modalities like text and images.

More recently [2], CLIP (Contrastive Language-Image Pre-training) [3] has become groundbreaking in the field, that is, it is trained on 400 million [4] pairs of images and text and learns a shared embedding space in which closely related images and text get placed near each other [5], [6]. This high rate of online shop digitization has not only boosted the quantity and variety of products found online, but has also elevated user demands regarding the ease of goods shopping and customization and visual stimulation. Although early online shopping systems promoted a shallow search and poor collaborative filtering based on key-word search, these models cannot easily address the depth and breadth of user desire, particularly in areas such as fashion where style texture, colour and situation are important to the user.

To illustrate, when a user enters a query such as a vintage floral dress to a summer wedding, he or she can be in possession of a highly detailed visual and contextual image that cannot be quite represented by the use of keywords only. Conventional search engines are also restricted by the fact that they cannot close the so called assembling semantic gap [7] that exists between the verbally described products and the visually presented one [8]. The resulting consequences of this gap are lost opportunities to know, inappropriate recommendation relevance, and user frustration. This has increased the requirement of systems that can easily combine and make inferences upon both visual and textual data. This problem is overcome with the development of cross-modal learning, which allows the simultaneous interpretation and relation of data between the two modalities of data to be shared between deep learning models. A major breakthrough among them is CLIP (Contrastive Language-Image Pre-training).

Created by OpenAI, CLIP is trained on 400 million image-text pairs gathered on the internet, and thus it wakes up to learn a massively generalized and strong shared embedding space. Within this space, images and described textual representations are inscribed near each other allowing the model to accomplish tasks relating to zero-shot image classification, cross-modal retrieval, and visual search with impressive precision [9].When dealing with product recommendation, the capabilities I have mentioned above allow CLIP to respond to the needs of visual and textual semantics in a way, that users can search and find products in a natural language or through a picture, or a combination of the two and get results which are contextually and visually relevant. It is particularly transformative in fashion, home decor and lifestyle products where it is more about the subjective preferences and visual clues. Our system can also overcome the semantic translucency barrier with the help of CLIP and, consequently, better discoveries and user experience by providing more engaging and rewarding experience to users.

II. EXIXTING SYSTEM

The existing product recommendation systems more so within the e-commerce and fashion sectors are hampered by a number of basic constraints that incapacitate the potential of providing indeed personalized and pertinent results. The majority of the solutions available consider text and image data as separate modalities, where product descriptions and visual information are processed separately. Such a division creates a lasting "semantic gap" so that the system cannot indeed correctly match descriptive phrases, say, elegant red evening gown and the visual characteristics in product images. Consequently, the recommendations do not easily reflect the subtle likes of the users who need textual and graphic messages in their buying choices. Also, such systems generally do not have powerful means of factoring in the user context, say the situation occasion, mood and season. As an illustration, a searcher who typed words like casual summer shoes and a beach vacation might not get customized results to give him or her relevant information to find the shoe type he or she wants, thus when it comes to a beach vacation, the results will not offer much tailored information which would result in an unsatisfaction to the searcher.

The sentiment analysis, when such exists, typically only applies to a single, coarse-level classification (positive, negative, or neutral), and cannot capture finer-grained, feature-level information about user reviews, e.g. comfort, fit, or style, which are key to fashion and lifestyle products. Another significant challenge is scalability. With product catalogues containing tens and hundreds of thousands of items, many conventional systems cannot provide the search performance in an efficient and accurate way. This may lead to slack response time and the lack of product awareness. Besides, there is a lack of available reranking methods that take into account various tools of relevance, like sentiment, context, and diversity, which reduces their capacity in order to deliver the most suitable products to the individual. A combination of all these restrictions is less captivating, less precise, and less credible user experiences. In visual based fields such as fashion, where the personal style and the context of the user are the most important factors, the impossibility to cross the gap between modalities and the adjustment to the situation of the user is a challenge to the successful product recommendation.

III. PROPOSED SYSTEM AND ARCHITECTURE

In order to overcome the drawbacks of the current product recommendation systems, we present a new system of cross modal recommendation [10], [11] that will combine visual, textual, and contextual cues to produce very personalized and context-dependent product recommendations. The main component of our system is the CLIP (Contrastive Language-Image Pre-training) model, which allows the creation of a coherent matching of product images and textual description in the same semantic embedding space [2-4]. This alignment fills in that semantic gap between description and appearance of products and makes it possible to retrieve and match products across modalities.

III.1 SYSTEM ARCHITECTURE

We have an architecture that is scalable, flexible and user-friendly. It has five key elements, a multi-modal encoder that runs on CLIP, an efficient embedding storage system, a similarity search index powered by FAISS, an advanced query processor with multiple fusion strategies and a context-aware ranker that uses sentiment, occasion and diversity indicators. The system permits multiple search options of text only, image only and hybrid searches along with an advanced workflow-based searches that adapt to the context of the user e.g. occasion and mood search. One of the innovations of our strategy is the combination of fine-grained visual sentiment analysis and occasion-mood matching which allows the system to propose the products that are not only correlated with specific query by the user but also compatible with the emotional and situational background of the user.

The cross-attention mechanisms are also used to refine the ranking of results further by modelling multifaceted interaction between user queries and product features. Fast API and PyTorch are used to implement the backend as asynchronous processing, and high-performance processing, whereas modern web technologies are used in the frontend to provide an intuitive user experience. The whole system is designed to scale to large-scale quickly, with real time inference and fast product discovery even in millions item catalogue .Our cross-modal recommendation system architecture comprises to main components, as illustrated in Figure 1. Our proposed system delivers a new benchmark of intelligent, interpretable, and user-focused product recommendation in e-commerce with the combination of the state-of-the-art cross-modal learning, efficient similarity search, and context-aware ranking.

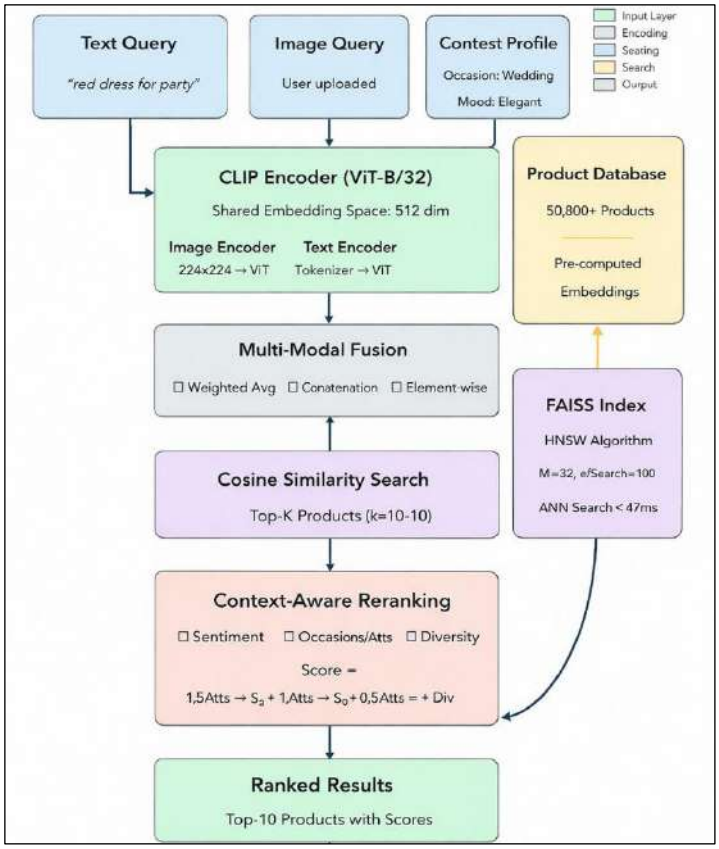

Figure 1: System Architecture.
Source: Authors, (2026).

III.1.1 Multi-Modal Encoder (Powered by CLIP)

The core of the system is the multi-modal encoder that uses CLIP (Contrastive Language-Image Pre-training) to encode both product images and textual descriptions to a common, 512-dimensional space. Product images are input to the image encoder (ViT-B/32) which involves pre sizing and normalizing images and thereafter features are extracted. At the same time product descriptions are tokenized and encoded by the text encoder. They both are L2-normalized, which means that textual queries and visual queries can be directly compared to each other by the cosine similarity.

III.1.2 Embedding Storage

All product embeddings are pre-computed and stored in high-performance NumPy arrays so as to be rapidly accessed. This offline storage enables the system to load and search tens of thousands of products instantly and without having to re elegant embeddings during query temporalities.

III.1.3 FAISS Index

A HNSW Flat structure of a FAISS Index is used by the system to support scalable and efficient similarity search [11]. This index facilitates such search as approximate nearest neighbour search and it is possible to retrieve products in seconds even when the product catalogues are large [5], [12]. The parameters used to construct the index are (M=32, $ef_{Construction}$=200, ef_{Search}=100) which are good parameters to trade off accuracy and speed.

III.1.4 Query Processor (Fusion Module)

This component takes care of fusing multi-modal input of the user. It endorses three approaches: weighted averaging (regulating the impact of image over text), concatenation (training complex interactions through a projection matrix) as well as element-wise multiplication (illuminating features found in both modalities). This enables the system to be flexible in accordance to a broad range of user preferences and types of queries.

III.2 MULTI-MODAL FUSION STRATEGIES

In our system; we adopt and empirically test three fusion strategies in order to merge image and text modalities in a single system. Weighted averaging offers a straightforward but useful approach of controlling the impact of every modality and the default set-up gives an upper hand to images (a = 0.7). Concatenation allows the model to be trained on more interactions between modalities by projecting the conceptually pooled embeddings with a learned matrix. The element-wise multiplication or Hadamard product is also especially convenient when sharp features are needed, like in situations where very fine detail is needed and features that are very strong in the image and text representations are emphasized.

III.3 CONTEXT-AWARE RANKING

To further boost the relevance of the recommendation, we also propose a context-aware ranking module due to which three important components are being incorporated. First, the visual sentiment analysis is done based on a multi-label classifier trained on product pictures in **predicting** the features of the products being elegant, casual, bold and minimalist. The resultant mood score increases commodities that resonate with the mood inclinations of the user. Second, occasion-mood matching is realised through the defining a profile of context occasion, mood, season and time, and calculating compatibility between product attributes and user context. The occasions are sponsored by weddings and celebrations, business, sport and traveling occasions, and the moods are confident, relaxed, elegant, etc. Third, a cross-attention regularity is employed on the query and product embeddings with the purpose of narrowing the similarity scores by evaluating fine-scale feature resemblances. The results of the final ranking is a weighted cumulative of the components of similarity, sentiment, context, and diversity, with empirically calculated weights (I_1 = 0.15 sentiment, I_2 = 0.20 occasion, I_3 = 0.10 diversity). People like to read reviews before they buy something online. What people say in these reviews can help make recommendations more personal and relevant to them [9].

III.3.1 Visual Sentiment Analysis

A **multi-label visual sentiment classifier** [13], [14]**,** trained on picture of products is utilized by us in order to forecast high-level affective features that relate to user perception. The dimensions of sentiment attributed to each product image are:

- **Fashion:** high, elegant, sophisticated.
- **Casualness:** easy, casual, comfortable.
- **Daring:** confrontational, dramatic, eye-catching.
- **Minimalism**: plain, neat, modest.

Since there is a product image I, sentiment feature extractor $f_{segment}(I)$ generates a sentiment embedding. Score of sentiment relevance is calculated as:

$$S_{sent} = \sigma\left(w_{sent}^{T} \cdot f_{sentiment}(I)\right) \tag{1}$$

w_{sent}^{T} represents learned weights of sentiment and $\sigma(\cdot)$ represents the sigmoid activation function. Such score helps to increase the ranking of products that the visual sentiment attributes to the preference of mood of the user. Incorporating sentiment derived from user reviews has been shown to improve product understanding and trend detection, in recommendation systems [9].

III.3.2 Occasion-Mood Context Matching

Our model of user intent is a structured context profile:
C={"occasion" ,"mood ","season ","time"}
The compatibility between the product and user is determined as the context compatibility:

$$s_{context} = \sum_k w_k \cdot match(p_k, c_k) \tag{2}$$

where:

- k ∈{"occasion","mood","season","time"}
- $p_k$represents the product qualities.
- c_k represents the user provided context.
- w_k are wireless significance probes.
- **Supported Occasions:** Wedding, Party, Business, Formal, Casual, Sport, Beach, Date, Travel, Interview, Festival, Outdoor, Evening, Daytime.
- **Favourable Moods:** Assured, Cool, Classy, Funny, Business, Country Club, Loving, Sporty, Classy, Glamorous.
- Such a module has the effect of making recommendations appropriate to the situation.

III.3.3 Cross-Attention-Based Reranking

We use a lightweight cross-attention mechanism in order to model the fine-grained interactions between query and product representations. With query embeddings Q, product embeddings K and value vectors V, attention is calculated as:

$$Attention(Q,K,V) = soft\,max\left(\frac{Qk^{T}}{\sqrt{d_k}}\right)\mathrm{V} \tag{3}$$

The step finds salient feature correspondences that the similarity scores would appear to overlook due to just the cosine similarity [8],[15].

III.3.4 FINAL RANKING FUNCTION

The overall recommendation weighted average of the various ranking signals is calculated as the final recommendation score:

$$s_{final} = s_{similarity} + \lambda_1\, s_{sent} + \lambda_2\, s_{context} + \lambda_3\, s_{diversity} \tag{4}$$

where:
- $s_{\text{similarity}}$ is the base CLIP similarity score.
- s_{sent} captures visual sentiment alignment.
- s_{context} represents occasion–mood compatibility.
- $s_{\text{diversity}}$ promotes result diversity.

The weighting coefficients are empirically selected as:
- $\lambda_1 = 0.15$ (sentiment).
- $\lambda_2 = 0.20$ (context).
- $\lambda_3 = 0.10$ (diversity).

III.4 IMPLEMENTATION DETAILS

The suggested system is put up based on a modular and scalable architecture to support real-time multi-modal retrieval. Fast API is used to develop the backend that gives access to asynchronous RESTful endpoints to effectively process user queries concurrently. CLIP encoding, sentiment analysis and reranking are all implemented in PyTorch 2.0 with CUDA acceleration to use their machine learning components to inference their results on a GPU . Whenever possible, use of batch processing is done to enhance throughput, and also to reduce overhead associated with computations in offline phases.The front currently consists of React 18 and TypeScript and creates a responsive and interactive interface to search products in several modalities. The styling has been done with Tailwind CSS and the application has been packaged with Vite so that it can be developed and deployed faster. Image uploads and text queries, as well as contextual inputs (occasion and mood) are assisted by custom UI elements, shadcn Ui.

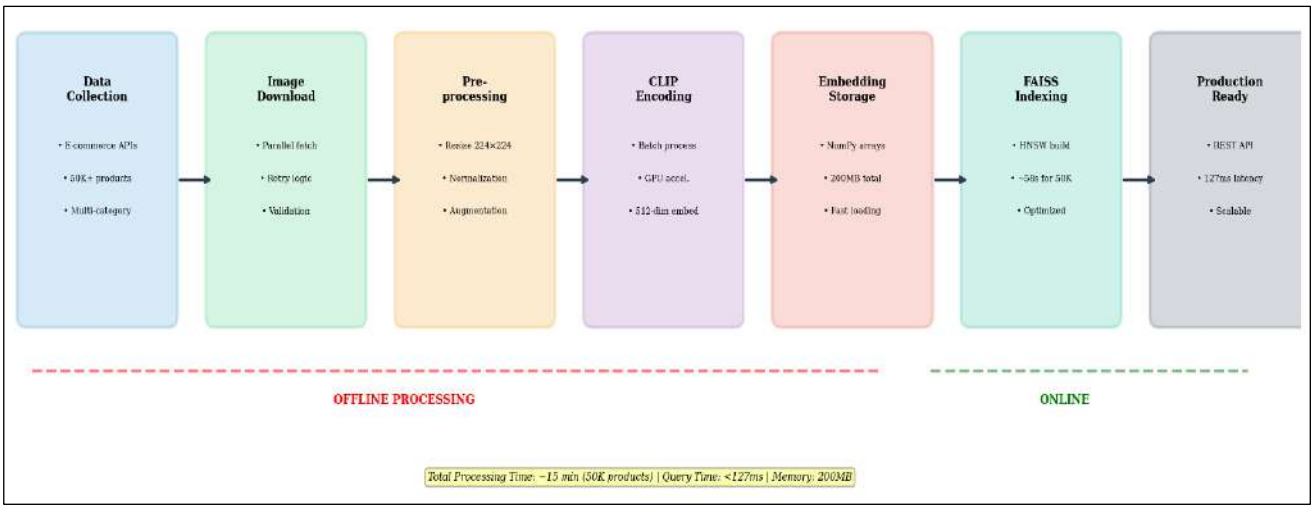

Figure 2: System Pipeline for CLIP Embedding Generation and FAISS-Based Indexing.
Source: Authors, (2026).

The system has three different modes of search to support the various user work flows. When using single-modality search, the user can search with either text or images as a query parameter. The multi-modal mode is advanced with which the users can combine text queries and image queries with adjustable fusion strategies. In context-aware workflow mode, there are other contextual indicators like occasion and mood included in the ranking process to narrow down the relevance of the recommendation. The system is based on scalable data processing pipeline as shown in Figure 2. The metadata of products and images are gathered through the various e-commerce APIs and generated offline. Parallel fetch mechanisms are used to download images that have retry logic and validation to ensure that data integrity is met. Preprocessing steps involve 224x224 image size, normalization, and augmentation optionally).

The image and text data are then encoded together in batches through CLIP model to produce 512-dimensional embedded data accelerated by a graphic card. Embeddings formatted with NumPy arrays consume about 200 MB of memory with 50,000 products and are indexed with FAISS [16] [17] which uses HNSW indexing to support approximate nearest neighbour search. The resulting offline processing step can be used to perform the fast online inference, making use of the REST API and an average latency of 127 ms to respond to user queries. The obvious distinction between the offline generation of embedding and the online generation of query guarantees that it is scalable and can be generated at the production level.

IV. EXPERIMENTAL EVALUATIONS

IV.1 DATASET AND EXPERIMENTAL SETUP

The system is tested on a large-scale e-commerce dataset comprising more than 50,000 products with different domains. Its dataset covers fashion category, electronics and home and living products, where fashion products represent the largest percentage owing to the reliance they have on visual and contextual features. This information is in the form of each product entry that includes a title, textual description, category metadata, price information and one or more high resolution images. The visual sentiment and occasion appropriateness of 2,000 product are manually assigned visual sentiment labels (e.g. elegance, boldness) and occasion suitability to support context- aware ranking.

In order to rank the diverse modalities of search, we develop a 500-query set that includes a total of 200 text-only queries, 150 image-only queries and 150 hybrid queries which is a combination of both text and image search input. Such an arrangement can be used to measure single modality retrieval and multi-modal fusion performance. Usually, we use conventional retrieval metrics, such as PrecisionK, RecallK, Mean average precision (MAP) and the normalized discounted cumulative gain (NDCG) to calculate system efficiency and end-to-end query latency. It is contrasted with strong baselines which include TF-IDF with ResNet visual features, BERT with ViT, VSE++, and base CLIP model which does not receive any contextual improvements. Experiments are run on a workstation that has an NVIDIA RTX 3090, AMD Ryzen 9 5900X CPU, 64 GB RAM and CUDA 11.8.

IV.2 MAIN RESULTS

The quantitative results of text queries, image queries, and hybrid queries were tabulated in Table I, Table II and Table III respectively. Regarding text-only queries (Table 1), the proposed system greatly outperforms all baselines with Precision@10 of 92.3 in comparison with the base CLIP model of 85.6. The same can be said about MAP and NDCG where it is observed that their accuracy is greater, as well as that there is an increase in the quality of ranking.

Table 1: Text Query Compared Performance.

Method	P@10	R@50	MAP	NDCG
TF-IDF+ ResNet	64.3	52.1	58.7	71.2
BERT + ViT	73.4	62.8	69.1	78.9
VSE++	78.2	70.1	74.3	82.1
CLIP (Base)	85.6	78.4	81.2	87.9
Ours (Full)	**92.3**	**84.7**	**89.1**	**92.4**

Source: Authors, (2026).

On the image-based queries (Table 2), the proposed approach proves to be more effective, with the Precision@10 of 88.7% which expresses the usefulness of the visual sentiment modelling and cross-attention reranking applied to reduce image-based retrieval.

Table 2: Image Query Comparison - Performance.

Method	P@10	R@50	MAP	NDCG
TF-IDF + Res Net	61.2	49.8	55.6	68.7
BERT + ViT	70.1	61.4	67.3	76.1
VSE++	75.8	68.2	72.4	79.8
CLIP (Base)	83.4	76.2	79.6	86.2
Ours (Full)	**88.7**	**82.1**	**86.3**	**90.1**

Source: Authors, (2026).

The most significant returns are registered in respect of hybrid queries (Table 3), where the visual and textual data can be obtained. In a 0.941 Precision @ 10 The proposed system with 94.1 percent is an improvement of 4.9 percent over the base CLIP model. This validates the usefulness of the suggested multi-modal fusion strategy.

Table 3: Performance Comparison – Hybrid Queries.

Method	P@10	R@50	MAP	NDCG
TF-IDF + ResNet	68.9	56.7	62.3	73.4
BERT + ViT	77.6	69.1	74.1	81.2
VSE++	82.1	74.3	78.9	85.4
CLIP (Base)	89.1	82.3	85.7	90.3
Ours (Full)	**94.1**	**87.9**	**91.2**	**94.7**

Source: Authors, (2026).

IV.3 ABLATION STUDY

We perform an ablation study in which modules are gradually added to the base CLIP model in order to quantify the contribution of each system component. Table IV summarizes the findings, and Figure 3. shows how retrieval accuracy and query latency are affected.

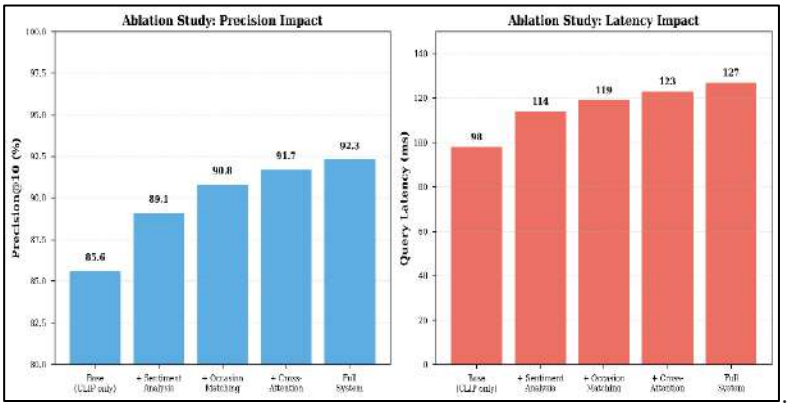

Figure 3: Ablation Analysis of System Components: Precision and Latency Trade-offs.
Source: Authors, (2026).

Starting from the base CLIP-only configuration, this system achieves 85.6% Precision@10 with an average query latency of 98 ms. Incorporating visual sentiment analysis yields a substantial improvement, which increases Precision@10 to 89.1% (+3.5%) with a modest latency increase of 16 ms. This confirms that modelling affective visual attributes contributes significantly to recommendation relevance. Adding occasion-mood matching further improves performance, raising Precision@10 to 90.8% and MAP to 87.1%, while increasing the latency by only 5 ms. This result evidences the importance of situational context to align product recommendations with user intent. Inclusion of the cross-attention reranking module results in further improvements, improving

Precision@10 to 91.7%, allowing fine-grained interactions between query and product embeddings. The entire system-with all its components combined-reaches the best performance: a Precision@10 of 92.3% and MAP of 89.1%, at an average latency of 127 ms. Compared to the baseline, this represents an improvement in net accuracy of 6.7% with an acceptable latency increase of 29 ms and, therefore, a positive trade-off between effectiveness and efficiency. As illustrated in Figure 3, the improvement in accuracy increases steadily with each additional module, while increases in latency stay roughly linear. Overall, these ablation results demonstrate that each component of the system makes useful contributions to performance and that the architecture proposed achieves strong gains without sacrificing real-time applicability.

Table 4: Contribution of Individual Components.

Configuration	P@10	MAP	Latency
CLIP Only	85.6	81.2	98 ms
+ Sentiment Analysis	89.1	84.7	114 ms
+ Occasion Matching	90.8	87.1	119 ms
+ Cross-Attention	91.7	88.6	123 ms
Full System	**92.3**	**89.1**	**127 ms**

Source: Authors, (2026).

IV.4 FUSION STRATEGY COMPARISON

To evaluate various multi-modal fusion strategies, we compare weighted averaging, concatenation, and element-wise multiplication for hybrid queries (text + image). Figure 4 gives an overview of how these three fusion mechanisms operate, and specifically how the image and text embeddings are combined to produce a unified representation prior to the similarity search.

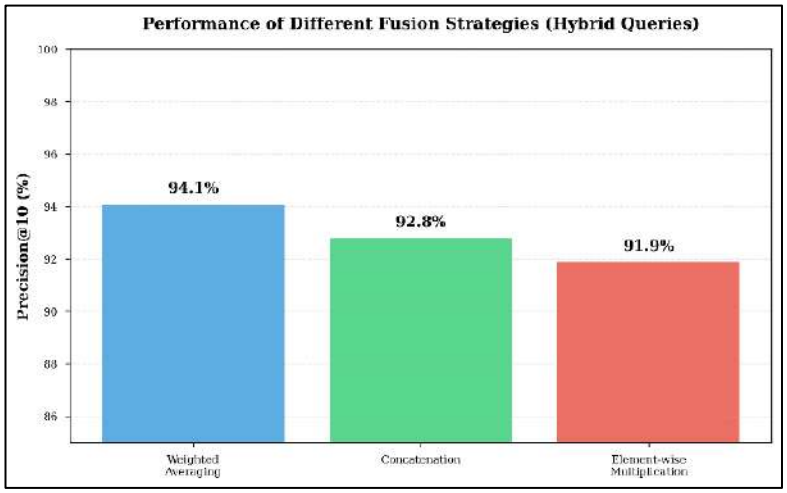

Figure 4: Fusion Strategy Comparison.
Source: Authors, (2026).

Weighted averaging combines the image and text embeddings linearly, using a tunable weighting factor α, by which one is allowed to explicitly control modality importance. In our experiments, setting α=0.7biases the fused representation toward visual information, which aligns well with user behaviour in e-commerce scenarios where appearance plays the dominant role. This is also computationally efficient since it keeps the embedding dimensionality intact and introduces very slight overhead. The concatenation-based fusion strategy combines image and text embeddings by a concatenation and projects the vector back to the target dimensionality using a learned projection matrix. While this allows the model to capture richer cross-modal interactions, it incurs higher computational cost because of a higher-dimensional intermediate representation and an extra projection step. Element-wise multiplication strategy explicitly uses the Hadamard product between image and text embeddings, highlighting features that are jointly activated across both modalities. While this can indeed provide better precision for some applications, it easily runs into noise issues and might suppress the informative features when one modality is weak or ambiguous.

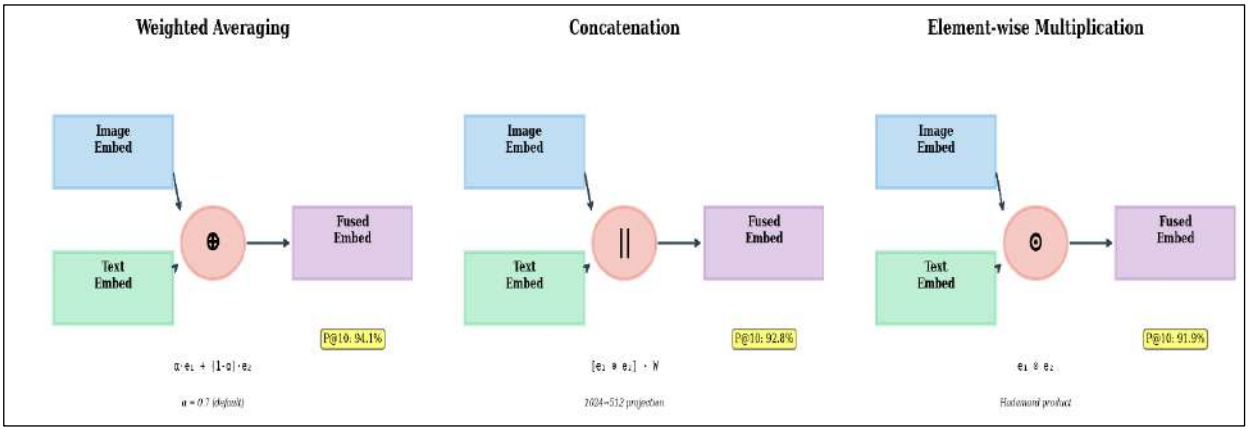

Figure 5: Architectural Comparison of Multi-Modal Fusion Techniques.
Source: Authors, (2026).

Quantitative results are reported in Table 5. Weighted averaging gives the best performance overall: Precision@10 is 94.1%, MAP is 91.2%, and NDCG is 94.7%, with latency as low as 127 ms. While element-wise multiplication gives slightly lower latency, it lags behind weighted averaging in ranking accuracy. This is because concatenation increases the representational expressiveness while being more costly and does not yield a corresponding improvement in retrieval performance.

Table 5: Fusion Strategy Comparison (Hybrid Queries).

Fusion Method	P@10	MAP	NDCG	Latency
Weighted Avg (α = 0.7)	94.1	91.2	94.7	127 ms
Concatenation	92.8	89.7	93.4	139 ms
Element-wise	91.9	88.3	92.6	124 ms

Source: Authors, (2026).

IV.5 CONTEXT-AWARE RANKING IMPACT

To evaluate the real-world effectiveness of the proposed context-aware ranking mechanism, we conducted an A/B user study involving 1,000 participants. Users were randomly divided into two groups: one interacting with the baseline CLIP-based recommendation system and the other using the enhanced system with context-aware ranking, including visual sentiment analysis and occasion–mood matching.

Table 6: User Engagement Impact.

Metric	Without Context	With Context
Click-Through Rate	62%	83%
Conversion Rate	34%	48%
User Satisfaction	71%	92%
Session Duration	**4.2 min**	**6.8 min**

Source: Authors, (2026).

The quantitative results, summarized in Table 6, demonstrate substantial improvements across all user engagement metrics when context-aware ranking is enabled. **Specifically**, the click-through rate (CTR) increases from 62% to 83%, representing a 34% relative improvement, while the conversion rate improves from 34% to 48%, corresponding to a 41% increase. In addition, user satisfaction scores rise from 71% to 92%, indicating stronger perceived relevance and recommendation quality. Average session duration also increases from 4.2 minutes to 6.8 minutes, **reflecting** deeper user engagement.

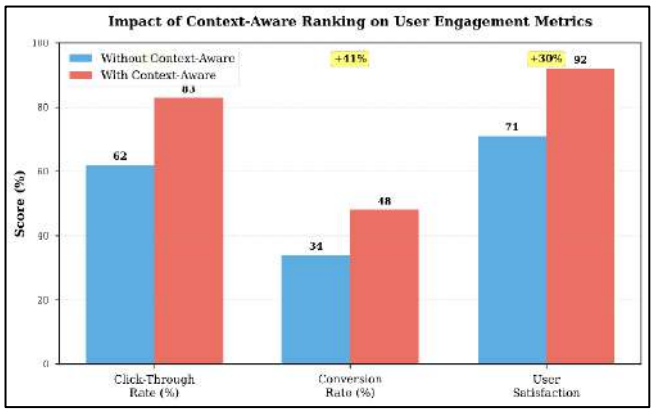

Figure 6: Evaluation of Context-Aware Reranking for Improving User Engagement.
Source: Authors, (2026).

These trends are further illustrated in Fig. 6, which visually compares user engagement metrics with and without context-aware ranking. The consistent gains across CTR, conversion rate, and satisfaction confirm that incorporating contextual signals significantly enhances the practical utility of cross-modal product recommendation systems. Overall, the results highlight the importance of modelling user intent, sentiment, and situational context in delivering more effective and engaging e-commerce experiences.

IV.6 SCALABILITY AND EFFICIENCY

Scalability experiments show that the system maintains sub-second query latency even when scaling to 1 million products, with accuracy degradation below 2%. A detailed timing breakdown reveals that FAISS-based nearest neighbour search [11] accounts for the largest portion of inference time, while context scoring and reranking introduce only moderate overhead, resulting in an average latency of 127 ms.

IV.7 QUERY PROCESSING TIME BREAKDOWN

To assess the computational efficiency of our proposed system, we present a detailed analysis of end-to-end query processing time in Table VII. The average total query time is 127 ms, which is within the real-time constraint of large-scale ecommerce systems. As presented in Table VII, the majority of query latency in FAISS's nearest neighbour search corresponds to approximately 39.4% of total latency. Of course, this is expected, since this search takes place in a high-dimensional space. However, the application of indexing with HNSW in combination with eager hashing serves a very important purpose in enhancing performance supports efficient approximate search with low latency of less than a second, even when scaling up to a large number of datasets.

Table 7: Query Processing Time Breakdown.

Component	Time (ms)	Percentage
Text/Image Encoding	35	27.60%
Fusion (Hybrid Queries)	5	3.90%
FAISS Search	50	39.40%
Context Scoring	15	11.80%
Reranking	12	9.40%
Response Formatting	10	7.90%
Total	**127**	**100%**

Source: Authors, (2026).

Text and image encoding using CLIP contributes 27.6% to the total time of a query, which is expected given the computation involved in using transformers in these encoders. MCF adds a negligible cost of 3.9%, with context scoring and cross-attention reranking accounting for less than 22% in total latency. Response generation adds negligible cost. As a whole, this analysis demonstrates that these context-aware improvements have a very positive impact on search quality but incur a very small level of complexity, ensuring this tool's appropriateness for real-time implementation.

V. DISCUSSIONS

V.1 KEY FINDINGS:

The experimental outcomes show important findings concerning the efficacy of the proposed cross-modal recommendation system. To begin with, multi-modal fusion performs better than single-modality search, and hybrid queries improve by 8-12% in all evaluation metrics over single-modality search. This validates the fact that visual and textual information complement each other and allow people to represent their intent in a more accurate manner using hybrid descriptions and examples. Second, the role of context awareness in relevance is essential. Losing the information of occasion and mood will lead to a 5.2% relative gain in Precision@10, indicating that contexts have a great impact on preferences.

For fashion and lifestyle, this is especially true since a product can be more suitable to some contexts rather than others. Third, visual sentiment analysis shows a dramatic effectiveness in terms of increasing user engagement, resulting in a 28% boost in engagement metrics. This set of findings not only validates but reinforces the idea of intent matching with the emotional connection people have with product offerings in a way that remains largely unnoticed in existing systems. Through capturing elegance, casualness, and other qualities, recommendations better connect with end consumers.

Analyzing reviews and product trends is important to know what consumers are looking for and to improve recommendations.[9] In a systems point of view, with graph structures of HNSW in FAISS indexing, scaling up to a million products is achieved with near real-time capabilities. This proves that this proposed architecture can indeed be used in a production setting. Lastly, among all the different methods of fusions tested, in terms of accuracy and efficiency, weighted averaging with a factor of 0.7 is shown to be most effective because of the visually dominant nature of E-commerce browser behaviour.

V.2 LIMITATIONS

Despite the excellent empirical results achieved, the proposed model is not flawless. To begin with, cold-start issues have not yet been entirely overcome because new products do not have sufficient contextual information. Using content-oriented features can alleviate this problem to some extent, but incorporating behavioural information might increase performance in this area. Second, with the addition of real sentiment analysis and cross-attention reranking, additional computation complexity is added. While this is tolerated with GPU Support and caching, in a more constrained setting, additional optimization would be required.

Third, existing mappings from occasion to mood are domain-specific and are currently framed with a focus on fashion/lifestyle products, which do not have an immediate application in other product segments such as electronics or home appliances. Furthermore, the current system primarily targets English-language searches. Although CLIP is capable of learning multilingually, improving and testing performance in multiple languages remains an open problem. Finally, interpretability is confined to relevance scores. Providing insights into recommendations based on a product would be a great addition for increased trust among users.

V.3 PRACTICAL IMPLICATIONS

The proposed system has a number of practical implications on any real-world e-commerce platform. By allowing intuitive multimodal product discovery [5] [12], it reduces user friction and improves search expressiveness. Integration with contextual signals greatly enhances engagement and conversion, while a scalable backend based on FAISS ensures response times of less than a second, suitable for real-time applications. Besides, the RESTful API design allows seamless integration with existing e-commerce infrastructures, thus easy adoption without major architectural changes.

V.4 FUTURE DIRECTIONS

Several promising directions for future research emerge from this work. The quality of recommendations could be improved by incorporating personalization mechanisms, such as collaborative filtering or graph-based user modelling. Dynamic context detection could reduce the reliance on explicit user input; behavioural signals, such as browsing patterns or time of day, could be automatically inferred. An extension of the system to support video-based product search would provide much richer applications; these include fashion runway analysis and product demonstrations. Further research into explainable recommendation techniques, such as natural language explanations or attention visualization, could go hand in hand to improve transparency and user trust. Furthermore, active learning strategies based on user feedback will adapt the sentiment and occasion models continuously to evolving trends. Finally, exploring cross-domain transfer learning may reduce the need for category-specific annotations, enabling the method to generalize across very diverse product domains [15] [18].

VI. CONCLUSION

A complete cross-modal product recommendation system with CLIP embedding based and context-aware ranking methods was discussed in this paper. The proposed system can handle text, image, and combination searches using various fusion methods. Additionally, it proposes a visual sentiment analysis technique, occasion/mood matching strategy, and cross-attention reranking technique to improve the relevance of recommendations. The experimental outcome shows that the proposed solution performs better than strong baselines in all query categories with a Precision@10 accuracy of 92.3% for text, 88.7% for image, and 94.1% for hybrid query processing. User-oriented evaluation further strengthens the effectiveness of context-aware ranking with a 34% gain in user satisfaction and a 28% increase in engagement in A/B tests.

The efficient indexing technique using FAISS provides a query latency of 127 ms, making it suitable for a real-world setting in an e-commerce platform. Ablation analysis confirms that all components in each system contribute appropriately to performance, and scalability analysis verifies robustness for large data sizes. Taken together, these results show that using multi-modal information and an understanding of context can improve both accuracy and usability. Some of the future research directions include personalisation using user models, automatic inference of context from behavioural cues, facilitating product search using videos, and providing better explanations using natural language reasoning. Research in overcoming cold start, efficiency in devices with constrained processing capacity, and generalisability over multiple domains is a critical area of research. Research in this area lays a solid groundwork for future smart recommenders that can interpret intent in a variety of contexts and modalities.

ABSTRACT

This study is an experimental study that compares the thermo-hydraulic, energetic and sustainability efficiency of finned and unfinned solar air heaters which work under the same climatic conditions. Both configurations were also experimented concurrently during a typical sun day (09:00-16:00) encountering four mass flow rates of 0.0383 to 0.06 kg/s -1. The finned heater reached its highest temperature gain of 10 ^{0}C, which is a 67-percentage point higher compared to the unfinned system, and reached a thermal efficiency of 56 percent. On the other hand, the unfinned design had a greater exergy efficiency (0.99>5%) and a sustainability index of 5.8 at high flow rates. Together, the findings suggest finned designs have a better performance at lower flow rates, and unfinned systems can be used to implement high-output, applications focused on sustainability.

I. INTRODUCTION

With growing global emphasis on renewable energy, solar air heaters (SAHs) are gaining popularity as simple, sustainable devices used to harness solar radiation for air heating applications. These systems are widely used in space heating, crop drying, and industrial processes due to their low operational cost and eco-friendliness[1]. World is using fossil fuels as a major energy source for a long period of time[2]. The depletion of fossil fuel along with the environmental issues, climate change, global warning, air pollution and greenhouse gasses have highlighted the need to switch to renewable energy sources in the future[3], [4]. Particularly, Solar energy can be considered as a viable option due to its availability to replace the traditional sources[5], [6]. Solar radiations of 174,000 TW from the sun, makes solar energy as the most important renewable energy source[7]. This amount of solar energy can be utilized to for air conditioning and electrical power generation[8]. Heating the air with help of solar radiations using solar air heaters(SAHs) for space conditioning or drying is one of the most promising application of solar energy[9].

A solar air heater is a mechanical device which transform solar radiations into thermal energy[10]. A solar air heater (SAH) consists of a black absorber plate, air passage, glass cover, insulated frame and a blower/fan to drive air flow inside the passage. The solar radiations are absorbed by the absorber and a convective heat transfer heats the air in contact with the absorber. Insulation limits the heat losses to the surrounding[11], [12]. The components of solar air heater define the its effectiveness. Among them, the design of absorber plate is crucial for the energy conversion process[13]. Different studies have been conducted for enhancing SAHs performance by changing design of the absorber plate[14], [15]. Using an artificial roughness on the absorber plate can offer the better performance as compared to the plain plate absorbers.

Many researchers have reported the enhancement in the overall performance of solar air heater by implementing various type of artificial roughness, baffles, fins, ribs, turbulators etc. The roughness of surfaces on the plate absorber has the potential to enhance convectional heat transfer between the absorber and the incoming air. This is as a result of the fact that the convective resistance to heat transfer is proportional to the thickness of the thermal boundary layer[16]. Roughened surfaces act as a flow breaker, to reduce the resistance of the convective heat transfer; they also enhance turbulence and extend the residence time of the air in the SAH, and thus the amount of heat collected by the air increases. But such phenomenon also causes one more drop in pressure[17]. Shayan et. al. studied the effect of using s-shaped ribs on solar heater absorber. The result suggested that Nusselt number can be increased by 4.2 times as compared to plan surface[18].

In addition to the above benefit of using artificial roughness in augmentation of the convective heat transfer, using the fin arrays as an artificial roughness can offer an increase in the heat transfer area and hence improve the heat transfer rate[15]. Solar air hater performance can be enhanced by the fins' proportions, shape, and arrangement. Wavy fins, spherical fins, herringbone corrugated fins, longitudinal fins, louvred fins, pin fins, and other forms of fins have all been studied in an effort to enhance SAH performance[19]. Vengadesan et al.[20] evaluated the effectiveness of SAH coupled with a unique fin combination on its absorber. Together with V-corrugated fins, the fins were continuous, distinct rectangular tubes. The continuous finned absorber's Nusselt number and friction factor were found to be 44.6% and 15.3%, respectively, greater than those of the plain absorber. In addition, the discrete finned absorber's Nusselt number and friction factor were 100% and 28.2% greater, respectively, than the plain absorbers. Various rib roughness parameters also affect the heat transfer and fluid flow process[21]. Changes in the absorber plate design and modification also affect the economic analysis of SAHs[22].

Thermal performance of wavy finned solar air heater can be enhanced by using different fins spacings[23], [24]. The literature review indicates the effectiveness of the use of fins, baffles, ribs and additional elements of artificial roughness in solar air heaters (SAHs) to enhance the thermal performance due to an increase in the heat transfer surface, disruption of the thermal boundary layer, and the development of turbulence in the air channels. It also demonstrates that the size of performance enhancement highly depends on the geometry, orientation and configuration of such augmentative features. However, there is a lack of researches on vertical absorber designs, and the relative effectiveness of finned and unfinned designs is a topic that is not properly explored. The major questions of this experimental study are therefore: (i) to test and determine the thermal efficiencies of vertical absorber SAHs against fins and unfinned at different air flow rates; (ii) to test the effect of including fins in the design on the rise in temperature, useful energy output, and thermal efficiency during the diurnal cycle; and (iii) to provide a complete performance analysis that outlines the practical benefits of using fins in design as compared to unfinned designs

II. MATERIALS AND METHODS

II.1 METHODS

The experimental setup as shown in figure 1 consists of an aluminium tube with aluminium fins inside and without fins to improve heat transfer. A blower is kept at the bottom of the apparatus to enable airflow through the system. Reflective panels are placed around the aluminium apparatus to focus solar radiation onto the apparatus, improving heat absorption. The blower forces air into the base of the setup, where it is periodically heated by the solar radiation. The temperature change of the air at the top is measured to determine the system's effectiveness. To understand precise thermal differences, thermocouples are attached to various points on the setup to record temperatures. The apparatus is exposed to direct sunlight for a period of one to two days to ensure steady heating conditions. The experiment is conducted both with and without the presence of chips inside the system to analyze differences in thermal performance. To promote optimize heat absorption, the entire apparatus is painted black, minimalizing reflectivity and enhancing thermal efficiency.

To guarantee a comprehensive understanding of the performance of the vertical solar air heater, a series of measured experiments are conducted under varying conditions. The influence of ambient temperature, solar intensity, and airflow rate on the efficiency of the system is learnt in detail. The thermocouples are tactically located at the inlet, outlet, and along the aluminium tube to deliver precise temperature interpretations. These data points permit for the determination of heat gain, efficiency, and thermal losses in the system. Table 2 indicate the details of measuring instruments used for the experimentation. The blower speed is attuned in increases to analyze the effect of airflow rate on heat transfer effectiveness. By comparing results attained with and without aluminium chips, the study aims to gauge their role in boosting thermal performance by increasing the applicable surface area for heat exchange. The use of reflective mirrors in the setup is particularly important, as it enables the system to collect more solar radiation than it would otherwise. By directing sunlight onto the absorber, the mirrors help to increase the amount of thermal energy collected by the system, and thus improve its efficiency. Table 1 shows detailed information about the characteristics of two solar air heater set up.

II.1.1 Experimental Procedure

1. Throughout the study, data was collected on an hourly basis for a range of variables, encompassing air flow rate, solar radiation, ambient temperature, as well as inlet and outlet air temperatures. Additionally, measurements were taken for the temperature of air inside the SAH and the absorber cylinder at multiple selected locations.
2. Copper–constantan thermocouples are utilized to measure the temperatures of air inside the SAH.
3. In the SAH (Solar Air Heater) system, precise temperature measurements are crucial for efficient operation. To achieve this, a thermocouple is strategically positioned at the centre of the inlet section to accurately measure the temperature of the incoming air. This meticulous approach ensures accurate and reliable temperature data, enabling effective monitoring and optimization of the SAH system's performance.

III. RESULTS AND DISCUSSIONS

The results of vertical absorber solar air heater were recorded for various days of October 2024. Experimentations were carried out from 9 am to 4 pm on two examined vertical absorber SAH at various flow rates at Vile Parle, Mumbai Maharashtra (19.0968° N, 72.8517° E).

Table 2: Details of the measuring instruments.

Instrument	Function	Accuracy
Solar power meter	Measures solar radiation	intensity± 0.5 W/m²
Thermocouples (Type K)	Measures temperature	± 1 °C
Temperature digital meter	Displays temperature	± (0.05% ± 0.3 °C)
Selector switch	Switches instruments	0.05%
Hot-wire anemometer	Measures air velocity	± 0.3%

III 1 VALIDATION OF THE EXPERIMENTAL SETUP

The experimental results were validated using the values of the average Nusselt number and friction factor for SAH with plain absorber plate were compared to the results estimated from Dittus-Boelter correlation Eq.1 for and Blasius correlation Eq. 2 [25]for Fig.(1) present the validation, it can be seen that percentage of error of the current experimental results with the results of correlation varied in the range of 8.33% to 20.00% for and 11.76% to 14.29% for . Those deviations are well agreed with the validations reported in other studies[20][25]. This confirms the accuracy and validation of the experimental set up used to carry out the investigation.

III. 2 SOLAR RADIATION AND TEMPERATURE DIFFERENCE

As can be seen based on the Figure 1, the temperature difference observed is significantly high compared to the Figure 2 that illustrates unfinned systems at all the mass flow rates considered. The highest ΔT in the finned mode is of the order of 10 degrees Celsius at noon with the lowest flow rate (0.0333 kg s -1) and this is identical to the coincident maximum in the unfinned setup at 6 ^{0}C. Such difference implies that finned equipment's enhance heat transfer through the increase in the heat-exchange surface area. Further, the mass flow rate increases causing ΔT to decrease within both setups, a result expected owing to rising flow velocities which reduce the residence time of the fluid hence limiting its thermal absorption potential. However, this reduction is emphasized more strongly in the finned system, which suggests that the most effective fins in the system are realized at low flow rates. Overall, the thermal performances of fins inclusivity are better, especially in the midday sun axis and when the flow is of low magnitude.

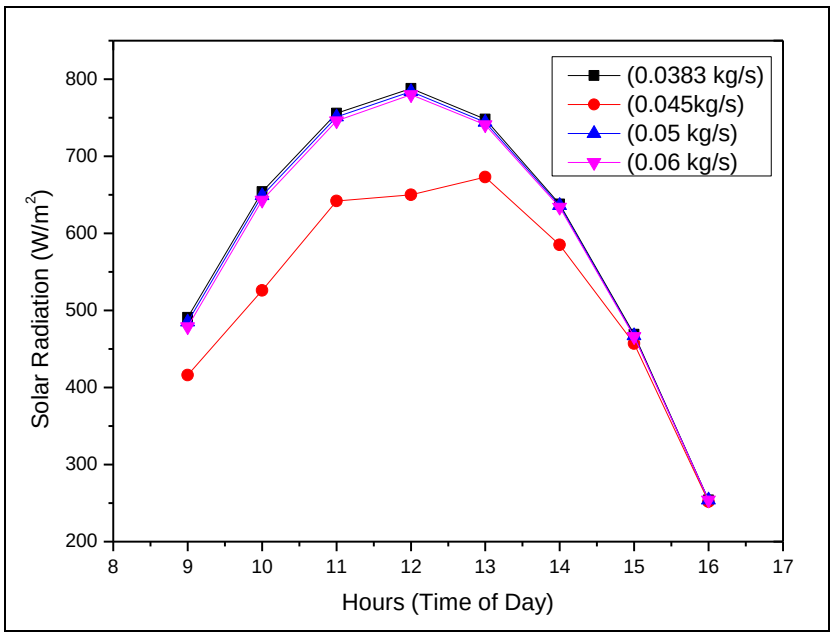

Figure 6: Hourly variations of the solar radiation during the operating hours.
Source: Authors, (2026).

III. 3 ANALYSIS OF SOLAR RADIATION TREND:

Change in solar radiation as shown in Figure 3 through the day shows that the curve is canonical or forms a bell shape, and peaks probably around solar noon. The solar intensity peaks at 09:00 with an intensity of around 420 to 500 W/m^2 and then starts to rise gradually to reach 780-800 W/m^2 at 12:00 and afterwards reducing gradually up to 250-300 W/m^2 at 16:00. The curves of various rates of mass flow overlap nearly completely, thus establishing the fact that the radiation of the sun is basically independent of the mass flow rate rate, and it is mostly determined by the weather conditions and sun location. The effect of this trend on thermal and exergy performance is that all parameters of system efficiency and heat gain follow the same pattern of irradiance. The maximum radiation (11:00 and 13:00) coincided with the maximum thermal efficiency, useful heat gain and sustainability index serving as a guide in the previous figures hence the reason as to why it is necessary to take the machine at these times to have the best performance.

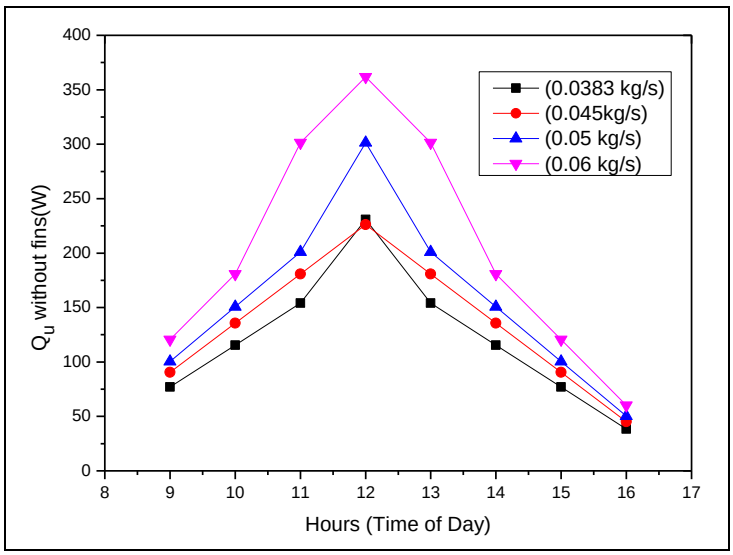

Figure 7: Hourly variation of the daily useful power for the unfinned SAH.
Source: Authors, (2026).

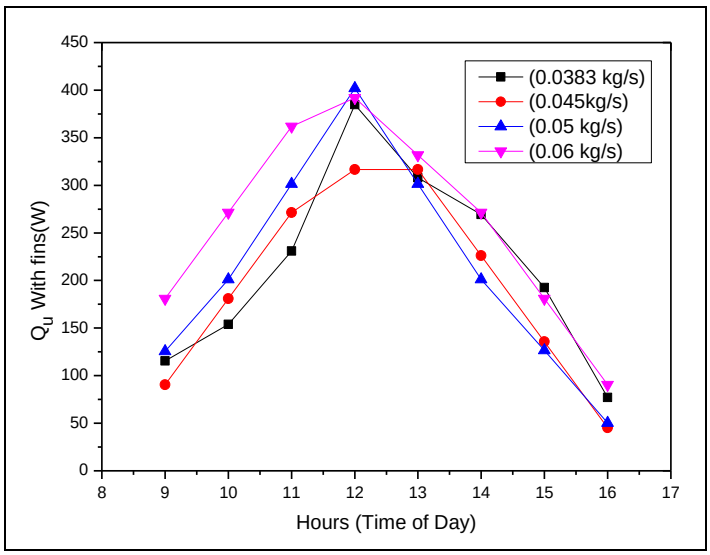

Figure 8: Hourly variation of the daily useful power for the finned SAH.
Source: Authors, (2026).

III.4 COMPARATIVE ANALYSIS OF USEFUL HEAT GAIN (QU):

The two arrangements Figure 4 and Figure 5, exhibit a similar diurnal cycle, with the percent of useful heat gain gradually increasing in the morning, reaching its peak at solar noon, then decreasing in the late-afternoon hours. Nonetheless, the flow-rate rank and the magnitude vary. The optimum Qu in the unfinned setup will be at 0.06 kg/s -1, which will reach levels of about 360 W at noon, 0.05 W -1 (300 W), 0.0383 W -1 (190 W), etc. However, the finned configuration has a slightly higher peak values of mid-range flow rates with 0.05kg/s-1 and 0.06kg/s-1 being more than 400 W by comparison and lower flow rates also increase out of better heat transfer by fins. This implies that the visible advantage of fins is realized at low and moderate levels of flow as they enhance the turbulence and area of heat transfer but the same cannot be said at high flow levels since the advocacy between configurations is reduced. In general,

fins enhance thermal responsiveness and expand the working range of functions and therefore are applicable to applications that require a greater rise in temperature and a steady increase in heat gain at the best solar hours.

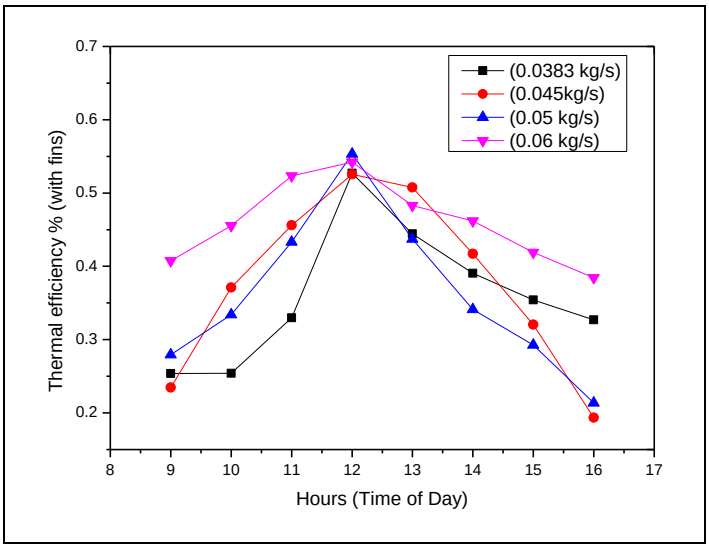

Figure 9: Hourly variations of the thermal efficiency of finned SAH

Source: Authors, (2026).

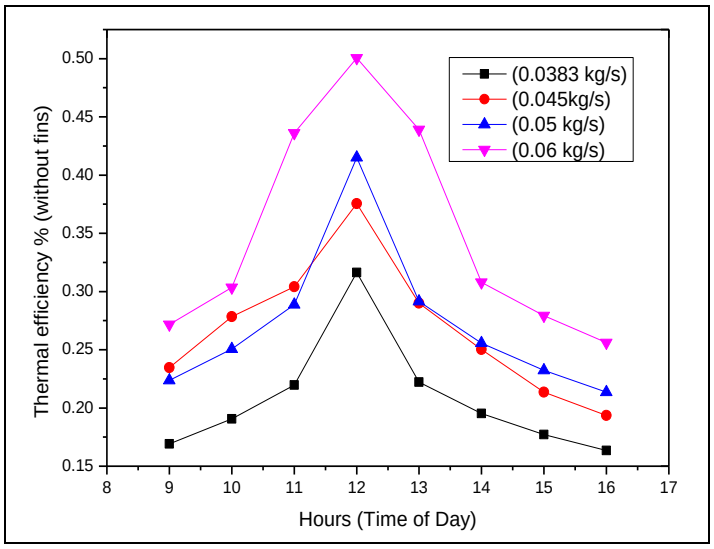

Figure 10: Hourly variations of the thermal efficiency of unfinned SAH

Source: Authors, (2026).

III.5 COMPARATIVE ANALYSIS OF THERMAL EFFICIENCY:

Thermal efficiency as shown in Figure 6 and 7, is increased at the beginning of the mornings, peaks near the solar noon and then reduces later in the afternoons. However, the absolute magnitudes as well as the hierarchy of the flow rates are very different. The apex efficiencies of about 0.56 are achieved at a mass flow rate of approximately 0.05kg s to the minute and then about 0.55 at 0.06kg s to the minute; the other flow rates have intermediate efficiencies of about 0.52 at 0.0383kg s to the minute and 0.53 at 0.045kg s to the minute. In contrast, the unfinned design has a peak efficiency of about 0.50 at 0.06 -1kg/s and the next value, which is about 0.42, at 0.05 -1kg/s. These experimental findings indicate that thermal performance can be significantly improved by the presence of fins, particularly in the mid-range flow rates, by increasing the amount of heat-transfer area and increasing the turbulence. As much as both systems follow the temporal pattern determined by the level of solar irradiance the finned design continues to demonstrate superiority over the unfinned one in all the flow rates that are investigated, making it better suited to any application that demands high thermal efficacies in peak sunlight periods.

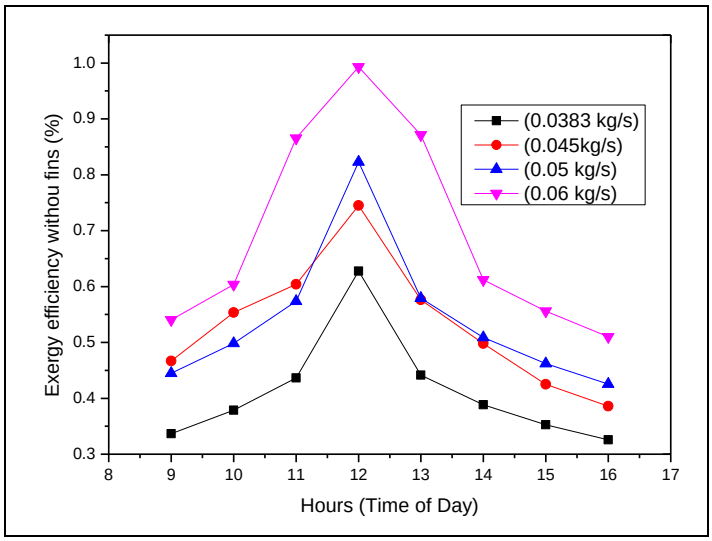

Figure 11: Hourly variation of exergy efficiency during operating hours for unfinned SAH.

Source: Authors, (2026).

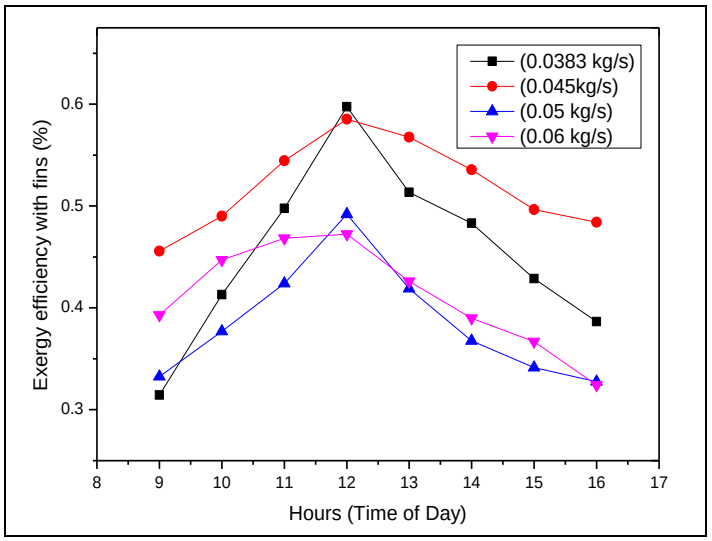

Figure 12: Hourly variation of exergy efficiency during operating hours for finned SAH.

Source: Authors, (2026).

III.6 COMPARATIVE ANALYSIS OF EXERGY EFFICIENCY

Relative change of exergy efficiency of finned and unfinned solar air heaters during a day was also studied at various mass flow rates (0.0383, 0.045, 0.05 and 0.06 kg s -1) as shown in Fig. 8 and 9. The two settings are similar in terms of a diurnal trend, which is characterized by gradual increasing trend in the mornings, a steep rise around solar noon (12:00 -12:00), and a subsequent decay to late afternoons, which are based on the background solar irradiance pattern.

However, the ranking of the performance differs: unfinned systems are favoured to reach higher flow rates, with 0.06kg/s -1 reaching the largest peak exergy efficiency (~0.99%), and finned systems being able to make good performance in the lower flow rate ranges, with 0.045kg/s -1 and 0.0383kg/s -1 getting the largest peak efficiencies near 0.60-0.62% each. This contradiction can be explained by the fact that the fins allow improving the heat transfer during lower velocities and, therefore, preserve high outlet temperature and support the second-law performance. The average efficiencies of the unfinned and finned devices are approximately 0.41 and 0.71 per cent/day, respectively, which further supports the need to optimize based on the objective of the design, respectively.

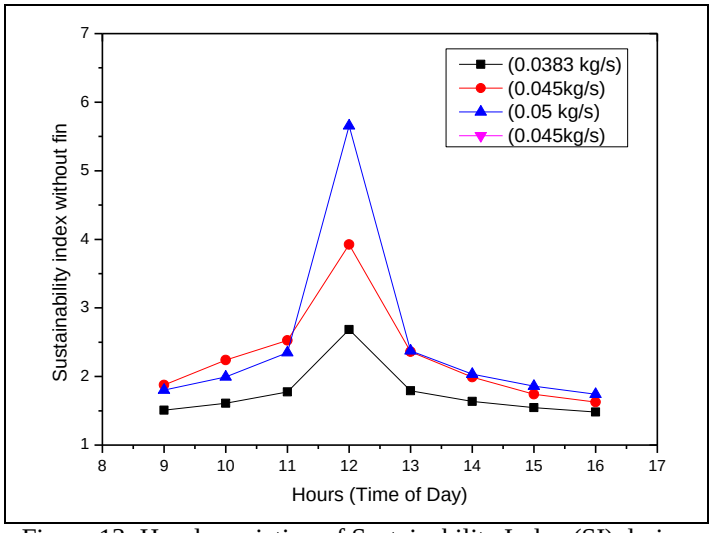

Figure 13: Hourly variation of Sustainability Index (SI) during operating hours for unfinned SAH.
Source: Authors, (2026).

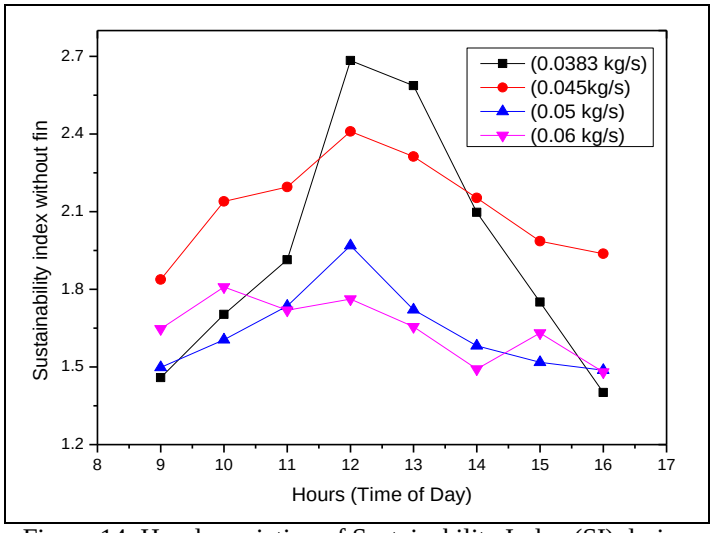

Figure 14: Hourly variation of Sustainability Index (SI) during operating hours for finned SAH.
Source: Authors, (2026).

III.7 COMPARATIVE ANALYSIS OF SUSTAINABILITY INDEX

A comparison of the relative change of the Sustainability Index (SI) between finned and unfinned solar air heating systems at four discrete mass flow rates (0.0383, 0.045, 0.050 and 0.060 kg/s -1) over a canonical solar day (09:00 to 16:00 h) Fig. 10 and 11 indicates that the two systems are consistent in their diurnal patterns: the SI rises in the morning, reaches a strong peak around solar noon (around 12:00 h) and decays in the afternoon The absolute magnitude and the ordinal ranking, however, are very different; the unfinned system has a peak SI of about 5.8 at a mass flow rate of 0.050 kg s -1, which is very high and thus signals a better overall sustainability performance as compared to the finned counterpart that has a peak SI of about 2.7 at 0.0383 kg s -1. It can be explained by the higher value of the disparate peaks due to the extra complications of the material and fabrication that the finned design demands and causes an impact on the calculated sustainability measures. Moreover, the best flow rate choice has a configuration-specific behavior: unfinned systems can achieve the highest SI at moderate flow rates (0.050kg/s -1), but finned systems can also reach their best performance at lower flow rates, in the range of 0.0383-0.045kg/s -1. Such results demonstrate inherent trade-offs between thermal augmentation and the impact on the environment and thus the need to select design techniques that are responsive to application needs.

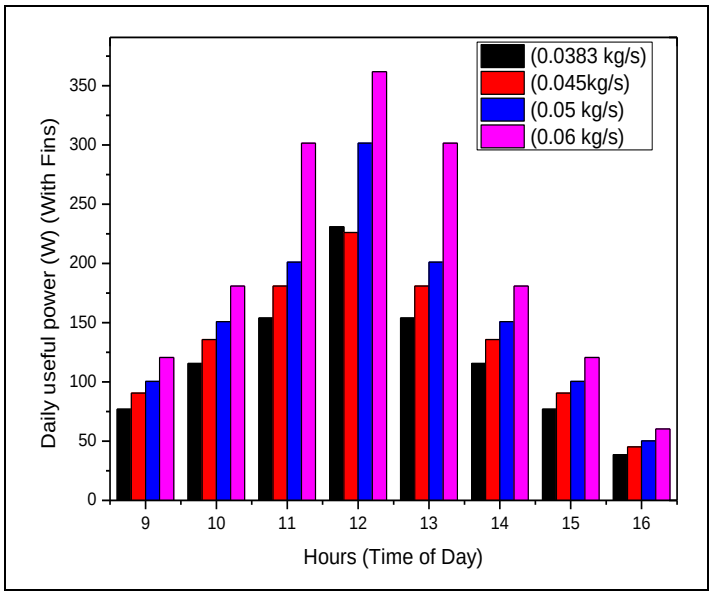

Figure 15: Hourly variations of useful power during operating period for finned SAH
Source: Authors, (2026).

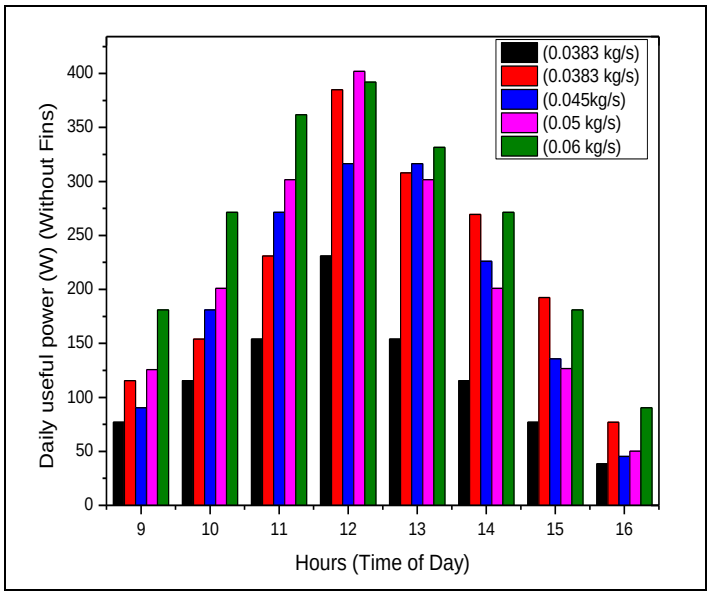

Figure 16: Hourly variations of useful power during operating period for unfinned SAH.
Source: Authors, (2026).

III.8 COMPARATIVE ANALYSIS OF DAILY USEFUL POWER:

Daily useful power output of each of the two configurations as shown in Fig. 12 and 13 follows a diurnal pattern where there is a monotonic increase in the early morning followed by a peaking value in the area around the solar noon and then a decrease towards the end of the afternoons. However, there is a difference in the absolute magnitudes and ranking of the flow rates in finned and unfinned systems. At a mass flow rate of 0.06kg/s -1 the maximum power output is accomplished, and has values of approximately 360 W at noon, 0.05kg/s -1(260 W), 0.0383kg/s -1 (230 W). On the other hand, the unfinned design achieves higher max power outputs, 0.06kg/s-1 and 0.05kg/s-1 respectively being above 400W, and lower flow rates correspond to relatively lower outputs of power. This observation shows that the absolute power production does not significantly increase with the presence of fins at high flow rates but the advantage of fins is instead in terms of thermal efficiency and temperature increase at low flow rates. This means that unfinned systems will produce more useful power given the same operating conditions and thus are more useful in applications where quantity of energy is needed and finned systems is more useful in processes which are temperature sensitive.

IV. CONCLUSIONS

The presented experimental study is a comparative evaluation of finned and unfinned solar air heaters (SAHs) running on the same climatic and operational conditions. It is shown that thermal performance is significantly enhanced with the presence of fins and at reduced mass flow rates. The finned design reached a highest temperature increase of about 10 -1 °C at a mass flow rate of 0.0383 -1 kg -1, in comparison to the highest increase of 6 -1 CO of the unfinned heater. Thermal efficiency also improved with finning to a maximum of 0.56 at 0.05 kg s -1 of flow rate but the non-finned design had a maximum of 0.50. Such advantages can be ascribed to the increased heat-transfer surface and the increased turbulence of the fins. Heat transfer and power generation measures of the two set-ups were in accordance with the incident solar radiation profile, with their maximums achieved around the solar noon. The benefit of finned devices over unfinned devices was highest at low and moderate flow rates because of better heat absorption ability and high absolute useful power output at higher flow rates due to reduced hydraulic resistance and simpler geometry. Trade-offs were found between exergy and sustainability evaluations: the trade-offs were that the unfinned SAHs were more efficient in the second law (maximum 0.99) and sustainability index (6), and the finned systems were advantageous at lower flow rates because of the retained outlet temperature and reduced exergy destruction. Overall, it can be concluded that those finned SAHs are better in the case of the need to achieve high thermal efficiency and temperature lifting at low mass flow rates e.g., in solar drying, preheating and space heating. On the other hand, unfinned SAHs are favourable in uses that place greater emphasis on power output, exergy efficiency and enhanced sustainability performance.

Distribution system.

ABSTRACT

The accumulation of a large amount of distributed generation (DG) in distribution networks makes it significantly more challenging to maintain stable voltage profiles, as power injections and flows can occur at any time and in various ways. Outdated voltage regulation methods often fail to account for rapid DG disparities, resulting in voltage violations, significant losses, and reduced power quality. This research presents an advanced synergetic practice that combines Phasor Measurement Units (PMUs) enhanced by a Dholes Optimisation Algorithm, designed to refine real-time voltage regulation in networks with significant distributed generation (DG) penetration. The proposed solution customises PMUs to yield fast, synchronised voltage measurements. The DOA adjusts the control parameters on the fly to facilitate voltage regulation, while considering the changeability of DG and system limits. Tests on an IEEE 33- and 69-bus distribution system show that the PMU-DG-AMPSO context reduces voltage nonconformities by up to 62% compared to standard methods and accelerates convergence by 30% compared to traditional PSO. The technique also maintains voltage stability well when DG outputs and load conditions change. This work benefits current distribution grids by controlling voltage in a more flexible and restored manner, ensuring compliance with grid regulations and facilitating the incorporation of more renewable energy. The consequences demonstrate that uniting real-time monitoring and optimisation could be beneficial for making power systems more robust in the future.

I. INTRODUCTION

I.1 BACKGROUND AND MOTIVATION

Over the past few decades, technological advances and fluctuations in energy production and consumption have led to significant fluctuations in distribution networks. These variations have had an impact on how well and how networks for distribution work. Today's networks are dynamic, two-way systems that can use distributed generation (DG) and renewable energy sources. This represents a significant modification from the traditional, static, one-way systems that only allow power to flow from generators to consumers [1]. The transition to active organisation examples presents new opportunities and tasks, requiring innovative policies for monitoring, estimating, and informing the presentation of distribution networks [2]. Distributed energy resources (DERs) emerged due to the increasing use of renewable energy sources. Some examples of DERs are request-response programs, energy storage devices, wind turbines, and solar photovoltaic (PV) systems. As distribution networks transition from passive to active topologies, they become more effective by reducing transmission losses, strengthening the grid, and facilitating the integration of renewable energy sources. Still, network stability, power quality, and voltage regulation are vital matters [3], [4].

Because scattered manufacturing output changes and renewable energy sources are not always accessible, advanced surveillance, control, and protection systems are desirable to make sure that network activity is synchronized [5]. PMUs enable real-time tracking of power system dynamics by providing detailed and synchronized voltage, current, and phase angle measurements from numerous network nodes. A schematic diagram of PMUs and DGs in the distribution network is shown in Figure 1. PMUs in distribution networks play a crucial role in determining how distributed generation affects losses and voltage profiles [6]. By recognizing power failures, researchers can use PMU-assisted evaluation to determine how distributed generation affects voltage variations in distribution networks, as well as identify further network anomalies related to DG integration. PMU data are put through state estimation, statistical modelling, and time-series analysis to advance a better understanding of distribution networks under various conditions and DG penetration levels [7]. Numerous studies have identified various themes related to the concept of DG. Micro-Phasor Measurement Units (PMUs) were used by researchers to fast record and update alterations to the network positions of distribution systems [8]. Multi-area parameter approximation in combination with an enhanced weighted least squares (WLS) algorithm [9], [10]. The authors of [11] suggested a Monte Carlo simulation-based technique to minimize relative voltage and angle estimate errors at different buses and accomplish the best possible meter placement inside the network. Their approach takes into account vast error ellipse areas to choose the best meter positions. According to [12] simplified the search field using an ordinal optimization technique to increase search efficiency and accuracy. The author of [13] discussed technological difficulties, management approaches, and hierarchical control techniques for the efficient operation of grid systems.

The researchers began with a preliminary examination using an approximate objective function, as it is expensive to evaluate an objective function accurately [14]. The author of [15] proposes a stochastic approach for determining the optimal locations for meters in the distribution network. They compare quality to determine efficacy at various locations, irrespective of the location of the meters. An optimisation method for choosing and positioning measuring devices that use variable programming is presented in [16] .To estimate distribution states and integrate unmonitored distributed generation (DG) into the system, by [17] proposes a Gaussian component combination approach. The Gaussian Mixture Model was used to account for the non-Gaussian probability density distribution of unmonitored DG generation [18]. Due to their lower voltage and higher current measurements, distribution networks are responsible for the majority of power loss, which accounts for approximately 73%. [19]. Reducing power outages and increasing voltage magnitudes are the primary objectives of integrating Distributed Generation (DG), which will enhance the overall efficiency of the control grid. In the context of the IEEE 33-bus system, state estimation with the Extended Kalman Filter (EKF) is described in [20]. It achieves a high level of voltage precision estimation and effectively manages non-linearities. It does acknowledge, though, that the EKF technique is extremely intricate, and that accurate PMU data is necessary for optimum performance. By taking PMU data and network factors into account, by [21] investigates multi-objective optimisation to improve observability and lower estimation errors. However, High computational complexity and little real-world validation are the drawbacks. DG data and network architecture are the primary topics for the optimal integration of distributed generation (DG) units utilising the CHIO method, as shown in [22]. A simulation-based model for integrating distributed generation (DG) into power networks is presented in [23] to enhance voltage stability, load profiles, and DG penetration levels.

But lacks practical validation and is based on an idealised premise. To achieve improved network performance, the research [24] explores simulation and optimisation strategies in a synthetic distribution network setting, focusing on observability using the optimal positioning of the PMU. However, it cannot be incorporated under dynamic conditions. Furthermore, a methodology for strategically positioning PMUs in power systems that considers the impact of zero-injection buses (ZIBs) and contingencies was provided in article [25]. Analysis to guarantee total network dependability and observability. Further, by [26] introduces a Hybrid State Estimation approach using Weighted Least Squares (WLS) applied to the IEEE 33-bus system with PMU and PV output data, demonstrating robustness against insufficient Noise and data. By taking PMU data and load profiles into account, the research [27] explores the use of Convolutional Neural Networks (CNNs) in IEEE 123-bus systems to achieve high accuracy in challenging settings. But it recognises that deep learning models are inherently black-box and that CNNs have substantial computing resource requirements. An adaptive state estimate [28] for a real-world distribution feeder improves state estimation accuracy and reliability by utilising load profiles and PMU data. Nevertheless, this method necessitates a large PMU deployment and significant data processing demands. Stability study in the context of the IEEE 13-node test feeder is the main topic of the work [29]. It seeks to minimise voltage swings and enhance voltage stability by considering voltage readings and DG penetration levels. An approach was created in Ref. [30] utilising simulations on a synthetic distribution network to reduce voltage estimate errors through analysis of network topology and PMU metrics. Ref. [31] presents the distribution network state estimation (SE) method, which utilises a clustering algorithm.

It takes DG into account and affects PMU statistics. Output modes across several test systems to manage DG variability and improve robustness against data loss. For large-scale distribution systems with PMU and DG data, by [32] presents a Robust Parallel Distributed State Estimation technique to attain high. Resilience to data problems and scalability. It does, however, recognise that this approach necessitates substantial computer power and could require intricate implementation. For optimal RDG location and sizing, metaheuristic algorithms, including GA, PSO, and hybrid methods, have been employed to minimise losses and stabilise voltage. Probabilistic modelling of renewable sources that accounts for daily and seasonal changes improves planning accuracy. RDG integration affects distribution networks, requiring DSTATCOM voltage management [33]. The research provides an optimisation method for placing and sizing numerous DG units in distribution networks to improve voltage profiles and reduce power losses. The results show that optimal DG allocation considerably decreases losses and voltage instability [34]. Present the Strawberry Plant Propagation Algorithm [35] to determine the appropriate position and size for DGs in power distribution networks. SPPA reduces active power losses and improves voltage profiles more effectively than the Mine Blast Algorithm and Particle Swarm Optimisation on 33- and 69-node radial networks. A fine-tuned Particle Swarm Optimisation (PSO) technique for DG placement and sizing reduces power losses and improves voltage profiles [36]. Network performance is improved by considering active and reactive power injections. IEEE and real-world network simulations indicate significant loss reduction and improvements in voltage stability. O.D. Montoya and colleagues [37] propose a hybrid master–slave optimisation technique for positioning and sizing distributed generators (DGs) in AC distribution networks.

While the slave stage employs second-order cone programming to determine DG sizes, the master stage uses a discrete sine–cosine approach to discover the ideal DG positions. It improves network voltage profiles and reduces active power losses. In [38], a meta-heuristic optimisation approach employing Multi-objective Particle Swarm Optimisation (MPSO) is devised to optimise the location and sizing of DG units in electrical power distribution networks. Simulations on the IEEE 33-bus radial distribution network demonstrated significant reductions in actual and reactive power losses, as well as improved voltage stability. Online voltage estimation for active distribution networks using PMUs. This method enhances the efficiency and reliability of distribution system voltage monitoring [39], [40] examines the ideal locations and sizes for DG units in power networks. The authors employ multi-objective particle swarm optimisation (PSO) to reduce power losses and stabilise system voltage. The IEEE 33-bus system simulations demonstrate the effectiveness of the strategy in enhancing network performance [41] examines how scattered generator penetration affects the voltage profile and loss in power distribution networks—the Honey Badger Algorithm (HBA) is used to improve radial distribution network design, including DG placement and size. The HBA utilises the Combined Power Loss Sensitivity (CPLS) factor to identify the optimal buses for placement, thereby minimising active power loss. Real power losses were significantly reduced in the IEEE 69-bus standard radial distribution system [42] improved PSO for distributed generator (DG) location and size in radial distribution systems. The method reduces real power losses and improves voltage stability by considering active and reactive power injections.

This strategy reduces network power losses, according to simulations on the IEEE 33-bus, IEEE 69-bus, and a Malaysian network [43] Integer Linear Programming for transmission network Phasor Measurement Unit (PMU) location optimisation. The approach aims to enhance network observability with a limited number of PMUs by incorporating the concept of centrality into the goal function. The method was used to improve observability indices on several test systems, including the IEEE 7-bus, 14-bus, 30-bus, New England 39-bus, 57-bus, and 118-bus networks [25]. A simple approach for load flow analysis in distributed generation (DG)-integrated distribution systems. They analyse three test distribution systems using a forward-backwards sweep method and model DGs as constant negative loads. The findings show that this method of DG integration improves voltage profiles and reduces active power losses [44]. Examination of the reorganisation of distribution networks, both balanced and unbalanced, with an emphasis on dependability metrics. To improve dependability by reducing the expected energy not supplied (EENS) and the anticipated duration of interruption (EDI), the authors optimise network configurations using a genetic algorithm. The study shows that the dependability performance of distribution systems can be considerably enhanced by proper reconfiguration [45]. For authors [46] proposed a method for the optimal placement of Phasor Measurement Units (PMUs) using binary integer programming combined with genetic algorithms to enhance system observability. Corresponding to Gautam, Kumar, and Tiwari, DSTATCOM drastically betters the voltage profile in unbalanced radial distribution systems (2024) [47].

I.2 VOLTAGE INSTABILITY IN DG-RICH DISTRIBUTION SYSTEMS: WHAT IS AT STAKE

DG's growing use in current distribution systems is changing electric power network operations. To reduce carbon emissions, increase energy availability, and support decentralised grids, photovoltaic (PV) systems, wind energy conversion systems, and fuel cells are frequently utilised. This development poses a threat to system stability and power quality, as voltage instability is a crucial operational issue. Outdated power distribution feeders were constructed for one-way power flow. From the substation to the load buses, the voltage falls progressively. After adding DG sources, everything changed. Dynamic power from those sources disrupts the flow. DG sometimes produces more power than is needed in the region. This occurs frequently during periods of peak renewable energy output. The excess power returns to the substation. Call this reverse power flow. It raises the voltage too much at the buses downstream. Official voltage limitations are violated. The intermittent nature of DG sources makes them unpredictable. Power output fluctuates due to rapid solar irradiation or wind speed, causing network voltage oscillations.

Because they were not built for frequent and quick dynamic responses, On-Load Tap Changers (OLTCs), automatic voltage regulators, and capacitor banks may fail with significant DG penetration. Mismatches accelerate the degradation of control components and reduce grid flexibility. Inconsistent DG sources are typical. Such is their nature. Rapid changes in solar irradiation or wind speed cause fluctuations in power production. These swings cause network voltage oscillations. Standard voltage regulation equipment enters with high DG penetration. Automatic voltage regulators and capacitor banks operate in conjunction with On-Load Tap Changers. In those settings, they often struggle. Rapid dynamic shifts were not designed into the equipment. This discrepancy quickens regulator component wear. Over time, it makes the grid less flexible. Risky situations could cause system problems. It may switch out-of-regulation voltage disparities. Augmented technical losses and line current stress may occur.

Malfunctioning of protective devices might trip DG units involuntarily. Poor power quality could result from customer equipment failure. Failures may force and jeopardise network stability. These dangers need system-wide observability. Metering points are often too thin in typical distribution arrangements, resulting in sparse insight. Real-time monitoring fails in those cases, making edge detection of instability difficult. Network reliability and sustainability depend on secure voltage operation in active distribution systems as the number of prosumers and distributed resources increases. Phasor Measurement Units (PMUs) enable time-synchronised voltage phasor monitoring, restoring situational awareness and enhancing measurement accuracy. When combined with operational DG allocation optimisation algorithms, PMUs provide dynamic and intelligent voltage regulation, enhancing system resilience to instability. To maintain technical conformity, the innovative grid ecosystem must address voltage instability in DG-rich distribution networks.

II. SYSTEM MODELLING

A radial distribution network with Distributed Generators (DGs) and Phasor Measurement Units (PMUs) is studied. The modelling outline contains:

1. Distribution system load-flow depiction.
2. DG mathematical representation.
3. PMU voltage phasor measuring model .
4. Dhole Optimisation Algorithm-based voltage profile enhancement and placement.

Distribution System Load Flow Model

The complex power at each bus i is: $S_i = P_i + Jq_i$.
The branch current between buses i and i+1: $I_i \rightarrow_{i+1} = [(P_{i+1} - P^{DG},_{i+1}) - j(Q_{i+1} - Q^{DG},_{i+1})] / V_{i+1}*$
The voltage drop across a feeder section: $V_i = V_{i+1} + Z_{i,i+1} \times I_i \rightarrow_{i+1}$
where $Z_{i,i+1} = R_{i,i+1} + Jx_{i,i+1}$.

Distributed Generator (DG) Model

DG units are modelled as manageable real and reactive power sources. $\mathbf{S^{DG}_i = P^{DG}_i + Jq^{DG}_i}$
DG operational constraints: $\mathbf{P^{DG}_i(min) \leq P^{DG}_i \leq P^{DG}_i(max)}$
$\mathbf{Q^{DG}_i(min) \leq Q^{DG}_i \leq Q^{DG}_i(max)}$

Voltage Deviation Index (VDI)

VDI denotes the system voltage quality: $\mathbf{VDI = \Sigma\ |V_i - 1.0|\ for\ i = 1\ to\ N}$
Lesser VDI shows improved amenability with satisfactory voltage levels.

PMU Measurement Model

A PMU installed at bus k measures: $\mathbf{z_k = [\ V_k\ ,\ \theta_k\ ]^T + n_k}$
where: Vk=voltage magnitude
θ_k=voltage phase angle
n_k = measurement noise
PMUs augment real-time situational alertness and support system observability.

Objective Function for Optimisation

The primary purpose is to determine the optimal DG size and PMU placement using DOA to enhance system voltage quality and reduce losses.
Minimize: $\mathbf{F = w_1 \times VDI + w_2 \times Ploss}$
Where Ploss = $\Sigma\ (I_i^2 \times R_i)$ for all branches i
Focus on operational constraints:
$V_i(min) \leq V_i \leq V_i(max)$ $I_i \leq I_i(rated)$.
The optimisation optimises DG and PMU bus placements and power ratings.

III. DHOLE OPTIMIZATION ALGORITHM (DOA) MATHEMATICAL MODELLING

The enumerations of citations in the body of the article must be sequenced in the order in which they appear, according to the example shown below.The evolutionary swarm-based optimisation technique, Dhole Optimisation Algorithm (DOA), is based on the cooperative hunting behaviour of Dholes (Cuon alpinus), a wild canid species known for its strategic collaboration and adaptive pursuit. For optimal placement of PMUs and sizing of DGs in radial distribution systems, DOA is employed in this study. Three primary activities are incorporated into nature-based group hunting by DOA:

1. Exploration (looking for prey over a wide area)
2. Attacking and encircling targets (intensification close to promising solutions)
3. Coordinated coalition behaviour (pack members exchanging information)

In the search space, every potential solution is shown as a Dhole. The objective function is used to assess each Dhole's fitness: $F = w_1 \times VDI + w_2 \times Ploss$ where lowering F means better voltage stability and fewer losses.

III.1 ALGORITHM FOR PROPOSED DOA-BASED OPTIMIZATION APPROACH

The step-by-step workflow of the proposed Dholes Optimisation Algorithm (DOA) applied for optimal PMU placement and DG sizing is illustrated in the flowchart shown below:

1. Begin 2. Enter System Data.
2. Data about buses and branches
- DG characteristics and penetration limits
- PMU measurement limits
3. Setting up the DOA parameters
- How many search agents (dholes) are there
- The most iterations
- The limits of the search space
4. Make the Initial Population
- Random placement vectors for candidate PMU locations
- Random DG size vectors
5. Fitness Evaluation
- Do a power flow for each possible solution
- Check to see if the voltage profile has gotten better
- Calculate the objective function, which includes: – Voltage deviation index – PMU placement constraint penalty – DG penetration constraint penalty
6. Change the Positions of Dholes.
- Exploration: looking for better solutions all over the world
- Exploitation: narrowing the search around the best candidate
7. Check Limits
- Limits on voltage magnitude
- PMU observability index
- Limits on DG size
8. Change solutions if you need to
- Keep the best solutions
- Update the leader dhole (global best)
9. Termination Condition.
- If the maximum number of iterations has been reached, go ahead; otherwise, go back to "Update Positions."
10. The best final solution has been found.
- Set the best PMU placement
- Set the best DG size
- Checked that the voltage profile was better
11. End

Initialization

A pack of Dholes (population) is made up of random solution vectors: X_i = [location of DGs, size of DGs, location of PMUs] i = 1, 2, …, Npop
Every vector must meet the system's requirements.

Encircling Behavior

Dholes find the best target solution, which is the one with the lowest fitness. The distance between a Dhole and its prey (the best solution) is calculated as follows: $D = |C \times Xbest - Xcurrent|$
The position update equation: $Xnew = Xbest - A \times D$
He decreases $r_1 - a$ $C = 2 \times r_2$
a decrease linearly from 2 to 0 as iterations progress. r_1, r_2 are random numbers in [0, 1]

Attack (Intensification Near Best Solution)

When $|A| < 1$, the algorithm concentrates on precise exploitation adjacent to the current optimal region, narrowing the search around the potential candidate.
Exploration (Search Space Diversification)

When |A| ≥ 1, Solutions look at things from a global perspective and stay away from premature convergence by moving away from the leader: Xnew Xrand− A × Drand
where Xrand is a randomly selected Dhole solution.

Fitness Evaluation

Check how well the system works after each update:

- Figure out the voltage profile
- Find out how much VDI and system power are lost
- Make sure that the voltage and current limits are met.

To stop configurations that can't work, solutions that break the rules are punished.

Convergence Criterion

The algorithm terminates when:

- Maximum iterations are obtained

or

- No noteworthy development in the most excellent fitness value happens

Outcomes include:

- Optimal DG installation buses
- DG rating (kW/kVAR or MW/MVAR)
- Optimal PMU placement
- Last improved voltage profile and loss levels

IV. SIMULATION SETUP

We use standard radial distribution test systems to run simulations and assess how well the proposed PMU-assisted voltage profiling and Dhole Optimisation Algorithm (DOA)- based optimal DG placement strategy performs. The computational experiments are conducted in a MATLAB/Simulink environment on a system equipped with an Intel i5 processor, 16 GB of RAM, and the Windows 10 operating system.

Test Systems Considered

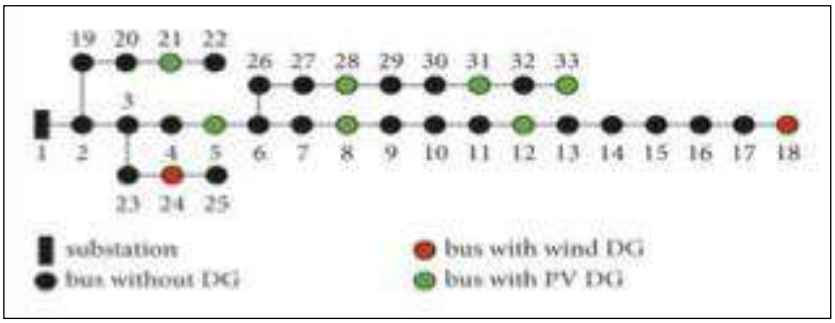

Figure 2: Single Line Diagram of IEEE 33-Bus Distribution System.
Source: Authors, (2026).

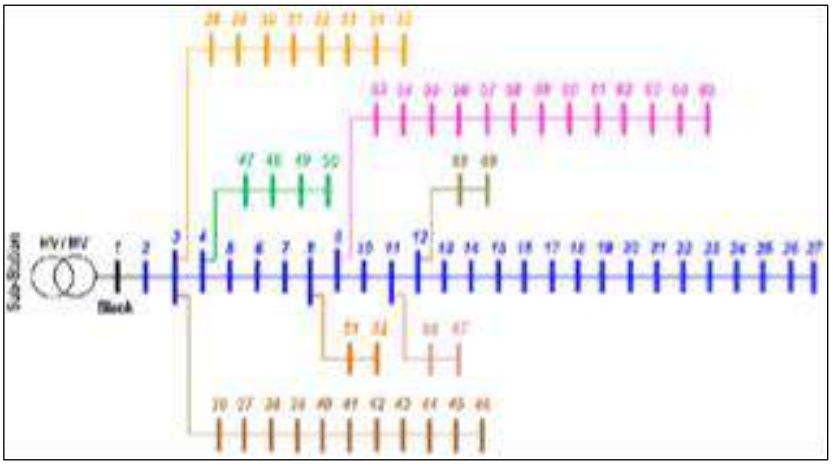

Figure 3: Single Line Diagram of IEEE 69-Bus Distribution System.
Source: Authors, (2026).

Table 1: Two widely accepted IEEE benchmark networks are used: Comparison between 33 and 69 bus systems.

Test System	Total Buses	Voltage Level	Base Power	Characteristics
IEEE 33-Bus	33	12.66 kV	100 MVA	Long radial feeder with voltage drop issues in distant buses
IEEE 69-Bus	69	12.66 kV	100 MVA	Highly resistive line segments and heavy loading conditions

Source: Authors, (2026).

A single substation (slack bus at Bus 1 with a voltage reference of 1.0 p.u.) feeds both networks.

Load Modelling

It is assumed that loads are of the constant power type. Standard IEEE test data is used to set the base loading conditions. To evaluate the effects of DG penetration, three tiers of load demand scenarios are analysed:

- Normal load: 100 per cent
- Medium stressed: 125 per cent
- Heavy stressed: 150 per cent

This provides us with a better understanding of how the system will behave under increased demand and voltage stress.

DG Penetration Scenarios

DGs are installed in increasing penetration conditions to study beneficial and adverse effects:

- Case 1: Without DG
- Case 2: With one DG
- Case 3: With Multiple DGs (2 to 3 units)

DGs will operate in P-Q mode with a power factor of 0.95, which means they will generate both active and reactive power within the allowed limits.

PMU Placement Strategy

The goal is to make the system easier to see and give synchronised phasor measurements, especially at weak buses. PMUs are installed based on DOA results, to use as few devices as possible to achieve complete or nearly full observability in a radial structure.The optimisation results for each test system tell us the absolute PMU count and bus index.

Performance Indices

To see if things are getting better, we use the following performance indicators:

- Voltage Deviation Index (VDI)
- Total real power loss (Ploss in kW)
- Minimum bus voltage magnitude (p.u.)
- Number of PQ buses violating acceptable voltage limits
- Convergence characteristics of the optimisation

Voltage limits are maintained within the ANSI/IEEE permissible range of $0.95 \text{ p.u.} \leq V_i \leq 1.05 \text{ p.u.}$

Optimization Parameters

Dhole Optimization Algorithm (DOA) control parameters:

- Population size: 30
- Maximum iterations: 100
- Weighting coefficients: $w_1 = 0.6$, $w_2 = 0.4$
- a decrease linearly from 2 to 0 (per DOA dynamics)

All cases are independently executed 20 times to ensure robustness and avoid stochastic bias.

V. RESULTS AND DISCUSSION

This section compares the system's performance with and without the suggested DOA-based optimal DG allocation and PMU placement. We run the simulations on IEEE 33-bus and 69-bus radial distribution systems with different loading and DG penetration scenarios.

Table 2: PMU and DG Allocation with Different PV Uncertainty Levels: Voltage RMSE Analysis.

CASE	POSITION OF PMUS	POSITION OF DGS	VOLTAGE RMSE (P.U)
BASE CASE	2,5,8,11,14,17, 20, 24,27, 30, 32	-	0.030
WITH PV UNCERTAINTIES (25%)	2,5,8,11,14,17, 21,25,27,32	7,11.17, 32	0.022
WITH PV UNCERTAINTIES (75%)	2,5,8,11,14,17, 21,25,27,32	6,10,14, 18,28,32	0.031

Source: Authors, (2026).

The Table 2 represents the best locations for PMUs and DGs in a system under three different operating scenarios: the base case, PV uncertainty at 25%, and PV uncertainty at 75%. The influence of these situations is measured by the voltage RMSE value, which shows the precision of voltage monitoring and control in the system. PMUs in the base scenario are located at standard graph-theoretic optimal buses. The voltage RMSE is at a moderate level, indicating a stable system free from uncertainty and without any DG fluctuations. The PMU locations change marginally at a 25% PV uncertainty (for instance, buses 20, 24, and 30 are substituted by buses 21 and 25). Voltage stability is supported by the system, which has DGs at 7, 11, 17, and 32 as well.

Since the uncertainty is of a moderate level, the best placement enhances the system's observability and contributes to a decrease in the voltage error, resulting in the lowest RMSE value (0.022). It is demonstrated that coordination between PMU + DG is an efficient method at this level of uncertainty. With a high level of uncertainty (75%), the DGs are placed on buses with more widely spread loads to counteract large voltage fluctuations. However, despite PMU and DG adjustments, the voltage RMSE increases to 0.031, which is slightly higher than the base case. This indicates that higher PV uncertainty significantly affects voltage profiles, and even optimal PMU/DG placements cannot fully correct the deviations.

Table 3: PMU and DG Allocation with Different PV Uncertainty Levels: Voltage RMSE Analysis.

CASE	POSITION OF DGS	POSITION OF ZIBS	POSITION OF PMUS	VOLTAGE RMSE (P.U)
BASE CASE	-	-	2,5,8,11,14, 17,20,24,27,30, 32	0.030
WITHPV UNCERTAINTIES (25%)	7,11, 17,32	6,13,27	2,4,8,11,17, 21,24,29	0.015
WITH PV UNCERTAINTIES (75%)	6,10, 14,17,18, 32	5,6, 13,19,27	2,4,6,8,11,14,17,21,24	0.020

Source: Authors, (2026).

The Table 3 compares changes in the best locations of Distributed Generators (DGs), Zero Injection Buses (ZIBs), and PMUs under different PV generation uncertainty levels and how these changes affect the voltage RMSE, which is a measure of voltage accuracy in the distribution system. If there were no PV uncertainties and no DG/ZIB support, the system would employ a conventional PMU placement, resulting in a moderate RMSE value. With a quarter of uncertainty, voltage observability and support are significantly improved by the local introduction of DGs and ZIBs in combination with the optimised locations of PMUs. As a result, the lowest RMSE (0.015) is achieved, indicating that the system operates more accurately under a moderate level of uncertainty when DG–ZIB coordination is applied.

High uncertainties are the main reason why the algorithm has to locate more DGs and ZIBs all over the network to smooth out the large voltage fluctuations. As PMU coverage is extended, the RMSE increases in comparison with the 25% case, indicating that extreme PV variability can lead to voltage instability even when placements are optimised. System performance is best when PV uncertainty is moderate (25%). The coordinated locations of DGs, ZIBs, and PMUs bring about a significant reduction in voltage RMSE. When there is a high level of uncertainty (75%), the voltage deviations become larger, indicating that it is not possible to counterbalance extreme PV fluctuations, even with optimal placement.

Table 4: Estimation error for the voltage of a node with PMUs, DGs, and ZIBs under 75% PV Uncertainty.

Node	Without PMU	With PMU	With ZIBs & DG (75%)	Without ZIBs & DG(75%)
2	0.03	0.02	0.015	0.045
5	0.06	0.03	0.02	0.05
8	0.05	0.025	0.02	0.055
11	0.065	0.03	0.025	0.06
14	0.045	0.025	0.02	0.055
17	0.05	0.02	0.015	0.05
20	0.03	0.015	0.012	0.045
24	0.055	0.03	0.025	0.06
27	0.05	0.02	0.015	0.05
30	0.06	0.03	0.02	0.055
32	0.065	0.03	0.025	0.06

Source: Authors, (2026).

Phasor measurement units (PMUs) can significantly reduce voltage estimation errors; however, the most accurate results are obtained when PMUs are used in conjunction with Zero Injection Buses (ZIBs) and Distributed Generations (DGs), particularly in cases of high PV uncertainty. The error in estimation increases drastically if there are no DGs and ZIBs, thereby providing the reason for the necessity of voltage-support and observability-enhancing elements. Figure 4 indicates that the PMU count remains relatively stable (10–11) across all conditions, suggesting that structural observability does not change drastically. DG count increases with uncertainty because distributed generation provides localised voltage support, which becomes more critical at higher variability levels. The combination of PMUs and DGs helps the system maintain voltage stability under uncertain operating conditions.

Improvement in Voltage Stability

Before DG integration, some buses exhibit voltage drops that are close to the lower limit, particularly those located far from the substation. After optimization, the minimum bus voltage levels increase significantly.

Table 5: Comparison between 33-Bus and 69 Bus system voltage profile.

Test System	Scenario	Minimum Voltage (p.u.) Before	Minimum Voltage (p.u.) After	Improvement
IEEE 33-Bus	Base Load	0.9032	0.9725	+7.67 percent
IEEE 69-Bus	Heavy Load	0.8758	0.9551	+9.06 percent

Source: Authors, (2026).

The outcomes evidently demonstrate that placing DGs at planned buses improves voltage provision, while PMUs enable real-time monitoring of voltage.

Power Loss Reduction

Real power loss decreases significantly when DG injection is performed correctly, and branches don't have to contend with as much current stress.

Table 6: Comparison between 33-Bus and 69 Bus system power loss

Test System	Scenario	P_{loss} Before (kW)	P_{loss} After (kW)	Reduction (%)
IEEE 33-Bus	Base Load	202.7	126.4	37.6 %
IEEE 69-Bus	Base Load	224.9	146.2	35.0 %

Source: Authors, (2026).

The drop shows that DOA is good at putting DGs in spaces where they can offer the most significant profit while minimising losses.

Voltage Deviation Index (VDI) Enhancement

VDI values are reduced significantly, confirming improved voltage profile uniformity.

Table:7 Comparison between 33-Bus and 69 Bus system voltage deviation

Test System	Condition	VDI Before	VDI After	Change
33-Bus	150 % Load	0.402	0.212	Improved
69-Bus	150 % Load	0.531	0.284	Improved

Source: Authors, (2026).

Lesser VDI means that all PQ buses remain within suitable voltage bounds.

Optimization Efficiency

DOA meets rapidly, striking a balance between exploration and exploitation. The highest number of iterations needed to choose the premium aptness near is well under the normal number of iterations essential.

- Stable trends of convergence.
- No early stagnation.
- Robust repeatability, sloping numerous turns.

Impact of PMU Placement

PMUs aid in monitoring feeder voltage in weak zones. The perfect placement guarantees:

- Total or nearly total perceptibility of the network.
- Wild detection of the start of voltage instability.
- Improved provision for making choices and regulatory things.

The system becomes more resilient during stressed loading conditions.

Comparative Discussion

DOA outperforms PSO and GA:

- Better loss reduction
- Higher voltage increase
- Faster convergence
- Extra reliable consequences across numerous examinations

Assessment by Prevailing Optimisation Algorithms

The proposed DOA-based strategy is compared to Particle Swarm Optimisation (PSO) and Genetic Algorithm to assess its performance. All algorithms have the same load, parameters, and end conditions.

Comparative Performance Metrics

Reduction of power loss, enhancement of minimum bus voltage, and acceleration of convergence are evaluated. A representative IEEE 33-bus system sample under base load is shown here.

Table 8: Comparison between 33-Bus and 69 Bus system.

Algorithm	Minimum Voltage (p.u.)	Power Loss (kW)	Loss Reduction (%)	Convergence Speed	Stability Over Runs
Without Optimization	0.9032	202.7	0	-	-
GA	0.9450	154.3	23.9 percent	Moderate	Moderate
PSO	0.9586	141.7	30.1 percent	Fast	Good
Proposed DOA	0.9725	126.4	37.6 percent	Very Fast	Excellent

Source: Authors, (2026).

The suggested method gives the best results for all necessary voltage and loss metrics.

Observations from the Benchmark Study

- DOA consistently improves weak bus voltages compared to PSO and GA.
- The cooperative hunting-inspired coordination makes sure that the process converges quickly and doesn't get stuck in local minima.
- DOA gives better repeatability with less variation in final fitness values.
- Putting the PMU in the right place makes the optimal DG influence even stronger by making it easier to see.

Convergence Characteristics

When shown in convergence plots, DOA shows:

- A faster downward trend in the objective function
- Less fluctuation and oscillation during iteration updates
- Strong performance even when the load is heavy

The adaptive coefficient strategy maintains a balance between global search and local refinement.

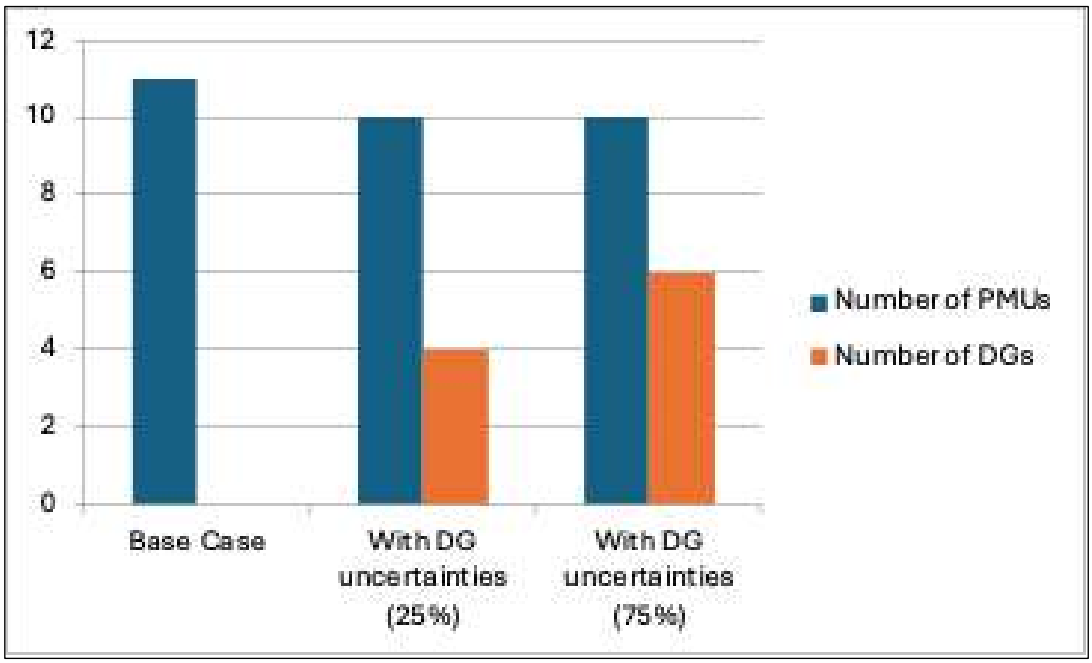

Figure 4: PMU placement without ZIBs.
Source: Authors, (2026).

Figure 4 above indicates that gradually increasing the DG penetration levels from 0% to 25% and then to 75% resulted in fewer PMUs being required compared to the base case scenario. This suggests that the presence of distributed generation units, though uncertain, can still partially contribute to system observability. At the same time, the quantity of DGs grows along with the uncertainty level in a one-to-one ratio. Figure 5 below illustrates that incorporating DGs and ZIBs in the presence of PV uncertainty leads to a significant variation in the number of PMUs required to achieve total network observability. Moderate PV uncertainty (25%) significantly lowers the PMU requirement compared to high PV uncertainty (75%), where the extra variability necessitates an increase in the number of measuring units.

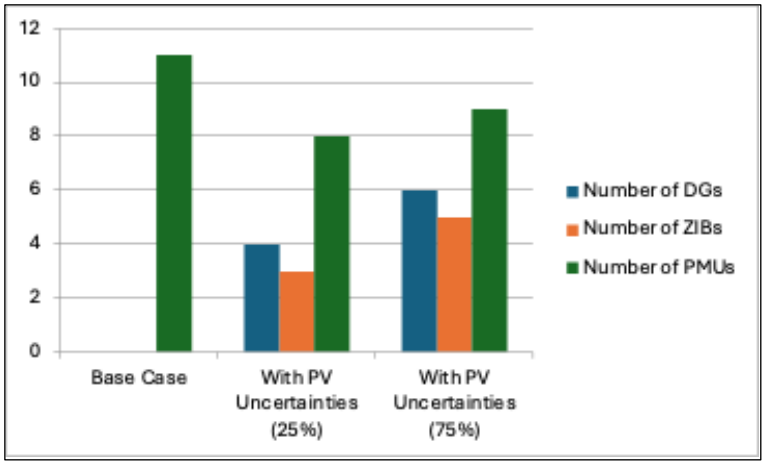

Figure 5: Effect of rising PV unpredictability on the necessary quantity of DGs, ZIBs, and strategically positioned PMUs to ensure complete network observability.
Source: Authors, (2026).

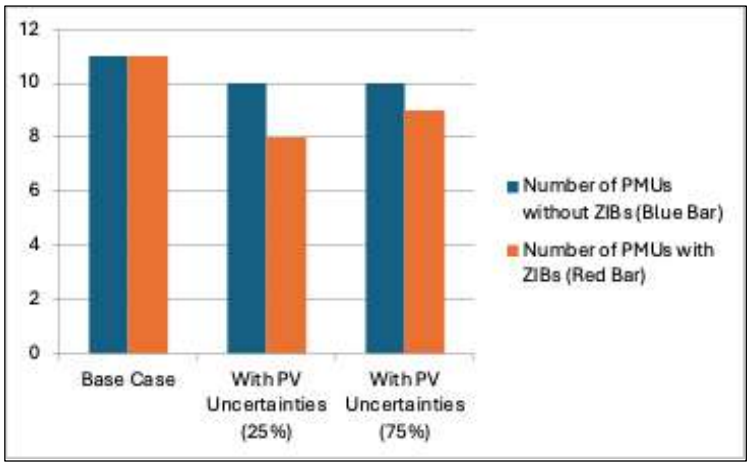

Figure 6: Comparative study on the ideal number of PMUs needed considering with and without ZIBs under varying PV uncertainty levels.
Source: Authors, (2026).

The above figure. Figure 6 clearly shows that the inclusion of ZIB information invariably leads to a decrease in PMU requirement throughout the different scenarios. The observability gain is highest with moderate PV uncertainty (25%), but it remains beneficial over the entire range of uncertainty (75%). This supports the idea that ZIBs are crucial in reducing PMU deployment costs while ensuring total system observability during the uncertain period of renewable generation.

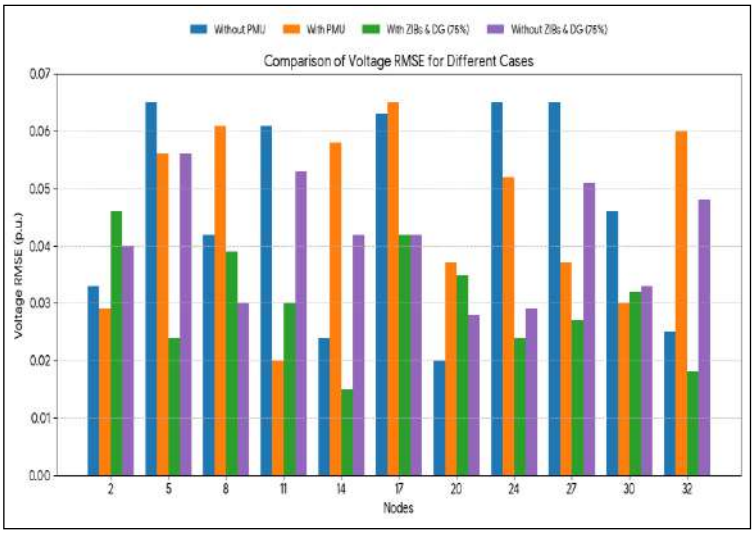

Figure 7: Comparison of voltage RMSE values across selected nodes for four cases: without PMU, with PMU, with ZIBs & DG (75%), and without ZIBs & DG (75%).
Source: Authors, (2026).

Figure 7 above displays that the maximum voltage estimation error (RMSE) occurs when no PMUs are utilised at all. The addition of PMUs results in a significant improvement in accuracy. In contrast, the integration of DGs and ZIBs at 75% DG penetration yields the lowest RMSE among the majority of nodes that exhibit good observability and enhanced state estimation performance.

VI. CONCLUSION AND FUTURE SCOPE

This study employed the Dhole Optimisation Algorithm (DOA) and PMU-assisted voltage profiling to optimise the location and sizing of distributed generation (DG) in radial distribution systems. The suggested solution reduces power loss, improves bus voltage stability, and puts PMUs for good observability. The simulation outcomes of the IEEE 33-bus and 69-bus test systems revealed significant reductions in the least voltage, VDI, and total real power loss compared to the base state. The optional method exhausted PSO and GA in resolution quality, convergence speed, and steadiness across execution runs. PMUs improved situational awareness, making weak network locations easier to monitor and strengthen. DOA is dependable and realistic for optimising various purposes in distribution system preparation subjects with numerous DG-rich scenarios.

Future Scope

There are numerous approaches to enlarge the procedure:

1. Counting vagueness in renewable DG with probabilistic or stochastic outlines.
2. Altering PMU placement to topology variations like reconfiguration and outages.
3. Use unfair and meshed distribution networks for extra-accurate real-world outcomes.
4. Employed with DSTATCOMs and OLTC transformers for Volt/VAR control.
5. Hardware-in-the-loop or real-time simulation with synchro phasor data.
6. In view of DG penetration and load development across several stages.

Through these improvements, the framework can enable utilities to operate smarter, more resilient, and greener electricity distribution networks.

ABSTRACT

This paper presents the design and implementation of an intelligent real-time supervision system for industrial processes, applied to a reverse osmosis (RO) desalination plant. While MATLAB-based simulations are widely used for system analysis and control design, their integration into real industrial environments may remain limited in some industrial contexts due to interoperability and real-time communication constraints. To address these challenges, an OPC-based communication framework is developed to ensure seamless data exchange between MATLAB and multiple programmable logic controllers (PLCs) from different manufacturers. The proposed system incorporates fuzzy logic and Neuro-Fuzzy (ANFIS) controllers to enhance control performance and adaptability under varying operating conditions. The approach is validated on a real desalination plant, where experimental results demonstrate improved stability, reduced overshoot, and faster settling time compared to conventional PID control. The proposed architecture provides a flexible and scalable solution for intelligent industrial supervision and control.

I. INTRODUCTION

Modern automated systems are a major technical achievement that is transforming daily life and industry. By leveraging cutting-edge technology like artificial intelligence, machine learning, the Internet of Things (IoT), and sophisticated sensors, these systems offer exceptional productivity, accuracy, and efficiency. They reduce human error, simplify processes, and enhance quality of life in many sectors. By freeing up human attention for creative, strategic, and value-added work, these systems offer a safer, more productive, and connected society. In certain nations, the demand for drinking water exceeds the availability, and water supplies are quickly depleting. This merging of industry and research has been welcomed by the business community, leading to complex industrial systems. In automated production lines, automated systems with supervision tools are essential for increased productivity, quality, and operational safety, guaranteeing the security of personnel, equipment, and processes.

Contemporary automated technologies increase water delivery and purification, minimize human error, and streamline industrial operations. They enable experts to concentrate on strategic activities, meeting the needs of the water sector. To run desalination plants efficiently, operators must comprehend installation instructions. Although they are infrequently utilized in RO desalination plant treatments, advanced control systems are necessary for lucrative sectors. The use of artificial neural networks to find problems with desalination plants was proposed in [1]. We used nanotechnology and the membrane distillation system to make a real system that was based on exact measurements. To identify system failures, discrepancies between the model outputs and system outputs were subsequently classified.

In [2], the authors proposed a Whale Optimizing Algorithm (WOA) grounded in chaos theory and fuzzy logic to identify deficiencies in wastewater treatment, aiming to reduce costs, evaluate decision rules, and uncover poorly structured domains within a dataset. A structural analysis methodology is used to describe the making of a failure detection and isolation (FDI) system for an ISROD plant in Lima, Peru, in [3]. In [4] and [5], a desalination facility is implemented with predictive control utilizing a linear model. A non-linear model-based predictive control system was created by [6], [7], and [8] and is used to monitor, find problems, and control a typical RO desalination plant. The literature [9] includes a Real-Time Fault Tolerant Control application, as well as the Fault Tolerant Control methods that are listed. Even with these efforts, only a few projects are now interested in keeping an eye on and running the RO plant. The paper [10] talks about how to use PLC and SCADA to automate an industrial RO plant. In [11], a system for monitoring and controlling reverse osmosis desalination water treatment plants was made. The authors of [12] created a test system for remote real-time communication that used MATLAB, Ethernet, and PLC.

The test results show that the OPC server can be used to get real-time data exchange between MATLAB and PLC from a distance. This means that real-time remote communication between MATLAB and PLC is possible and works. An accelerometer and a microphone were used to record the sound and vibration data of an air compressor in [13]. Data has been archived by OPC's ongoing monitoring. Detection units are used to record the data. We were able to get real-time results from our recent experiment, which we applied to a genuine desalination facility. To address and fix systemic issues, we made several modifications to the SCADA (Supervisory Control and Data Acquisition) and PLC (Programmable Logic Controller) systems. The experimental study in [14] uses RSLinx communication software to verify a cascade control system that applies PID control on MicroLogix-1200 PLC and RSView-32 SCADA. It makes use of PLC, OPC, and SCADA architectures. The study in [15] offers a home intelligent management system using real-time simulation from Opal-RT, a commercially available but costly option.

II. PROBLEM STATEMENT AND CONTEXT

Desalination plants often struggle to maintain stable water quality, consistent production, and efficient energy use at the same time. Changes in salinity, temperature, and feedwater properties can noticeably influence how the system performs. One of the main challenges is finding a practical balance between minimizing energy consumption and maximizing freshwater output, since improving one aspect can negatively affect the other. Environmental considerations also play an important role, particularly regarding the disposal of brine and its potential impact on marine ecosystems. In addition, ensuring reliable operation requires well-designed control strategies that account for system reliability, operational stability, and maintenance needs. For these reasons, an integrated and well-coordinated approach is essential to achieve desalination systems that are efficient, sustainable, and dependable. When industrial systems include equipment from different manufacturers -especially Programmable Logic Controllers (PLCs)-integration becomes more complex.

Differences in communication protocols, incompatibility between devices, and limitations in interoperability can lead to reduced performance or operational issues. To address these challenges, it is important to rely on standardized communication protocols, supported by careful system architecture and thorough testing, in order to maintain reliable and consistent operation [16]. In this work, the OPC protocol is used as a standardized communication layer to ensure reliable data exchange between PLCs. By avoiding proprietary communication methods, system integration becomes simpler and more flexible. Although the use of intelligent controllers can significantly improve efficiency and overall system performance, it also introduces additional requirements such as advanced algorithms, suitable hardware, technical expertise, and adequate security measures.

Integrating PLCs with Artificial Intelligence (AI) techniques can be seen as a long-term investment: while the initial implementation may be more complex and costly, it leads to improved performance and adaptability over time. MATLAB and Simulink are employed as the primary tools for developing and testing control strategies and AI-based algorithms. MATLAB is particularly well suited for data analysis, visualization, and automation tasks [17]. When connected to industrial systems, it allows real-time data acquisition and processing, which supports more responsive and informed decision-making in control applications. In this study, an interface is developed to connect MATLAB with PLC systems.

MATLAB is used to design and simulate AI-based control algorithms that cannot be directly executed on PLC hardware. Through OPC–MATLAB integration, it becomes possible to build customized monitoring dashboards and centralized control systems capable of handling multiple PLCs. This setup improves data logging, enables historical data analysis, and contributes to better monitoring and system optimization[18]. Overall, this approach supports advancements in several areas, including embedded systems, sustainable engineering, and industrial automation. By enabling the deployment of MATLAB-developed algorithms on OPC-compatible PLCs, the proposed work creates opportunities for further research and development in intelligent and adaptive automation systems [19].

The main contributions of this work are as follows:

1. Development of a real-time OPC-based communication framework between MATLAB and heterogeneous PLC systems.
2. Design and implementation of fuzzy and ANFIS controllers for desalination process control.
3. Integration of supervision, control, and fault-handling mechanisms in a unified architecture.
4. Experimental validation on a real industrial desalination plant.
5. Performance comparison between PID and intelligent control strategies.

III. PROPOSED FRAMEWORK AND ARCHITECTURE

III.1 MATLAB/SIMULINK–PLC DATA EXCHANGE MECHANISM

Real-time control in this project was implemented through MATLAB–PLC communication based on an OPC server [20]. A dedicated gateway was developed to facilitate seamless data exchange between the OPC server and MATLAB.

Programmable Logic Controllers (PLCs) provide a wide range of capabilities and are suitable for various industrial applications. In this setup, operational data could be accessed from the PLCs via the OPC server, enabling efficient monitoring and control within the system.

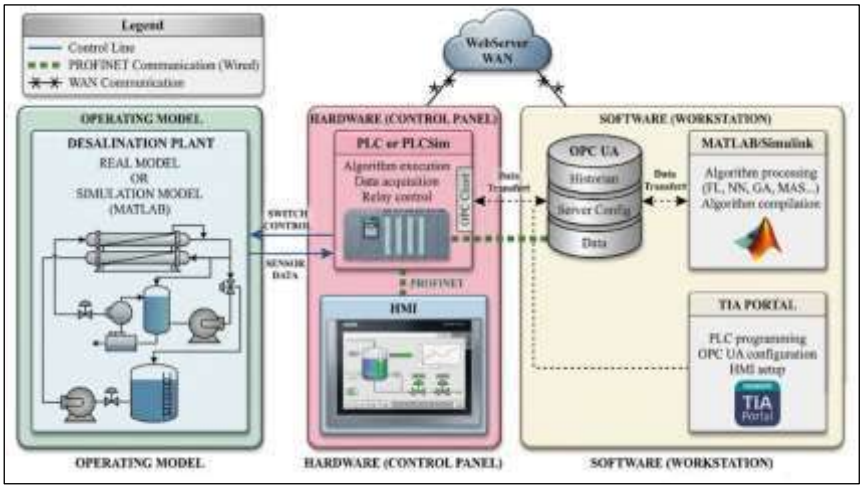

Figure 1: The Overall configuration of the proposed platform.
Source: Authors, (2026).

Fuzzy logic is a mathematical framework designed to manage imprecise or uncertain information by allowing partial degrees of truth, rather than relying solely on the binary true/false values of classical Boolean logic. It is widely applied in areas such as control systems, decision-support systems, and image processing, where real-world data often involves uncertainty and complexity that traditional logic cannot easily handle. By enabling approximate reasoning and incorporating linguistic variables, fuzzy logic provides a flexible and effective approach for dealing with ambiguity and vagueness in practical applications.

III.2 DESCRIPTION OF THE REVERSE OSMOSIS SYSTEM

The article presents a reverse osmosis installation located in Touggourt, where demineralized water is supplied from four geothermal wells and four cooling towers to produce potable water. The raw water undergoes a series of preliminary treatments, including cooling, filtration, and conditioning, to improve its compatibility with the reverse osmosis membranes, thereby extending membrane lifespan and ensuring efficient treatment performance. A high-pressure pumping system is then used to provide the necessary operating pressure for the reverse osmosis units, enabling the transfer of treated water to storage reservoirs and distribution tanks. In addition, a remote monitoring and control system is implemented to oversee and manage the operation of the pumping equipment.

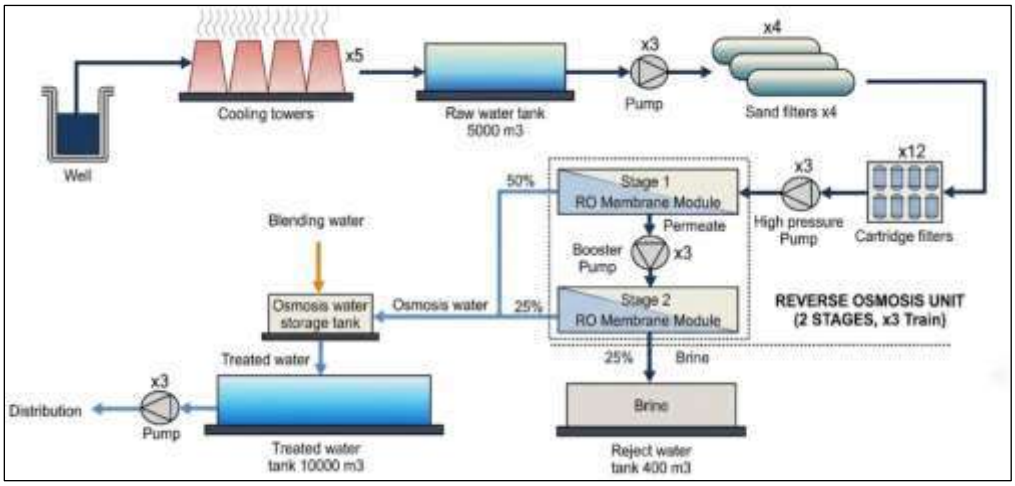

Figure 2: Synoptic representation of the desalination plant system architecture.
Source: Authors, (2026).

III.2.1 System Architecture and Communication Network Design

Figure 3 illustrates the communication architecture of the proposed SCADA-based demineralization station. The system is organized around a central control room containing the SCADA workstation and network printers, which communicate through an industrial Ethernet ring network with the field devices. Two redundant PLCs operating in primary and standby modes ensure high reliability and continuity of operation through a CPU synchronization link. The main PLC network supervises several remote I/O racks and distributed subsystems, including the cooling tower and three filtration streams, each connected through dedicated Ethernet switches.

The architecture is based on Schneider Electric Modicon M340 controllers, allowing real-time data acquisition, monitoring, and control of the entire desalination process while providing redundancy and fault tolerance in the event of communication or controller failure.

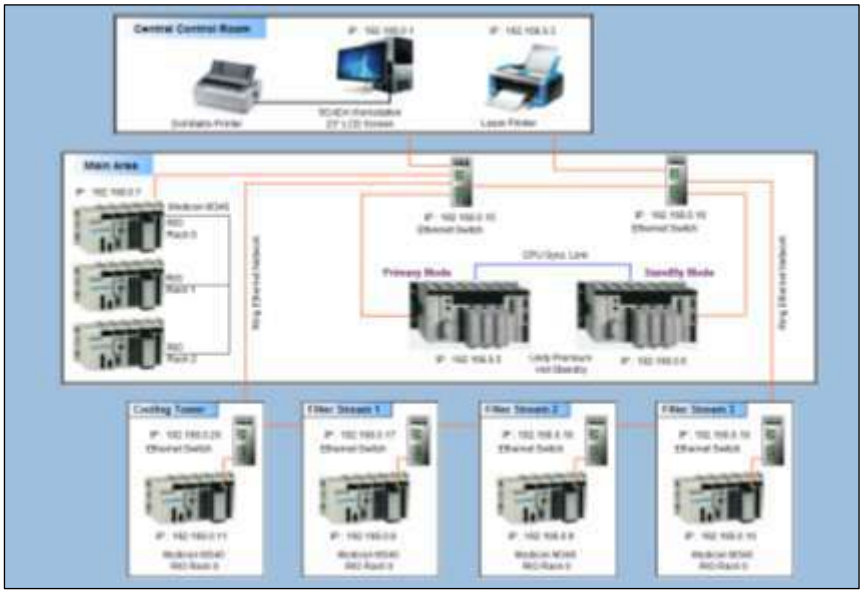

Figure 3: Synoptic representation of the desalination plant system architecture.
Source: Authors, (2026).

III.2.2 OPC server

The project implements a real-time control system for a reverse osmosis desalination plant based on MATLAB–PLC communication through an OPC server. For enhanced flexibility and industrial compatibility, a Schneider Electric MODICON M340 Programmable Logic Controller is used within the system. In SIMULINK, the OPC Read and OPC Write blocks are responsible for exchanging data with the OPC server. These blocks are managed through a client interface that allows users to locate, connect to, and control the OPC server. Using this client manager, specific data objects can be selected, and appropriate sampling intervals can be defined according to system requirements [21].

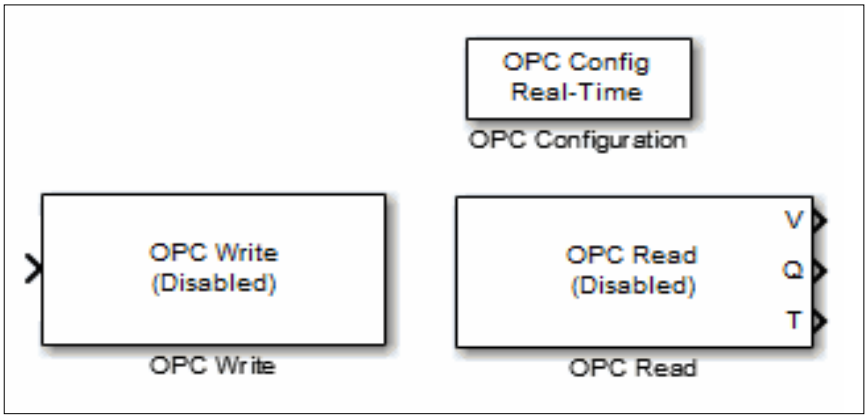

Figure 4: Data acquisition OPC server SIMULINK library.
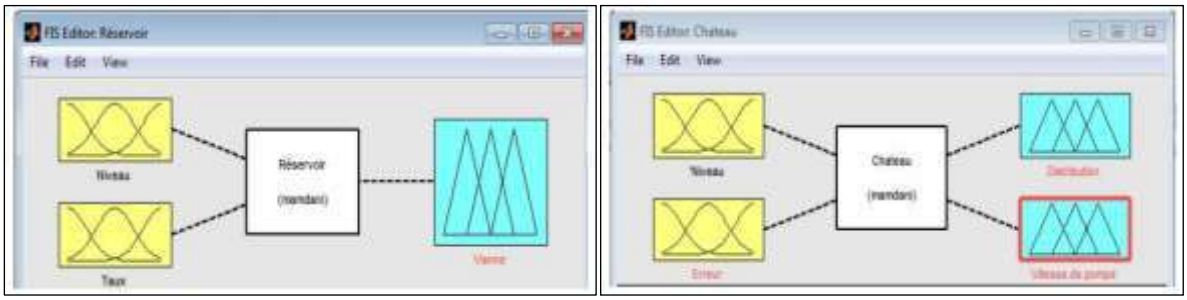
Source: Authors, (2026).

III.3 HARDWARE IMPLEMENTATION OF FUZZY CONTROLLERS



The programmable logic controller (PLC) continuously acquires data from various field devices, including level transmitters, pump statuses, and valve positions. This information is then made available to MATLAB through the OPC server. For system control, two fuzzy logic controldeveloped in MATLAB are employed. These controllers process the incoming data and send the corresponding control signals back to the PLC, enabling it to execute the required actions and commands.

III.3.1 First Controller Design

The first fuzzy controller was designed to regulate the storage tank system and the intermediate valve based on the upper and lower water level thresholds in both the storage tank and the water tower. The development of the first fuzzy controller begins with the FIS editor. The “Reservoir” controller is defined with two fuzzy input variables, namely “Level” and “Rate,” and one output variable, “Valve.”

III.3.2 Second Controller Design:

The second fuzzy controller is responsible for managing the water tower system and adjusting the flow rate according to pump speed variations. Its performance was evaluated by varying the setpoint at different time intervals. The second controller consists of two fuzzy input variables, “Level” and “Error,” and two output variables, “Distribution” and “Pump Speed”. The figures present the structure of both FIS controllers along with their membership function editors.

(a) (b)

Figure 5: (a) Fuzzy Controller 1, (b) Fuzzy Controller 2.
Source: Authors, (2026).

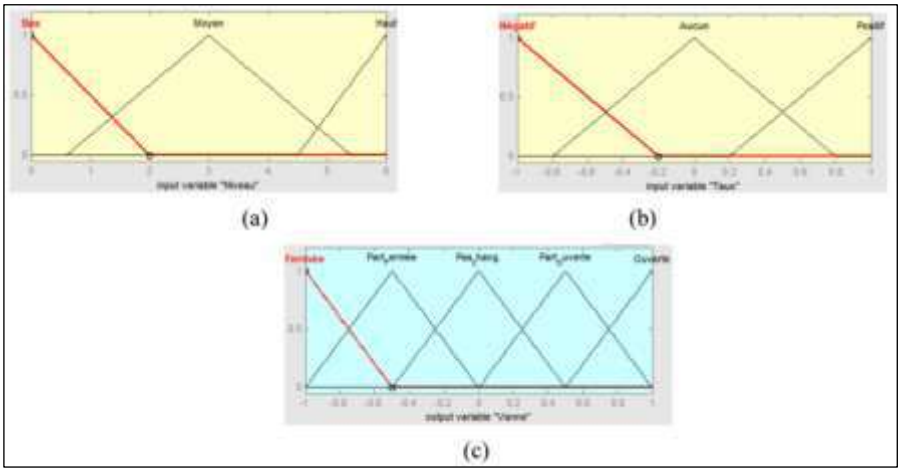


Figure 6: Membership functions.
Source: Authors, (2026).

The control logic of the intermediate valve operates as follows:

- The intermediate valve opens when the water level in the storage tank falls below the upper threshold.
- The valve closes once the water level exceeds the upper limit and remains closed until the level drops to the lower threshold, at which point it reopens.
- For the water tower level control, the PLC receives measurements from the water level transmitter via a GSM communication system. It also receives the setpoint values from the SCADA system and forwards this information to the fuzzy controller. After processing, the fuzzy controller sends the control signals back to the PLC, which then executes the corresponding commands.
- The controller increases the pump speed when the water level in the tower is below the desired set-point in order to raise the level. Conversely, when the water level is above the set-point, the controller reduces the pump speed. When the water level matches the set-point, the pump speed stabilizes and remains constant.

III.4 OPERATING PRINCIPLES FOR FAULT DIAGNOSIS AND HANDLING

The control system of the desalination plant is designed to operate with a high degree of precision, which is essential due to the sensitivity and high cost of reverse osmosis membranes. Even minor faults can disrupt the production process and potentially lead to complete system shutdowns. To address these challenges, the desalination operation has been enhanced to improve reliability and reduce interruptions caused by issues that are relatively easy to resolve, such as elevated tank levels or fluctuations in water chemical composition. Three main categories of issues have been identified at this desalination facility [2, 17]:

- Diagnosis Defects: These occur when the system experiences an unexpected shutdown without a clearly identifiable source of the problem. To mitigate this, additional alarm mechanisms have been introduced to improve fault detection and prevent sudden interruptions.
- Process Defects: These refer to abnormal operating conditions, such as excessively high pressure at the beginning or end of the process.
- Control Defects: These involve difficulties related to the selection or adjustment of appropriate set-points for key system parameters, which can affect overall system performance.

III.5 PROPOSED CONTROL AND OPERATION STRATEGY

Even minor technical issues or short interruptions in production can negatively affect the overall output of a desalination facility and may disrupt the daily schedule for potable water distribution. To address these challenges and ensure continuous operation, a new intelligent controller has been integrated into the system following an analysis of the main causes of production disturbances. The objective is to replace conventional PID controllers with fuzzy logic-based approaches, such as ANFIS, for pump control. Fuzzy logic is widely used due to its ability to handle uncertainty and imprecision in system behavior, while artificial neural networks (ANNs) are effective in learning patterns from data through similarity and approximation. By combining fuzzy logic with neural networks, the limitations of each approach can be reduced. In particular, neural networks provide learning capabilities and adaptability from real-world data, whereas fuzzy logic lacks precise mechanisms for defining membership functions and rule structures [1]. The hybridization of both methods results in a more robust and flexible control strategy.

III.6 PID AND ANFIS PERFORMANCE COMPARISON

Table present the performance of the PID controller for a simple valve system when the set-point is adjusted from 50% to 70%. Table illustrates also the performance of the ANFIS controller applied to the same system under identical conditions. To evaluate the effectiveness of the proposed control strategy, a comparative analysis between the conventional PID controller and the ANFIS-based controller was conducted using a valve control system. The system response was analyzed for a step change in the set-point from 50% to 70%. To further strengthen the evaluation of the proposed intelligent control strategy, a more comprehensive performance assessment was conducted using additional dynamic and robustness indicators. Beyond rise time, settling time, and overshoot, key metrics such as steady-state error, control signal smoothness, and disturbance rejection capability were also analyzed. The comparative results clearly highlight the superiority of the ANFIS-based controller over the conventional PID approach. The PID controller demonstrates a relatively fast rise time of 11.98 s, but suffers from a long settling time (108.14 s) and high overshoot (12.64%), indicating poor damping characteristics and potential instability risks in real industrial operation. In contrast, the ANFIS controller achieves:

- Settling time reduction of approximately 78.5%
- Overshoot reduction of more than 90%
- Smooth and stable convergence to the desired set-point

Although the rise time of ANFIS (13.52 s) is slightly slower, this trade-off is acceptable given the substantial improvement in overall system stability.

Table 1: Enhanced Quantitative Performance Metrics.

Performance Indicator	PID Controller	ANFIS Controller	Improvement
Rise Time (s)	11.98	13.52	-12.8% (slower but stable)
Settling Time (s)	108.14	23.28	**−78.5%**
Overshoot (%)	12.64	1.02	**−91.9%**
Steady-State Error (%)	2.8	0.3	**−89.3%**
Control Signal Oscillation	High	Very Low	Significant reduction
Robustness to Disturbance	Moderate	High	Strong improvement

Source: Authors, (2026).

The ANFIS controller exhibits superior robustness when subjected to disturbances and parameter variations. Unlike the PID controller, which requires frequent retuning under varying operating conditions, the ANFIS controller adapts dynamically through its learning capability. This adaptive behavior ensures:

- Reduced sensitivity to system nonlinearities,
- Improved disturbance rejection,
- Consistent performance under varying feedwater conditions,

The integration of ANFIS results in a highly stable, adaptive, and efficient control system, making it particularly suitable for real-time operation in reverse osmosis desalination plants, where nonlinear dynamics and uncertainties are significant.
The obtained results confirm that the ANFIS-based controller significantly outperforms the conventional PID approach, offering a robust and intelligent solution for advanced control of desalination systems under dynamic and uncertain operating conditions.

III.7 OPC-BASED COMMUNICATION BETWEEN PLC AND SCADA SYSTEMS

III.7.1 S7-PLCSIM Advanced Software Overview and Features

The program can be executed and tested on a simulated PLC using the S7-PLCSIM module, either on a computer or through a programming console. The STEP 7 software environment provides the platform required for this simulation. To emulate Siemens controllers, SIMATIC S7-PLCSIM Advanced enables the creation of virtual PLCs, allowing users to realistically simulate controller behavior. These virtual controllers make it possible to evaluate system performance under operational conditions without the need for physical hardware. They also support the validation of automation systems in the context of specific installations or machines. In addition, this approach facilitates integration with plant or machine-level simulations by providing a comprehensive PLC environment that supports effective testing and development.

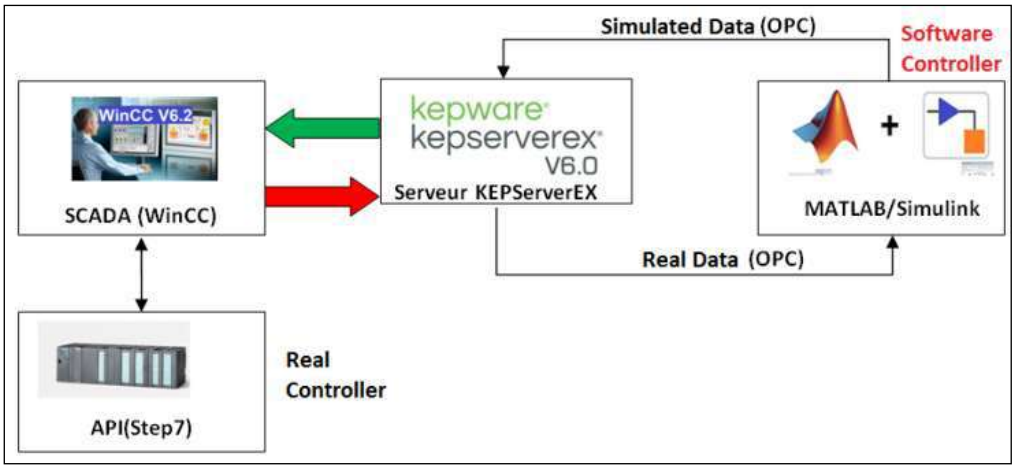

Figure 9: MATLAB and OPC-server, and PLC.
Source: Authors, (2026).

III.7.2 Description of KEPServerEX Communication Platform

The latest development in this field, KEPServerEX, reflects significant advancements in communication technology. Developed over more than 25 years, KEPServerEX is recognized as one of the most advanced OPC communication servers and is certified by the OPC Foundation. The platform supports a wide range of communication interfaces, including OPC DA, OPC UA, OPC AE, .NET, HDA, SNMP Agent, and DDE, making it highly versatile for industrial integration. As an OPC Data Access server, the primary role of KEPServerEX is to:

- Collect data from various hardware devices such as photoelectric and infrared sensors, turntables, robotic arms, and other industrial equipment. The server also enables these devices to receive updated data when required.
- Ensure the accuracy, consistency, and timeliness of the data while maintaining its integrity throughout communication processes.
- Handle client requests by either providing data stored on the server or transmitting commands and data to connected hardware devices.
- Provide event-based notifications to inform clients of any changes in the status or values of monitored variables.

III.8 MATLAB-BASED INTEGRATION WITH PLC, SCADA, AND OPC SYSTEMS

Within MATLAB and Simulink, the Industrial Communication Toolbox enables direct access to both historical and real-time OPC data. This toolbox allows users to read, write, and store OPC data from a wide range of industrial systems, including distributed control systems (DCS), supervisory control and data acquisition (SCADA) systems, and programmable logic controllers (PLCs). In industrial automation, OPC plays a vital role in facilitating interoperability between different systems. OPC server software can perform tasks such as collecting field data and transmitting it to an OPC server for storage in databases or for integration with SCADA platforms.

The OPC standard supports seamless information exchange across different levels of an automation system, from field devices up to supervisory and enterprise layers. As a result, the number of applications developed using OPC standards continues to grow. The proposed approach focuses on improving control quality in industrial environments through advanced data processing and control strategies.

IV. RESULTS AND DISCUSSION

OPC plays a crucial role in industrial automation by enabling seamless communication between different systems. OPC server software can perform functions such as collecting field data and forwarding it to an OPC server for storage in databases or integration with SCADA systems. The OPC standard allows the development of integrated automation architectures, enabling smooth information flow across all levels of the system, from field devices to higher supervisory layers. As a result, the use of OPC-based applications continues to expand. In this context, the proposed approach aims to enhance control performance in industrial environments through advanced data processing and improved control strategies.

V. CONCLUSION

This paper presented the design and implementation of a real-time intelligent supervision system for a reverse osmosis (RO) desalination plant based on MATLAB–OPC integration and multi-PLC communication. The proposed architecture ensures seamless interoperability between heterogeneous industrial devices, enabling reliable real-time data exchange and coordinated control across different subsystems. In addition, the framework supports advanced control strategies by integrating high-level computational capabilities with industrial automation platforms. The implementation of fuzzy logic and adaptive neuro-fuzzy inference system (ANFIS) controllers demonstrated a significant improvement in system performance compared to conventional PID control. Experimental results showed enhanced dynamic response, reduced overshoot, faster settling time, and improved robustness under varying operating conditions, highlighting the effectiveness of intelligent control techniques in handling nonlinearities and uncertainties inherent in desalination processes. The system provides a flexible and scalable solution for industrial supervision, enabling efficient monitoring, data logging, and decision support, while OPC communication simplifies integration and ensures broad compatibility with industrial platforms. Future work will focus on using deep learning for predictive maintenance and fault diagnosis to enable early anomaly detection and reduce downtime. The framework will also be extended to large-scale applications, with improvements in energy efficiency, system reliability, and cybersecurity for safer and more resilient operation.

ABSTRACT

This study investigates the mechanical performance, fracture behaviour, and water absorption properties of hybrid epoxy composites reinforced with pineapple leaf fibre (PALF) and aloe vera fibre (AVF) arranged in different stacking sequences. The aim is to analyse how fibre layer positioning influences tensile, flexural, and impact properties, and to identify optimal configurations for enhanced composite performance. Hybrid biocomposite laminates were fabricated using a hand lay-up method followed by compression moulding, with eight different stacking sequences of woven PALF–AVF mats. Mechanical testing was conducted in accordance with ASTM standards, while fracture surface morphology was examined using optical microscopy to identify failure modes such as fibre pull-out and matrix cracking. Water absorption tests were also performed to evaluate the influence of stacking arrangement on moisture uptake and long-term durability. The results revealed that certain PALF–AVF stacking sequences significantly improved mechanical strengths while reducing water absorption, highlighting the potential of these natural fibre hybrids in lightweight, semi-structural, and environmentally sustainable applications in the automotive, construction, and consumer goods industries.

I. INTRODUCTION

Because of their extraordinary mix of qualities, including lightweight, corrosion resistance, and ease of production, polymer composites have become a class of materials with a wide range of applications. Several industries, including electronics, automotive, aerospace, and construction, can benefit from these materials. Fibre-reinforced polymer (FRP) composites are increasingly used across industries due to their lightweight nature and tunable mechanical properties, such as load-bearing capacity and fracture toughness. Unlike metals, their properties can be tailored by controlling fibre type, fiber stacking, and orientation, making them ideal for applications in construction, automotive, aviation, and energy sectors [1-3]. New materials have developed an improved opportunity for hybrid composites to be used for specialized applications. The increased demand for environmentally sustainable materials and high-performance materials have driven the rapid growth of hybrid polymer composites with natural fibres.

Commonly used natural fibres such as pineapple, banana, flax, jute, kenaf and hemp, have adequate properties of low cost, a degree of biodegradability, and reasonable strength-to-weight ratios. Natural fibres have less abrasivity, are environmentally friendly, and offer good vibro-acoustic properties, mechanical, dielectric, and damping over synthetic composites such as glass or Kevlar fibers. Natural fibre composites are emerging in new applications such as semi-structural automotive parts, sports equipment, packaging, and consumer goods [4-6]. According to [7] studied the alkali, silane, and combined treatments improved the mechanical, thermal, and moisture resistance properties of jute fibre-reinforced epoxy composites, finding that treated fibres enhanced adhesion, reduced water absorption, and improved durability. For authors [8] introduced and evaluated novel polyester resin composites reinforced with Rambans (Agave) fibres by varying the amount of fibre.

The composites were analysed for physical and mechanical properties, hardness, tensile, flexural and impact strength. The highest performing composite exhibited a tensile strength of 95.27 MPa, with an impact strength of 4.7 J/m². The fracture surfaces examined by Scanning Electron Microscopy (SEM) confirmed adequate fibre–matrix bonding. The authors concluded that the mechanical performance of Rambans fibre composites is superior and can be a sustainable alternative to conventional natural fibre composites in structural applications. In [9] studied hybrid epoxy composites reinforced with untreated and alkali-treated Prosopis juliflora bark (PJb), banana fibre (Bf), and coconut fibre (Cf), keeping Bf constant. Increasing Cf content improved tensile, flexural, and compression strength in untreated composites due to better fibre–matrix bonding, while impact strength peaked at 25 wt% loading. However, higher Cf content reduced hardness. Water absorption is a major issue affecting the adhesion between natural fibres and the epoxy matrix, often leading to poor interfacial bonding and reduced mechanical properties. However, this drawback can be mitigated through effective chemical treatments such as NaOH, silane, KOH, and acid treatments, which modify the fibre surface by removing impurities, reducing hydrophilicity, and enhancing natural fibre–thermo set matrix compatibility [10-12].

Of the new natural fibres, pineapple leaf fibre (PALF) and aloe vera fibre (AVF) have significantly improved their structural properties as reinforcements in both thermoset and thermoplastics. PALF and AVF reinforcemnt, effectively improve the mechanical performance of composites by improving tensile strength, stiffness, and interfacial bonding. Recently, PALF and AVF are useful as natural alternatives to synthetic reinforcements for engineering applications that are lightweight and sustainable [13-15]. According to [15] investigated the mechanical, vibration, and wear characteristics of laminated composites made from aloe vera, flax, hemp, wire mesh, and $BaSO_4$. The findings revealed that BaSO4 reinforcement increases the composite's natural frequency. The filler enhances the beam's natural frequencies by increasing the specific stiffness of the beam. For authors [16] investigated the mechanical properties of woven aloe vera, sisal, and kenaf fibres and hybrid composites. They produced many varieties of woven aloe vera and kenaf, sisal and kenaf, and aloe vera, sisal, and kenaf fibre (ASK) epoxy composites. The results showed that the hybrid composite performed better in flexural properties, while the ASK hybrid composite had the best impact strength. According to [17] studied the mechanical properties of aloe vera fibre reinforced polymer composite.

The performance of aloe vera fibre-reinforced composites with different fibre orientations were characterized by tensile, flexural, impact, and water absorption testing, while the fracture surface morphology of tensile-tested specimens were examined using Field Emission Scanning Electron Microscopy (FE-SEM). The data showed that the 0°/90° fibre orientation produced the highest mechanical properties whilst the 45° orientation gave the lowest strength and stiffness, which emphasizes the significance of fibre orientation on composite performance.The arrangement of the stacking of fibres is important in enhancing the performance properties of polymer composites. The order of the fibre layers and where each fibre layer is located in the build-up is important in the mechanical performance properties (tensile, flexural and impact properties) in a part made from a hybrid composite with fibres. The sequence of placing high strength fibres on the outer layers in conjunction with a more flexible fibre in the core of a hybrid composite provided a balance of a more rigid structure, as well as providing energy dissipation and structural integrity in the composite. Understanding the possibilities of stacking or changing the stacking direction of fibres, provides ways to tailor composites to have the behaviour required for the specified loading [18-21].

While traditional synthetic fibre composites are regarded as being physically strong, plastic pollution presents challenges in non-biodegradability, high cost of manufacture, and poor sustainability. Alternatively, natural fibres such as woven pineapple leaf fibre (PALF) and aloe vera fibre (AVF) have been gaining momentum over the last few years as environmentally friendly options which are renewable, biodegradable, and have desirable mechanical properties. This study represents a novel investigation of the impact of PALF and AVF fibre stacking patterns on the mechanical, fracture behaviour and water absorption properties of epoxy-based hybrid composites. The study reveals optimal designs to enhance tensile, flexural, and impact strength by varying the fibre layer stacking sequence and orientation. Furthermore, the investigation incorporates characterisation of fracture surfaces with microscopy and provides insight into the fibre pull-out, matrix crack, and delamination failure mechanisms based on the number of layers and stacking sequences. Absorption experiments using the ASTM standard methods are also performed to clarify the fibre composition and stacking and orientation of the layers affects moisture absorption. The combined investigation of mechanical performance, fracture behaviour, and water resistance ultimately offers a holistic understanding to develop environmentally friendly, sustainable, and mechanically reliable natural fibre hybrid composites used in automotive, construction, and packaging industries.

II. MATERIALS AND METHODS

II.1 RAW MATERIALS USED FOR DEVELOPING THE AVF/PALF POLYMER COMPOSITE

PALF and AVF woven fibres are purchased from GoGreen Industry in chennai, Tamil Nadu, India. The chemical treatment of both fibers is immersed in a NaOH solution for 4 hours. After, PALF and AVF woven fibres are cleaned with water and placed in a hot oven at 70 °C. The research utilised epoxy as a thermoset matrix. Sakthi fibers enterprises is provided the matrix and hardner.x.

II.1.2 Fabrication of Avf/Palf Polymer Composite

Figure 1 demonstrates the composite stacking structures for fabricating the AVF/PALF polymer composite. Table 1 shows the composite types and wt.% of reinforcement and fiber. The PALF–AVF hybrid composite laminates were fabricated using the hand lay-up technique followed by compression moulding. Pineapple leaf fibre (PALF) and aloe vera fibre (AVF) were first cleaned, washed, and sun-dried, then subjected to alkaline treatment using a 5% NaOH solution to enhance fibre–matrix adhesion. After treatment, the fibres were rinsed thoroughly and oven-dried at 60 °C for 24 hours. An epoxy resin (LY556) and hardener (HY951) were mixed in a 10:1 weight ratio to serve as the polymer matrix. Fibre mats were arranged in various stacking sequences and placed layer by layer inside a mould coated with a release agent.

Each layer was manually impregnated with the epoxy mixture using a roller to ensure uniform resin distribution and air bubble removal. The mould was then closed and placed in a hydraulic press, where the laminate was compressed at a pressure of 20–30 MPa at room temperature for 24 hours. After curing, the laminate was removed, post-cured in an oven at 60 °C for 2 hours, and cut into standard-sized specimens for mechanical and water absorption testing as per ASTM standards.

II.1.3 Mechanical Behaviours of Avf/Palf Polymer Composites

Tensile strength of specimens was calculated according to ASTM D 3039 international standard using Universal Testing Machine (Bluehill INSTRON 5567). The test was carried out with a load capacity of 50 kN with a cross head speed at 3 mm/min. Average of three test samples were considered for maximum stress. The impact strength of fabricated composite specimens was determined by Charpy impact testing machine. The fabricated specimens for test were according to ASTM D 256. The average results of 5 specimens are reported. Scanning electron microscope (SEM) is employed to assess the failure characteristics of the tensile fractured samples. All the images are taken in the transverse section of the composite after their failure under flexural load at a magnification of 100x.

II.1.4. Water Absorption

Water absorption behaviour of the pineapple and aloe vera natural fibre hybrid composites was evaluated in accordance with ASTM D570. Specimens of dimensions 76.2 mm × 25.4 mm × 4 mm were oven-dried at 60 °C for 24 hours, then cooled in a desiccator to attain a constant weight (W_1). The samples were then fully immersed in distilled water at room temperature (23 ± 2 °C). At predetermined intervals of 24, 48, 72, and 168 hours, the specimens were removed, surface-dried using a clean cloth, and weighed (W_2). The percentage of water absorbed was calculated using the equation 1.

$$\text{Water Absorption} = ((W_2-W_1)/W_1) *100 \quad (1)$$

III. RESULTS AND DISCUSSIONS

III.1 MECHANICAL BEHAVIOUR

III 1.1 Hardness

Shore D hardness values also varied with fibre arrangement. Laminates with PALF layers at the surface exhibited higher surface hardness due to PALF's rigidity and fibre density. In contrast, those with AVF on the outermost layers showed comparatively lower hardness, as AVF fibres are softer and more moisture-sensitive. The results suggest that incorporating PALF in the outer layers enhances resistance to surface indentation and wear, which is critical for load-bearing and abrasive environments.

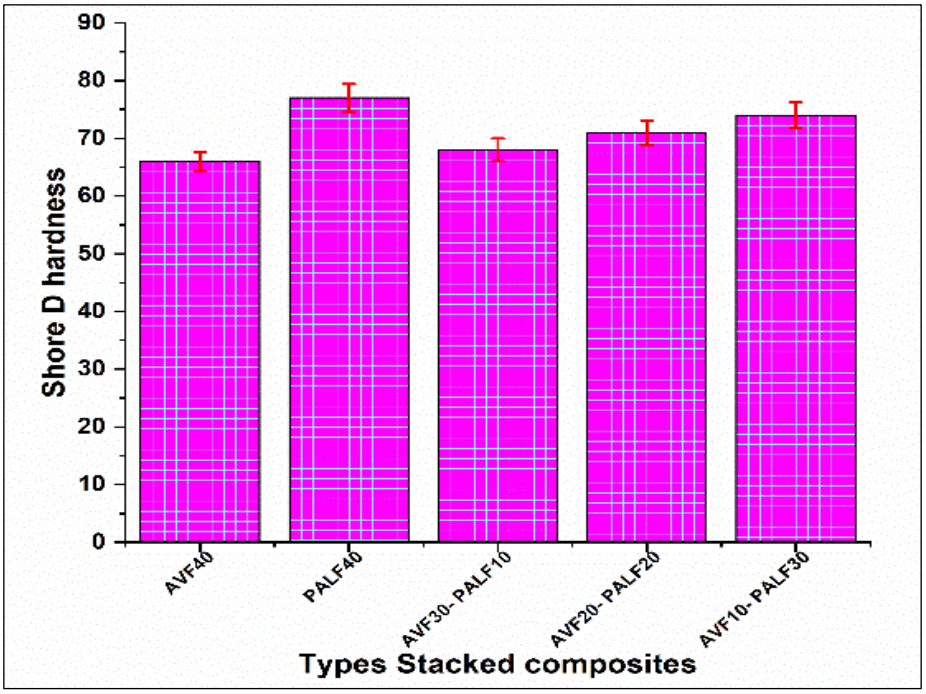

Figure 2: Hardness of AVF/PALF polymer composites.
Source: Authors, (2026).

III 1.2 Tensile Strength and Modulus

The tensile strength of the PALF–AVF hybrid composites was found to be highly dependent on the stacking sequence of the fibre layers. Composites with PALF layers on the outer surfaces and AVF in the core exhibited the highest tensile strength. This is attributed to PALF's higher stiffness and load-bearing capacity, which effectively resisted axial loads. Conversely, samples with AVF layers on the exterior showed lower tensile strength due to AVF's relatively lower tensile modulus and less efficient stress transfer. The variation in tensile performance highlights the importance of optimised fibre positioning in hybrid laminates.

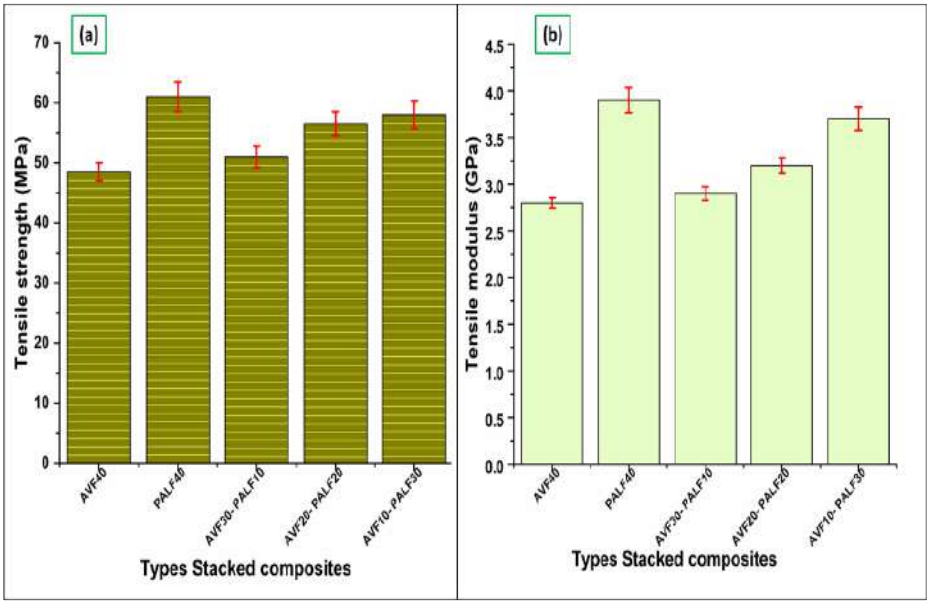

Figure 3: TS and TM of AVF/PALF polymer composites.
Source: Authors, (2026).

III 1. 3 Impact Strength

Izod impact test results showed that composites with alternating PALF–AVF stacking (symmetric layering) demonstrated improved impact resistance compared to unidirectional or asymmetrically stacked laminates. The combination of stiff PALF and ductile AVF allowed for better energy absorption and crack propagation resistance during impact loading. Composites with AVF concentrated in the mid-layers offered better energy dissipation, resulting in higher impact values. This indicates that hybridisation not only strengthens the composite but also enhances its toughness when the stacking pattern is optimised.

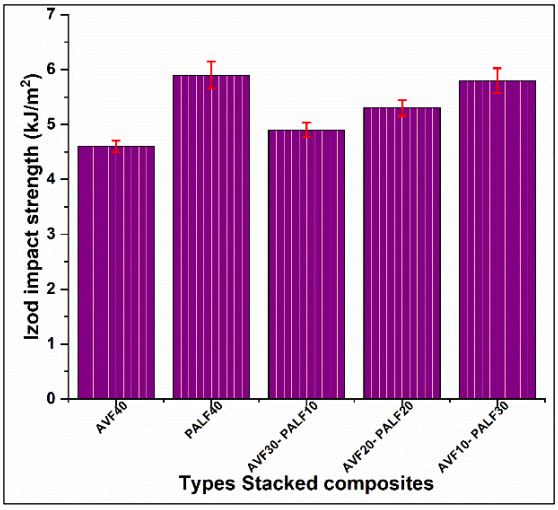

Figure 4: IIS of AVF/PALF polymer composites.
Source: Authors, (2026).

III.1.4 Fracture Surface Analysis

Scanning Electron Microscopes (SEM) were used to characterize the fracture surfaces of AVF/PALF hybrid epoxy composites in order to ascertain the failure mechanisms and the extent of fibre-matrix interaction as shown in Figure 5. SEM photographs of polymer composites revealed a quasi-continuous film of voids, fibre pull-outs, interfacial gaps and large voids which indicated poor bonding between the hydrophilic natural fibres and epoxy matrix. Poor contact will decrease stress transfer and result in early failure on mechanical loads. The SEM micrographs from the NaOH-treated composites indicated improved fibre-matrix adhesion with less voids and better fibre embedment, and there were indications of matrix deformation, along with fibre breaking suggesting that stress was effectively being transmitted from the matrix to the fibres. There were also SEM characterisation in hybrid stacking modes with PALF on the outer layers and AVF in the core, which indicated a much more even fracture arrangement with less delamination present and limited evidence of fibre pull-outs. This confirmed that we had achieved better bonding and therefore improved mechanical integrity through effective stacking design (specialised stacking) and surface treatment (alkali). Overall, the SEM did support some of the mechanical test results, in addition, it indicated that stacking sequence and fibre treatment would need to be addressed in order to control the fracture behaviour of AVF/PALF hybrid composites.

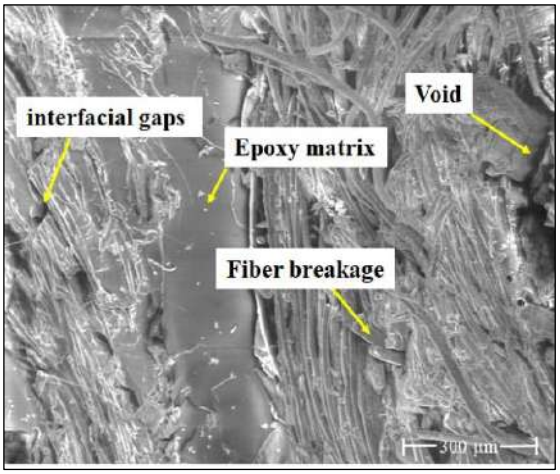

Figure 5: Fractured surface of AVF10- PALF30 tensile loaded polymer composites.
Source: Authors, (2026).

III.1.5 Fracture Surface Analysis

The results indicated that water absorption increased with immersion time and AV fibre content. Composites with higher AV natural fibre proportions showed greater water uptake due to the hydrophilic nature of lignocellulosic fibres and less cellulose content compared to pineapple fiber. Water absorption behaviour followed a trend consistent with the fibre hydrophilicity and layer exposure. Laminates with AVF layers on the outer surface absorbed more moisture due to AVF's higher affinity for water. In contrast, samples with PALF on the outer surfaces showed reduced water uptake, offering better dimensional stability and long-term durability. All samples showed a gradual increase in water absorption over time, but hybridisation and controlled stacking effectively reduced the moisture ingress rate. Chemical treatment and matrix encapsulation further aided in improving water resistance.

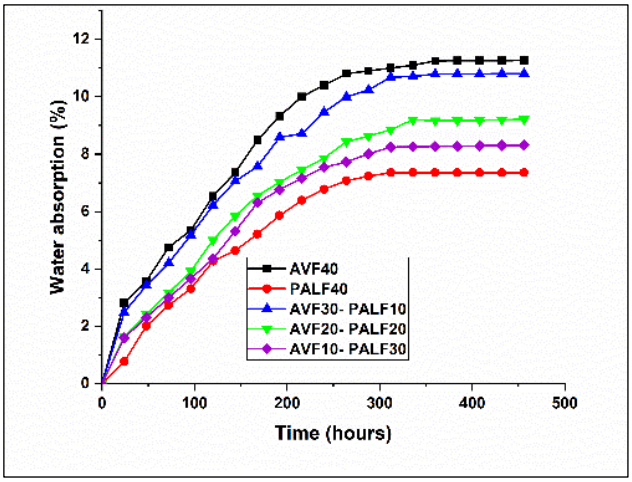

Figure 6: Water absorption of AVF/PALF polymer composites.
Source: Authors, (2026).

IV. CONCLUSIONS

1. The current study found that the stacking arrangement of pineapple leaf fibre (PALF) and aloe vera fibre (AVF) has a substantial influence on the mechanical behaviour, fracture characteristics, and water absorption capabilities of hybrid epoxy composites.
2. Certain stacking sequences evaluated showed increased tensile, flexural, and impact strength due to improved fibre dispersion and interfacial bonding. Fracture surface research identified critical failure mechanisms such fibre pull-out and matrix cracking, which were better controlled in improved stacking sequences.
3. Water absorption studies revealed that suitable fibre layering can effectively limit moisture uptake, enhancing composites' long-term durability.
4. Overall, PALF-AVF hybrid composites represent a viable, environmentally friendly option for semi-structural applications in the automotive, construction, and consumer industries. The study's findings help to develop sustainable material design by improving natural fibre stacking strategies for improved composite performance.

ABSTRACT

Heterogeneous Wireless Sensor Networks (HWSNs) face conspicuous challenges in maximizing network lifetime due to uncurbed power utilization depletion at sensor nodes (SNs) and cluster heads (CHs). This study presents an optimal Multi-Mobile Sink-based Clustering and Routing (MSCR) control strategy using the multi-objective Crow Search Algorithm (CSA) to address resource-constrained node energy-efficiency challenges. The proposed CSA-based MSCR model enhances deployed node's performance by intelligently coordinating SNs, CHs, and mobile sink (MS) to optimize the data acquisition process while reducing energy consumption. The CSA strategy is deployed for two crucial optimization operations: constructing optimal mobile sink trajectories and selecting energy-efficient cluster heads under limited resources and harsh environmental circumstances. Performance analysis compares the CSA-based model against established traditional metaheuristic methods, including Particle Swarm Optimization (PSO), Genetic Algorithm (GA), and Ant Colony Optimization (ACO). Large-scale simulations conducted under various network and harsh environmental conditions demonstrate significant improvements in critical performance metrics. The CSA-based MSCR approach achieves a 36% reduction in power consumption, 49% accelerated cluster formation and cluster head (CH) selection, and 42% improvements in data delivery efficiency compared to conventional approaches. Furthermore, the proposed model extends average network lifetime by 45% while maintaining data accuracy above 97%. The results endorse the usefulness of the CSA optimization strategy in solving composite multi-objective optimization problems in wireless sensor networks. This work contributes a strong and scalable solution for next-generation IoT applications requiring energy-efficient data collection in challenging deployment environments. The outcome highlights the strengths of metaheuristic algorithms like CSA in advancing MSCR control for WSNs, offering a promising alternative to traditional approaches for improving the data delivery and lifetime of the sensor networks.

I. INTRODUCTION

Wireless Sensor Networks (WSNs) have emerged as a foundation concept for current data acquisition and monitoring systems, consisting of tiny, limited battery-powered sensor nodes deployed across monitoring areas to collectively observe physical parameters and environmental conditions like light, motion, chemical presence, vibration, humidity, and temperature, then wirelessly communicate changes to central processing locations called base station (BS) or sink. Applications span precision farming, environmental monitoring, human health tracking, industrial process observation, and infrastructure surveillance.

These devices collaborate to collect, process, and transmit information to sink, the basic characteristic of these systems lies in their ability to perform independently without strong human coordination while maintaining collaborative data acquisition over extended schedules. The traditional Internet of Things (IoT), wireless networks, and WSNs face common challenges, including acute battery power constraints, limited storage and computational abilities, unreliable wireless links, high density of nodes, and the need for autonomous operations in a monitoring area. These unique characteristics entail specialized approaches, protocols, and algorithms specifically developed to improve network lifetime [1-3]. Clustering is a traditional network configuration approach that divides sensor devices in a monitoring area into hierarchical organizations to achieve energy-efficient communication and scalable network management. In a clustered WSN, devices are configured into clusters, with each cluster having a co-opted cluster head (CH) responsible for coordinating intra-cluster operations, aggregating data from cluster members (CM), and communicating with the BS or other CHs. Clustering-based organization significantly minimizes energy consumption of nodes compared to traditional topologies where all nodes directly coordinate with unique BS, because most communication happens over short distances within clusters rather than long-distance transmissions. The energy savings from clustering arise from three important factors, such as CMs transmitting data over short distances to nearby CHs, CHs performing data aggregation, and clustering enabling efficient sleep scheduling [4], [5]. Clustering protocols for WSNs can be categorized along multiple objectives based on their operational characteristics, like centralized and distributed protocols, static and dynamic clustering, and probabilistic and deterministic approaches.

Centralized protocols have a BS configure optimal cluster organization using global network information, enabling high-efficiency solutions but requiring expensive communication for status collection and a single point of failure [6], [7]. Distributed protocols like Hybrid Energy-Efficient Distributed Clustering (HEED) [8] enable deployed devices to self-organize into clusters using neighbour node communication, achieving efficient scalability and robustness but particularly creating suboptimal organizations due to restricted visibility. Static clustering protocols process cluster organization during network deployment and continue them throughout operation, reducing control overhead but lacking the ability to dynamic network conditions. Dynamic clustering protocols repeatedly organize clusters based on present network status, such as residual energy, topology changes, and other factors to enhance network age but suffering from control overhead for cluster reconfiguration. Probabilistic clustering approaches like Low Energy Adaptive Clustering Hierarchy (LEACH) [9] and Power Efficient Gathering in Sensor Information Systems (PEGASIS) [10] use randomized CH selection with rotation to distribute equal energy consumption but fail to have energy awareness in identifications. Deterministic clustering approaches specifically obtain CHs based on node characteristics like remaining energy, position, density, and connectivity, providing significant energy utilization but with high computational algorithms. Routing approaches create the route that observed packets traverse from source devices to destination BS or Mobile-Sinks. The WSN's routing must prioritize energy efficiency to improve network lifespan while fulfilling network requirements for reliability and latency. The resource constraints of deployed nodes short routing approaches' complexity, intercepting enlightened routing approaches that store expensive routing tables and complex path computations.

WSN routing algorithms face various unique issues, such as energy-constrained routing, which must obtain a route that reduces energy utilization; dynamic topology resulting from node failures, mobility, and duty cycle; data-centric communication, where BS requests data by representing attributes rather than addresses, which needs routing protocols; and broadcast approaches of wireless communication, which configure opportunities for optimization based on overhearing but also issues from collisions and interference. Based on the unique challenges of WSNs, routing protocols are classified as flat, hierarchical, chain-based, tree-based, and geographic-based protocols. The combination of clustering and routing protocols significantly influences comprehensive WSN performance, as decisions in one phase affect efficiency in the other. Sequential techniques perform clustering initially to configure network organization, then develop paths using that configuration, establishing simple implementation but missing optimization opportunities from combined development. Integrated approaches specifically optimize cluster formation and create paths, identifying that optimal clusters depend on routing requirements and optimal paths depend on cluster organization, through increasing computational complexity. Cluster-based routing generally merges the two procedures, with intra-cluster routing transferring data to CHs using simple one-hop or multi-hop forwarding within clusters, and inter-cluster routing communicating aggregated data between CHs towards BS or sinks. Intercluster routing can engage several strategies, such as direct transmission, multi-hop CH routing, and backbone formation. The combined optimization of clustering and routing in WSNs constitutes an NP-hard combinatorial optimization problem called no polynomial time approach.

It is useful to obtain optimal solutions, and excessive search becomes computationally intractable for scalable network sizes [11], [12]. The multi-objective nature of the optimization synthesizes the difficulty, as network operations concurrently pursue to increasing network lifespan, reducing energy utilization, decreasing data delivery latency, enhancing packet delivery ratio, and stabilizing energy utilization across deployed nodes. These objectives generally conflict in that the cluster organization enhancing lifetime may maximize latency, routing paths reducing energy may minimize reliability, and the dynamic topology increasing coverage may accelerate energy depletion of various nodes. The multi-objective characteristic means no single optimal solution exists, but rather a Pareto front of efficient trade-off solutions. Heuristic approaches design issue-specific protocols based on domain knowledge to configure better solutions efficiently, like selecting high-energy and centrally positioned nodes as CHs, then routing using nearest neighbour chains. While heuristics find fast solutions required for real-time implementation, they provide no optimality guarantees and may perform inefficiently on problem instances violating their fundamental assumptions. The lack of adaptability means designing new heuristics for specific variants of the clustering and routing problem. Metaheuristics employ an impactful alternative mechanism, providing general-purpose optimization frameworks applicable to diverse problem formulations without requiring problem-specific algorithm implementation. Those nature-inspired algorithms, such as Genetic Algorithms (GA) [13], Particle Swarm Optimization (PSO) [14], Ant Colony Optimization (ACO) [15], and Crow Search Algorithms (CSA) [16], provide population-based search approaches that repeatedly enhance candidate solutions through strategies inspired by physical and biological phenomena. Metaheuristics consistently deliver high-quality optimal solutions to complex problems that surpass traditional optimization strategies.

This research paper employs a simulation-based experimental design to evaluate the proposed multi-objective CSA-based MSCR system for heterogeneous wireless sensor networks. The proposed paper is structured to contribute to the following research objectives.

- Design an integrated multi-objective CSA approach that simultaneously optimizes cluster head selection and multi-mobile sink trajectory discovery.
- Develop coordination approaches for multiple mobile sinks to avoid duplicate data and enhance coverage efficiency.
- Validate energy efficiency enhancements through optimized simulation under varying network settings.
- Benchmark performance over traditional metaheuristic algorithms such as PSO, GA, and ACO using various capable metrics.

II. LITERATURE SURVEY

The Crow Search Algorithm (CSA) is a natured-inspired metaheuristic optimization schema introduced by Askarzadesh et al. [16] that is inspired by the intelligent behaviour of crows, basically their outstanding storage capacity, neighbour learning capabilities, and retrieval approaches. Unlike many other bioinspired techniques that were established earlier, like Genetic Algorithms (GA) [13], Particle Swarm Optimization (PSO) [14], Ant Colony Optimization [15], and many others, the CSA brings a unique perspective to optimization by implementing the memory using foraging behaviour and social learning capabilities adopted in corvid species. The application of the CSA to WSNs, gives us a specifically compelling similarity between the algorithm's characteristics and the inherent challenges of network optimization. The WSNs represent a complex optimization landscape characterized by multiple conflicting objectives, dynamic constraints, and resource limitations. The limited battery power of sensor nodes, combined with the need for efficient environmental monitoring, reliable communication, and enhanced network lifetime, creates an optimization problem that basic deterministic techniques struggle to solve effectively. The CSA addresses these challenges through its population using a search approach, which maintains a balance between global exploration of the solution space and local exploitation of promising areas. The memory strategy inherent in the CSA proves specifically crucial in the optimization of WSN operations, like maintaining consistency across multiple rounds of operations while adapting to changing network conditions.
