

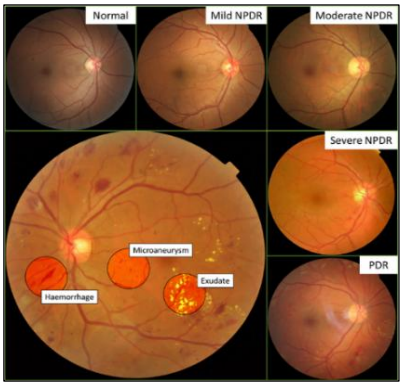

Figure 1: Different classes of Diabetic Retinipathy.
Source: [5].

The common symptoms of DR include *microaneurysms* which are usually seen in people suffering from diabetes when the capillary walls widen. They are usually seen in the form of small red dotlike structures when captured in colored fundus images and bright hypersensory spots when looked through fluorescein angiography. They are usually found in the early stages of DR [6]. *Hemorrhages* are the initial indicators used to detect DR when it enters in severe stages. Hyperglycemia causes damage to the blood vessels which results in their bursting, causing hemorrhages. There are different types of hemorrhages like *flame-shaped* hemorrhages found in the top layers and *dot-blot* hemorrhages found in the lower layers. Non-proliferative retinopathy is caused by the presence of large numbers of hemorrhages [7]. *Exudates* occur due to an increased blood sugar levels damaging the blood vessels, leading to leakage of yellow-white lipid and protein deposits.They are mainly categorized into - soft exudates and hard exudates. Soft exudates are the yellow-white colored lesions also known as the cotton wool spots generally found in the nerve fiber layer. They are fluffy in texture [8]. Hard exudates are comparatively brighter and reflective in nature. Found in different sizes, they are generally white- or cream-colored lesions. They are a strong indicator of diabetic macular edema (DME) and affect the central vision [9]. They are marked with sharp boundaries and have a waxy, shiny texture located into the outer layer of the retina.

Medical equipment like opthalmoscope and fundus cameras are used during eye-checkups. But using these traditional method is time-consuming as well as expensive, the doctor and patient ratio is 1:10,000 making it difficult to give personal attention to each patient. Thus it creates a need for an automated detection method which can easily, accurately and consume less time to classify the disease. Although it is not curable but if detected timely we can slow down its progress and save eyesight of the affected. Ophthalmologists study the fundus images for finding any abnormalities or lesions in the retina. Along with fundus images - Slit lamp Images, Ultrasonic Images and Digital Images are used for DR detection [10]. It can become difficult to detect DR in earlier stages as the symptoms are minor and can be missed by the human eye. So there is a need for Machine Learning-Deep Learning based models which can easily process images to detect and segment affected areas. It can also help in predicting the severity of disease [11]. Thus models trained using DL are used in modern-day medical analysis to analyze the fundus images, focusing on studying retina's blood vessels. The data is processed through numerous layers aimed for automatic recognition of patterns and extraction of complex features which is a fundamental requirement for classification of Diabetic Retinopathy using fundus images [12]. Along with DR detection technique the dataset also plays an important role in this. The symptoms may vary according to the demographic variety or factors like age,gender or previous medical conditions. So a stable dataset covering different varieties of patient is required to train the model in order to get accurate and unbiased results [13]. Table 1 discusses about the existing commercial systems used for DR detection and the limitation faced by the systems.

Table 1: Comparative Analysis of Commercial Diabetic Retinopathy (DR) Detection Systems.

System	Approval	Staging Capacity	Image Quality Dependency	Major Limitation
IDx-DR	FDA	Only referable DR	High	No detailed DR
EyeArt	FDA, CE	DR + DME	High	High false positives
RetmarkerDR	CE	Early DR focus	Moderate	Limited to detecting microaneurysms
Google DR AI	Clinical use	Multi-stage DR	High	Limited availability
EyePACS	Clinical use	Multi-stage DR	Moderate	Depends on graders
RetinaLyze	CE	Limited	Moderate	Not autonomous
Bosch DR AI	Clinical use	Referral-based	Moderate	Limited published validation
Remidio DR AI	CE	Limited	High	Smartphone image limitations

In this paper we have studied various state-of-the-art-methods implemented by multiple researchers in the domain of DR classification on various performance parameters based on the methodology used for classification task and symptom specific methods too. We have also identified the research gaps from the previous work and tried to highlight challenges in existing methods. The paper also includes the detailed discussion about the symptoms and types of diabetic retinopathy. The remainder of the paper is structred as follow. Section I discusses the literature review of the previous work, divided further according to the technology used for the model. It also discusses the works done for DR detection based on the symptoms of disease. The section also includes a detailed discussion on various datasets giving us an insight about the kind of data available to DR classification. In section II we will be discussing the challenges and future scopes faced by the researchers while developing a mode for DR classification. Section III concludes the survey done by summarizing the importance of DR detection and the ways used for the same.

II. LITERATURE REVIEW

Analyzing previous work can help us build a model by filling their research gaps and creating a more efficient, accurate, and reliable one. In this section, we will be discussing the works of various authors who have carried out research in this field and trying to understand the gaps present between their research and limitations faced by them. There have been several studies carried out for the classification of DR using algorithms based on Machine Learning, Deep Learning, and Hybrid Learning. Along with that, we can also focus on symptom-wise classification techniques of DR. Figure 2 is used to visually showcase the broader categorization of DR-detection techniques.

II.1 ML-BASED TECHNIQUES FOR DR CLASSIFICATION

Machine learning is a widely used technology among researchers for medical diagnosis of any disease owing to accuracy and wid adaptability. We can further classify the ML techniques based on the kind of classification it does - binary classification usually indicates the absence or presence of the disease whereas the multi-class classification is used to grade the disease severity.

II.1.1 Binary-Class-Classification

Ashim Chakraborty [14] created a model focused on detecting the three early signs of the Diabetic Retinopathy namely the Hard Exudates (HE) - the yellowish spots, Microaneurysms - the tiny red dots and Blood Vessels - the abnormal vessel growth. Then binary classifier 6 was used to detect if these features indicated presence of DR or not. Multiple datasets like DIARETDB0, DIARETDB1, Messidor, Kaggle DR dataset were used. Accuracy for DR detection based on the lesion is HE with 95.7%, MA with 93.45% and BV with 90% accuracy. But the model had several issues like dataset imbalance, risk of false positives. Krishnendu Barik and Anil Kumar studied the biomarker genes found in blood samples to check for the presence of DR using RNA sequencing dataset-GSE221521 containing 69 DR and 50 Healthy-controls (Non-DR) patient data for the identification of Differentially Expressed Genes(DEGs). They trained multiple ML-based models like SVM, Logistic Regression, Random Forest, Gradient Boosting, Neural Network on the 7-Key genes selected through Elastic Net regularization out of which SVM performed the best with an accuracy of 86% [15]. Researcher Hassaballah and Hameed introduced a metaheuristic algorithm combining standard Golf Optimization Algorithm (GOA) with genetic operators. They introduced three hybrid models - mGOA-SVM, mGOA-radial SVM, and mGOA-kNN developed for both binary and multi-class classification on Messidor and EyePACS dataset respectively. [16]. Michal Gandor et al. adopted feature engineering technique combining multiple data preprocessing techniques along with several feature extraction algorithms to develop a model for the early diagnosis of the disease. On the basis of the preprocessing techniques applied four variants were created - pure, no-vessels, no-vessels-no-optic-disk and no-optic-disk. They experimented with an aggregated dataset of 8 public datasets and 1 private dataset making the results non-biased and more accurate. Random forest and XgBoost were the two classifiers used for detecting DR. [17]. Penikalapati Pragathi et al. developed an integrated approach using SVM, PCA and Moth-Flame Optimization for detecting DR and achieved an accuracy of 86.3%. Usually using PCA reduces the performance of the algorithm and to balance it out Moth-flame optimization technique is used. It selects the optimal features improving the performance. The model was trained and tested on the Diabetic Retinopathy Debrecen dataset from the UCI ML repository [18]. Michele Bernardini et al. developed a model for Task 1 - Risk of DR and Task 2 - temporal stratification of DR risk in 0-2 years vs. 2-5 years creating a Clinical Decision Support System. The paper used 120K dataset from multiple Italian diabetologic centers consisting of EHR: demographics, pathology codes, and lab tests. Among the various ML algorithms used Random Forest (RF) achieved the highest accuracy [19].

II.1.2 Multi-Class Classification

Xiaoli Li et al. [20] used clinical data and OCTA (Optical Coherence Tomography Angiography) images to develop a model to grade DR into 3 classes each with a binary classification - DR Identification (Non-DR and DR), Referable DR (RDR) - Identification (Non-RDR and RDR), Vision-Threatening DR (VTDR) – Identification (Non-VTDR and VTDR). The paper focused on four ML models - Random Forest (RF), Gradient Boosting Machine (GBM), Logistic Regression (LR) and Deep Learning DL. Xu Wang et al. [4] focused on following a white-box approach by adopting SHAP (SHapley Additive exPlanations) interpretability model to reason out the findings hence increasing model's reliability. The model used 1000 records from diabetes complications early warning dataset and compared 5 distinct ML-algorithms Support Vector Machine(SVM), Random Forest, XGBoost, Gradient Boosting Tree and CatBoost. Researcher Gigi Tabacaru et al. [21] used PyCaret library to select the best performing model out of the 15 available models and found that the Gradient Boosting Classifier (GBC) is the best performer with an accuracy of 92.9%. They used Indian Diabetic Retinopathy Image Dataset (IDRID) to classify the results at different severity level - NoDR/Mild, NoDR/Moderate, and NoDR/Severe. Eman Abdelmaksoud et al. [22] proposed Multi-Label Computer-Aided Diagnosis (ML-CAD) system initially performing binary classification using SVM and GLRLM features to filter the cases then using the U-Net model to segment the pathological variations and lastly using a Multi-Label SVM (MLSVM) based on a Classifier Chain (CC) for grading the disease. Multiple datasets - DRIVE, HRF, STARE, CHASEDB1, DIARETDB0, IDRID, DIARETDB1, and Messidor were used for the experiment. Aqib Ali et al. [23] developed an image segmentation method called Center-Based Irregular Polygon Region-Growing Segmentation(CARGS) for isolation of lesions before performing feature extraction. An irregular polygon shaped seed is used to circumference the lesion boundary then using K-Means clustering these pixels are separated into 3 clusters - background, normal retina and lesions affected areas. Features like GLCM, histogram, wavelets, etc. are extracted and fed to ML classifiers like Sequential Minimal Optimization, Logistic Model Tree, Multilayer Perceptron classifier. Table 2 some of the top ML models reviewed and their features.

Table 2: Comparison of ML approaches for diabetic retinopathy diagnosis.

Ref	B/M	Preprocessing	Model	Dataset	Performance
[16]	B	Data Cleaning, Formatting	m-GOA radial SVM	Messidor, EyePACS	A: 99.12%, P: 99.15% A: 98.91%, P: 98.87%
[14]		CLAHE, Grey Scaling	Supervised ML model	Messidor, DiaretB0	A: 95.70%, P: 96.64%, F1: 96.37%, S: 96.11%
[15], [18]		PCA, Denoise, Normalization	SVM	Debrecen	A: 86.30%, P: 86.00%, F1: 86.00%, S: 94.20%
[15]		Normalization, Regularization	SVM	GSE221521	A: 86.36%, P: 100.00%, F1: 86.96%, S: 76.92%

II.2 DL - BASED TECHNIQUES FOR DR CLASSIFICATION

Deep Learning provides us with several models implemented using neural networks utilizing which we can easily analyze and study the images. Image analysis is an integral part of healthcare, and DL allows us to do that very efficiently by using variants of model like CNN.

II.2.1 Binary-Class Classification

In a study conducted by SamiaAkhtar et al., he created custom Convolutional Neural Network (CNN) model called RSG-Net (Retinopathy Severity Grading) used for both multi-class and binary classification with accuracy being 99.36% and 99.37% respectively. Gaussian Blur technique was used for reducing the noise in the image, Histogram equalization for enhancing the contrast and brightness of the image. The images were resized and augmented as well. The model was trained and tested for the Messidor-1 dataset with split ration of 70% Training, 10% Validation, 20% Testing. The limitation of the model being that it can be prone to issue of over-fitting and generalization to diverse dataset as it was tested only for Messidor-1 [24]. Amad Zafar developed a two-stage deep learning framework for the detection as well as the classification of the severity of the disease. A lightweight network was designed for binary classification. And if the disease is detected then in the next phase a transfer learning approach was implemented wherein the model trained in earlier staged is re-used and fine-tuned for the multi-class classification for the severity level. The primary dataset for the model being APTOS2019 and FairVision and DDR dataset for the validation purpose. The pre-processing techniques used were Data Augmentation, Normalization and Image Cropping [25]. M. Mutawa proposed a framework following randomized-based learning approach in traditional image processing techniques.

The preprocessing included techniques like Green channel extraction to reduce the noise, CLAHE for noise reduction and contrast enhancement and morphological operations to focus on the blood vessels and Otsu's thresholding for image binarization and segmentation of blood vessels. After that feature extraction is done on the preprocessed images using two parallel methods: Multi-Scale Discriminative Robust Local Binary Pattern (MS-DRLBP) responsible for capturing the local texture and edge patterns and CNN model (VGG16) responsible for automatically analyzing the complex features from the images. After that classification done using a hybrid CNN model - Radial Basis Function (CNN-RBF). It takes the combined features from both MS-DRLBP and VGG16 for the binary classification of the dataset. Randomization in framework was applied by the non-iterative nature of Otsu's method for thresholding and random initialization of RBF centres this reduced the complexity of computation and simplified the learning process. The model achieved an accuracy of 96.1%. A combined dataset of STARE, HRF, and FFA was used with a split of 60% for training and 40% for testing [12]. Saad Alanazi proposed a model called the FedCNN with VGG19 for segmentation and SMOTE with its core being the Federated learning (FedCNN) to maintain privacy of the patient's data by only sharing the local updates from each hospital's AI model learning instead of sharing the raw patient data. The CNN model VGG19 was employed for recognizing the intricate patterns and features in the images. Its primary work is to segment the important areas of the retinal images and after that extract detailed information of the features from the segmented areas. SMOTE(Synthetic Minority Oversampling Technique) was also used to create synthetic data to balance the model training. He worked on the EyePACS dataset from Kaggle. Pre-processing techniques like Weinmed Filtering(Weiner and Median Filter) and SMOTE were used to enhance the dataset achieving an accuracy of 98.0% [26].

Yixiao Li introduced an improved framework on an existing network KiU-Net making it more accurate and efficient at segmenting the HRF. HRF(hyperreflective foci) are the tiny, bright spots in OCT images used for detection DR. KiU-Net is a combination of two kinds of model called the Kite-Net branch for upscaling of the images to detect even the small lesions like the HRF. This allows us to to extract more fine-tuned and detailed knowledge about the small structures. Another model being the U-Net branch used for extract the high-level of semantic information unlike the Kite-Net in downscales the images to get a broader view of the image and anlayze the larger patterns. Further it uses the Cross-Attention Block(CAB) to combine the results of both of these to get the final information about the images. The dataset used here was 173 OCT images from 50 patients, obtained from the Department of Ophthalmology, Qilu Hospital affiliated with Shandong University, China. Common techniques like the Denoising the OCT images along with Bilateral Filtering and Augmentation were used to get the best of the dataset. For pixel-level segmentation using Kite-Net, the model achieved a Dice Similarity Coefficient (DSC) of 66.84% and for HRF number detection, the model achieved a Dice Similarity Coefficient (DSC) of 71.32% [27]. K. K. Mujeeb Rahman et al. gathered 560 fundal images combining Kaggle, DDR, Mendeley data and Zenodo datasets. The study involved both the SVM and DNN models with DNN getting an edge with an accuracy of 95.77%. The model was fed with features extracted using the GLCM(Gray Level Co-occurrence Matrix) technique [28].

Fasmin Shi, developed a technique called the Fair Adaptive Scaling(FAS) module which can be used as an add-on to other existing models. Its main focus is to reduce the difference of performance rates among different demographic groups like Whites and Blacks. FAS works on Individual and Group Scaling. Individual scaling focuses on giving more attention to the individual images who are having difficult time to be analyzed like if they giving wrong or uncertain results during the training stages. Group scaling focuses on the overall performance of the model for a particular demographic group. If a group shows higher error rate or is underrepresented its samples are given more weight. FAS is integrated with several Backbone models like the EfficientNet and ViT-B for 2D OCT images and ResNet18 and DenseNet121 for 3D OCT images. These backbone models are responsible for extracting complex features and patterns form the eye images. The study included both the private datasets from Massachusetts Eye and Ear - MEE like MEE In-House Color Fundus Dataset and MEE In-House Color Fundus Dataset and public datasets like ODIR-5K and Harvard-FairVision30k [29]. In a study by Manish Bali et al., a hybrid model was introduced called QuantumNet combination of a pre-trained ResNet-50 model and a Variational Quantum Classifier(VQC). The ResNet-50 model was responsible for extraction of features from the images of retina and VQC was tasked with classification of data from ResNet by encoding it into quantum states. The VQC uses a 4-qubit dressed quantum circuit to classify the 2048-dimensional feature vector into 4 dimensions. APTOS2019 dataset was split into 70% training, 15% validation and 15% testing set. Pre-processing techniques like Re-scaling and Image augmentation were employed. The model achieved and accuracy of 94.11%. The model faced limitations like requirement of advanced error correction techniques in quantum devices. Limited qubit counts and higher error rates in current quantum computers [30].

II.2.2 Multi-Class Classification

Lein Sun et al. developed MAFNet(Multi-Scale Adaptive Fine Grained Network) model for fine grading of the disease into all 5 stages and not only limiting to the binary prediction. The main crux of the model was ConvNeXt CNN and it consisted of three modules: HGCM(Hierarchical Global Context Module), MSAM(Multi-scale Adaptive Attention Module) and RMA(Relational Multi-head Attention). HGCM responsible for analyzing both the global region(big picture) and local region(small lesions) simultaneously. MSAM was tasked to focus on the most essential lesion areas of the retina. RMA focusing on finding relationships between different lesions. The model was trained for the purpose of both classification and regression. It used multiple datasets like the DDR, Messidor-2 and APTOS2019 split into a ratio of 6:2:2(train:validation:test). The model received highest accuracy of 88.2% on DDR dataset followed by APTOS with 87.4% and last Messidor-2 having 82.2% accuracy [2]. Amina Zedadra et al. developed a model called DRdiag which was an integration of CNN and GNN. The CNN model uses the DenseNet121 pre-trained on ImageNet dataset and the GNN model is a two layer Graph Convolutional Network (GCN). The CNN model focused on extracting the intrinsic feature from the fundus images whereas the GNN model was used to understand the complex relationship between the patients. The outputs of both the models were combined using the adaptive fusion mechanism. The two publicly available datasets Messidor-2 and APTOS2019 were used by the model. The model achieved an accuracy of 98% for the APTOS dataset and 97.6% for the Messidor-2. The limitation of the model being that it only considered one clinical risk factor i.e., the duration of diabetes for analysis and avoided other essential features [31]. A study by Hussain et al. proposed an enhanced P-EDR (Diabetic Retinopathy) method based on a Convolutional Neural Network (CNN) to diagnose diabetic retinopathy (DR) using retinal images.

It uses dataset of retinal images from the Kaggle DR. The data was preprocessed through normalization, augmentation, and resizing to improve image quality and feature extraction. The images were standardized to 224x224 pixels to ensure uniform input size for the machine learning models. The results showed that the CNN-based P-EDR model outperformed the other models. It achieved an accuracy of 93% [32]. S Jahangeer Sidiq, proposed an ensemble deep learning model for detecting and classifying the 5 different stages of Diabetic Retinopathy. The authors divided the classification of disease into a 12 multiple simpler binary classification task using a One-Versus-One (OVO) mechanism. It used pre-trained, lightweight models in the form of base learners and for the final result majority voting was used by combining their outcomes. Among the other base learners MobileNet, InceptionV3, and DenseNet121 were found to be achieving highest performance. The model worked on the APTOS2019 with MobileNet as the base learner, IDRID with InceptionV3 as the base learner, Messidor-2 using DenseNet121 base learner and DDR with MobileNet as the base learner. The images were pre-processed using the resizing and data augmentation process. The model achieved an accuracy of 92% for the APTOS2019 dataset, 85% for IDRID, 86% for Messidor-2 and 88% on the DDR dataset [33]. Omar Dib proposed a secure server-less framework called FL-BC-SMPC-SMOTE to avoid the risk of security breach of patient data. The model trains AI models with their patient data kept private from other hospitals by sharing only the encrypted updated data on a global model. Block-chain(Hyperledger Fabric) keeps track of the updates securely and SMPC (Secure Multi-Party Computation) is tasked to ensure that no user can see the actual changes of others data to strengthen the privacy of the model.

IPFS (InterPlanetary File System) is used to efficiently store the encrypted parts of AI model. SMOTE(Synthetic Minority Over-sampling Technique) is used for creating synthetic data for rare disease cases so as to avoid issue of under-fitting. Several CNN-based models like EfficientNet-B0, ResNet-18, SqueezeNet, Custom CNN were trained on the APTOS2019 dataset with the 80% - 20% training-testing split. The model achieved an accuracy of 90% with individual being ResNet-18: 91.65%, EfficientNet-B0: 90.08%, Custom CNN: 87.93% and SqueezeNet: 80.09% [34]. Sarra Guefrachi proposed a Multistage framework combining the feature extracting and fine-tuning techniques using multiple pre-trained CNNs. A custom classifier head was developed and added to base CNN models. Models like InceptionResnetV2, VGG16, VGG19, DenseNet121, MobileNetV2 and EfficientNet2L were used as base models achieving an overall accuracy of 96.61% on the Kaggle's diabetic retinopathy detection dataset with split ratio of 80%, 10% and 10%. General pre-processing techniques like removal of noisy and redundant images, image resizing and augmentation and contrast enhancement were implemented onto the dataset. As it was trained for only one dataset there might be an issue of the model sensitivity towards diverse datasets. Over-fitting issue being another limitation of the model [35]. The below given Table 3 summarizes some of the top DL models reviewed and their features.

Table 3: Comparison of DL approaches for diabetic retinopathy diagnosis.

Ref	B/M	Preprocessing	Model	Dataset	Performance
[24]	B	Resizing, Denoising	RSG-Net	Messidor-I	A: 99.37%, P: 98.86%, F1: 99.42%, S: 100.00%

II.3 HYBRID - BASED TECHNIQUES FOR DR CLASSIFICATION

Hybrid techniques combine multiple models together to utilize the best of both models to achieve the highest accuracy for the model. Integrating the model with various preprocessing techniques can also generate significant change in accuracy.

II.3.1 Binary-Class Classification

A hybrid model called Diabetic Retinopathy Detection-Capsule Network-Deep Learning combining the UNet++ for semantic segmentation and Capsule Networks for feature classification was proposed by I. Govindharaj et al [37]. The images pre-processed by the technique of CLAHE and Histogram Equalization are fed to the UNet++ model for segmentation of two essential structures of the eye namely the Optic Disc and Optic Cup. The segmented images are carry forwarded to the CapsNet to understand the underlying patterns and details of the image. It analyzes the images the segmented features to classify if the eye is normal or glaucomatous. The same architectural model is used for DR detection. Kerem Gencer et al. proposed a hybrid framework combining the Generative Adversarial Networks, Denoising Autoencoders and a fine tuned EfficientNetB0. GAN was used to generate synthetic retinal images to solve the issue of class imbalance and enrich the training dataset. The Denoising Autoencoders were responsible for enhancing the image quality by reducing the noise level and other factors like speckle noise, motion blur, and illumination inconsistencies present in both the original and GAN-generated images. The EfficientNetB0 was used for classification of the pre-processed images. The model used a custom created Optical Coherence Tomography image dataset consisting of 4274 images [38]. Govindharaj et al. proposed a hybrid model combining UNet++ for segmenting parts of eye indicating glaucoma and Capsule Network for finding intrinsic patterns and details hidden in the segmented image. Model was trained and tested on combined dataset consisting of RIM-ONE Database, DRIONS-DB and ORIGA-Light. Techniques like Histogram Equalization and CLAHE were used for pre-processing the retinal images to enhance their quality by improving the contrast and clarity of the image. The limitation of the model being highly computational and sensitive to image quality giving more importance to the pre-processing techniques [39]. K.V.

Naveen et al. proposed a hybrid model EffNet-SVM which combined the EfficientNetV2-Small 15 as a feature extractor and RBF kernel SVM as a classifier for the disease. Instead of soft-max layer generally used with CNNs, SVM was used as a classifier as it proves to be better at separating class. The model converted the multi-class APTOS 2019 dataset into a binary dataset and achieved an accuracy of 97.26%. The limitation being that the model was trained only for binary datasets and limited experiment only on two datasets namely, APTOS and HRF [13]. Ghulam Ali et al. combined ResNet-50 and Inception-v3 to study the features leading to DR. The extracted features are combined and fed to IR-CNN (Inception–ResNet CNN) and trained on Messidor and IDRiD datasets with the Messidor giving the maximum accuracy of 90.89%. The model aimed to solve the issue while detecting the lesions in early-stages [40]. Amar Shukla et al. [41] developed an integrated model of Self-Attention Network used for in detail analysis of retina features and Vision Transformer (ViT) being responsible for combining their results for DR detection. The model is named as HybridFusionNet and tested on Kaggle DR dataset achieving an accuracy of 99% for binary and 91% for multi-class classification. But the model had high computational requirements due to integration of transformer models and was sensitive to variations in quality of fundus images. Butt et al. combined transfer-learning models like GoogLeNet and ResNet-18 then the resized images are given as input to each of these model responsible to extract the deep hidden features which are further combined to create a 2000-dimensional hybrid feature set. Then for the DR identification and severity grading several ML classifiers like SVM, Random Forest, Naive Bayes, RBF, etc. are used on the APTOS 2019 dataset achieving an accuracy of 97.8% for binary classification and 89.29% multi-class classification [42].

II.3.2 Multi-Class Classification

A.S. Sabeena et al. followed a hybrid approach and combined Xception, MoNet and PolyNet models. They used APTOS 2019 dataset with split of 80% and 20%. The pre-processing steps included Median filtering, SwinUNet for segmentation based on Gradient Descent-Sea Turtle Foraging Algorithm. The model MoNetPolyNetXception achieved an accuracy 98.9%. But the model requires high computational powers and can be dataset bias [43]. Sukran Yaman Atci combined pretrained CNN models, CAD (Computer-aided diagnosis) system and SHAP explainability on three datasets including Kaggle DR fundus dataset for predicting DR severity grades. The CNN models are used to extract the lesion in retina then hybrid ensemble classifiers predicts DR stages and SHAP is responsible for highlighting the affected regions but the model suffers with imbalanced class and comparatively lower performance in moderate/severe DR stages [44]. Kazi Ahnaf Alavee et al. proposed a model which integrated explainable AI(Grad-CAM) with DL models (DL-XAI) 16 for their better interpretability b generating heatmaps for the fundus images. The model was experimented on multiple datasets like APTOS 2019 Kaggle dataset, Messidor-2 and IDRiD. Multiple existing CNN models were used to extract lesions from the fundal images and custom CNN was trained to do the classification task with an accuracy of 95.27% [45]. Ayesha Jabbar et al. used GoogLeNet and ResNet for feature extraction and optimized it with Adaptive Particle Swarm Optimization (APSO) responsible for selecting only the most apt features extracted making the classification task more efficient with accuracy of 94%.

These features were then used to train the classical ML classifiers - SVM, RF, DT, LR. The model was used to detect not only the early stage lesions but cotton wool spots, IRMA, capillary degeneration. The model was trained on Kaggle EyePACS1 dataset [46]. Yasashvini R. et al. developed multiple models using CNN and hybrid transfer-learning model for DR diagnosis and severity grading - Simple CNN, CNN + ResNet and CNN + DenseNet with an accuracy of 96.22%, 93.18% and 75.61% respectively using Kaggle DR dataset. But the models faced limitations of small dataset size and class imbalance [47]. Md Nahiduzzaman et al. applied SVD(Singular Value Decomposition) on the features extracted to reduce dimensionality and select the unique and most prominent features. ELM(Extreme Learning Machine) classifier was used to classify DR into severity grades with an accuracy of 98.09% for Aptos-2019 and 96.26% for Messidor-2 dataset and 99.73% accuracy for Binary classification. For the preprocessing stage Ben Graham and CLAHE techniques were used on the fundus images (9605633). Anas Bilal et al. developed a hybrid CNN-SVD model integrated with several transfer learning models like Inception-V3, GoogLeNet, AlexNet, and ResNet. Furthermore, two different U-Net models were used for Optic Disc and Blood Vessel segmentation in order to remove unwanted features. A basic CNN model was used to extract 256 features reduced to 100 using SVD with Inception-V3 performing the best with an accuracy of EyePACS-1 - 97.92%, Messidor-2 - 94.59% and DIARETDB0 - 93.52% [48]. The below given Table 4 summarizes some of the top HL models reviewed and their features.

Table 4: Comparison of HL approaches for diabetic retinopathy diagnosis.

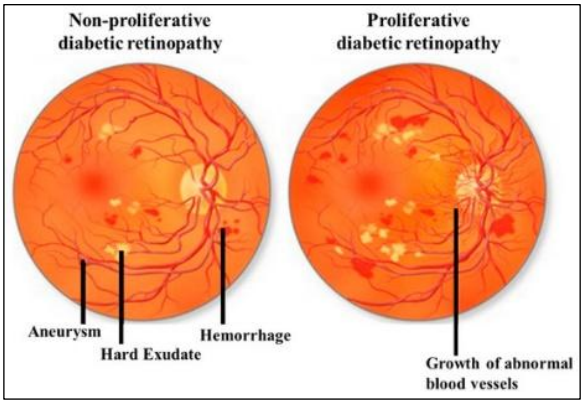
II.4 SYMPTOM - BASED TECHNIQUES FOR DR CLASSIFICATION

The main symptoms of DR include Microaneurysms, Exudates and Hemorrhages. Each symptom indicates different levels of severity of the disease. So it becomes essential to be able 18 to detect each of these accurately and efficiently from the concerned image datasets. Figure 3 broadly visualized the major stages and symptoms of the disease.



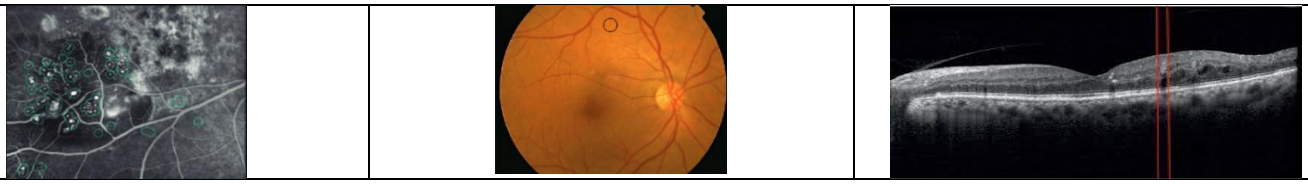


Figure 3: DR stages and symptoms
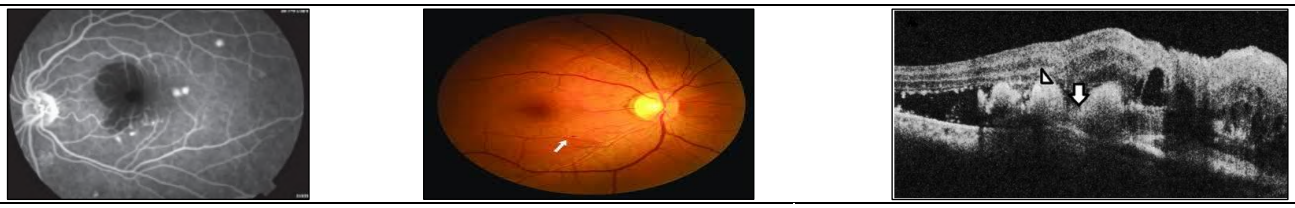
Source: [1]

II.4.1 Microaneurysms

Nianjia Wang et. al. developed an improved OCTA based image processing method to efficiently detect the Microaneurysms. It uses the OCTA blood flow signals along with Structural OCT hyper-reflective MA signals and 3D reconstruction to create a 3D-MA map known as the DVC-MA map to detect and visualize more Microaneurysms [50]. Abbas Rehman et. al. introduced FISM (Fundus Images Segmentation Model) based on Segment Anything Model (SAM) combining DL and reinforcement learning on the DDR dataset for the precise detection and segmentation of Microaneurysms (MAs). The model received AUC of 96.32% . But the model suffered from the limitation of using only one dataset [51]. Luís Mendes et. al. developed an automatic system - RetmarkerDR for the evaluation of Microaneurysms count and turnover using the fundus images at the hyperperfusion stage of non-proliferative diabetic retinopathy (NPDR). The dataset was collected from EUROCONDOR clinical trial helping us to keep track of DR progression. But the model only used fundus images and was highly dependent on the image quality [52]. Norah Asiri et. al. developed a DL-Based model using Dilated Residual Network (DRN) a better and modified ResNet-50 with dilation and technqiues like ROI pooling and Patch-based detection. The model was trained and tested on several datasets like e-ophtha-MA, DiaretDB1-MA, ROCh, IDRiD (MA masks) and DDR. The model was able to detect even the smallest lesions present in the retina [53]. Aditya Sharma et. al. developed a deep learning–based model along with the approach of transfer learning on the E-Ophtha (MA) dataset. The model helps in early detection of Microaneurysms and classifying the images into MA and non-MA. But the model is focused only on Binary classification rather than on DR grading [54]. Pedro Romero-Aroca et. al. used modified ETDRS grid to find the count and exact count of Microaneurysms and found that these dots are not randomly distributes across the retina, rather majority of them are found in temporal and inferior quadrants of the modified ETDRS grid. Higher the concentration, higher is the severity of DR. The study was conducted for Miradataset and Messidor dataset [55]. The below given Figure 4 shows comparison of the Microaneurysms across various image.



Fluorescence.	Fundus.	OCT.

Figure 4: Microaneurysm detection across imaging modalities.
Source: [56] [57] [58].

II.4.2 Hemorrhages

Gang-Min Park et. al. conducted two approaches - Severity-Based Approach using APTOS dataset and Lesion-Based Approach using NMC dataset for the binary and multi-class classification and multi-label classification. NMC dataset has various types of hemorrhages such as Retinal hemorrhages, Vitreous hemorrhages, and Preretinal hemorrhages. The study also used Cross dataset for fine tuning. It concluded that integrating both the approaches can result in more precise accuracy and interpretability of the model.EfficientNet was found to be the best performing model [59]. Saurabh Chavanke et. al. 20 proposed an automated system called the Rule-Based Hemorrhage Detection Architecture to automatically detect hemorrhages using DIARETDB0 and DIARETDB1 datasets. The focus is on pre-processing the fundus images in such a way as to highlight the hemorrhages spots by using techniques like extracting green channel of the image then enhancing it to make the dark hemorrhages more visible. Techniques like Top-Hat Transform and thresholding are used to highlight possible blobs.At last Rule based filtering based on size, shape and color is adopted for further classification [60].Instead of using traditional methods for lesion identification for DR detection Ronsong Sun et. al. proposed an AI model called EVision AI system to calculate two efficient indicators - ratio of haemorrhagic area to the total retinal area and ratio of the haemorrhagic area to the microaneurysm count for accurate detection of DR in type-2 diabetes patients.

The system uses non-mydriatic fundus images to detect hemorrhages. The EVision system used DL semantic segmentation algorithms integrated with CNN models [61]. Patsaphon Chandhakanond et. al. proposed a modified version of Iterative NICK Thresholding Region Growing (INRG) to effectively identify and segment Hemorrhages and Exudates. Watershed Separation technique for accurate segmenting of overlapped or poorly defined areas and Chi² Feature Ranking (Chi²) for accurate selection of features so as to efficiently classifying the segmented region were combined with INRG. DR2019 Mobile Dataset and JSIEC dataset were used for the study. INRG was used along with SVM classifier [62]. Sujuan Tang et. al. developed SAM-ada-Res tool to understand the overall context of the fundus images using the Segment Anything Model (SAM2) model integrated with an Adapter and ResNet101 Encoder for studying the tiny details and textures of the focused area for accurate detection of the complicated and irregularly shaped hemorrhage lesions. The information received from the Adapter and the Encoder is fused together and forwarded to U-Net decoder generating the final segmentation mask. The model was trained on OIA-DDR, IDRID and JYFY-HE datasets. Model performance was evaluated using two key metrics: normalized Intersection over Union (nIoU) and normalized Dice coefficient (nDice) [63]. The below given Figure 5 shows comparison of the Hemorrhages across various image.

Fluorescence.	Fundus.	OCT.

Figure 5: Hemorrhages detection across imaging modalities.
Source: [64] [65] [66].

II.4.3 Exudates

Esmat Ramezanzadeh et al. proposed a method to differentiate exudates from other bright structures like the optic disc, blood vessels, reflections and background noise using the textural difference between them and thus modified Radon transform technique into capturing textural changes and directional intensity patterns. Kirsch edge detection was used to highlight exudates by identifying its rough sharp borders differentiating it from vessels and bright noise.Further morphological reconstruction was applied to filter out the unwanted structures and smooth the image retaining only the true exudate regions. At last Otsu threshold was implemented to separate the bright lesions - exudates and the background. The technique was tested on DIARETDB1 and a local MUMS-DB dataset [67]. Chang Ki Yoon et al. used the OCT (Optical Coherence Tomography) scans instead of traditional fundus images to detect and segment HE which have 3D features at 3D-level by evaluating the volume of HE in the retina to better understand the presence and severity of HE. DUCK-Net - a modified version of U-Net was developed to segment HE which look like bright, hyper-reflective foci in OCT B-scans. Hard exudates are detected and segmented for each OCT slice then all the slices are combined to evaluate the 3D volume of the HE. The 3D OCT data is then projected to create a 2D fundus like image. The model achieved an excellent accuracy of 99.9% [68]. Rajesh et al. focused on grading the severity of diabetic maculopathy based on the closeness of the lesion to macula. Initially the retinal image is preprocessed to improve its quality by removing noise and applying contrast enhancement. Further various morphological operations were applied to eliminate the structures that look like exudate to retain only the 22 true exudates. Extended minima transform algorithm was used to isolate the exudate from rest of the image area by taking brightness, shape, and texture as a base.

And lastly Optic disc location and Relative distance is used to find the locate the macula and hence evaluating the closeness of exudate from the region. Based on the distance macula region is divided into three concentric circles - C1 (closest), C2 and C3 with the grading being severe if lesion is in C1 circle , moderate or mild if lesion in C2 or C3 and normal if no exudate found. The study was carried out on the Messidor dataset. The performance of system being 90% sensitivity for HE detection and 92% accuracy for Maculopathy detection [69]. S. Preetha developed a model using CNN classifier - ResNet100 to detect HE hence detecting DR. The model was tested on several datasets like Kaggle EyePACS, APTOS 2019 and IDRiD achieving an accuracy of 76% for DR classification. Their paper also included a survey on various DL models used for DR detection and concluded that CNN based models can generate high accuracy results if trained on large, good quality datasets [70]. The below given Figure 6 shows comparison of the Exudates across various image.

III. DATASETS

Datasets used for DR detection include retinal images taken from different angles to capture lesions that show presence of DR. A dataset with diverse demography helps us with accurate detection of the disease and a generalized model. Some of the commonly used types of retinal images are: 1 - Fundus image: 2D images used for capturing Retinal Surface, Microaneurysms, Hemorrhages, Hard exudates and blood vessels. It helps in early stage detection of DR. 2 - OCT (Optical Coherence Tomography): 3D images used to study retinal structure layer-wise. It shows thickness of macula and exudate volume, usually used for detecting Diabetic Macular Edema. 3 - OCTA (Optical Coherence Tomography Angiography): used for capturing Microaneurysms and non-perfusion areas, helps in detecting proliferative DR(PDR) [1]. 4 - FA (Fluorescein Angiography): mostly used to study where blood is flowing abnormally or leaking. Helps in early detection of fluid leakage and Microaneurysms (fluoro). Table 6 categorizes the various retinal datasets into broader categories of public and private based on their availability.

Table 6: Public and Private Diabetic Retinopathy Dataset Comparison.

Category	Type	B / M	Dataset Name	No. of Images	Resolution
Public	Fundus	B	STARE	90	700×605

IV. CHALLENGES

Detecting and classifying DR is a crucial task to avoid total blindness. Integrating AI into traditional methods can fasten the detection process and make the prediction task accurate. It also ensures earlier response-time hence avoiding the risk of disease getting severe. Employing hybrid technologies like RSG-Net, CNN-RBF model the accuracy of model can be increased significantly. Along with the model and techniques used diversity and size of dataset also plays a significant role in the performance of model. It is essential to use a balanced and diverse dataset so as to develop a generalized model. The fundus images are usually characterized by noise and taken in dark so using an appropriate preprocessing technique like image augmentation through GAN and denoising autoencoders is also a crucial part of model development. Medical images are required to be employed with sophisticated feature extraction techniques to highlight the affected areas so as to focus on regions having lesions. Employing hybrid architectures to increase the efficiency can lead to higher computational cost and complexity of the model hence it is required for the researchers to develop a light-weight, feasible architecture to be easily integrated into local clinics. Along with this binary classification usually enjoys a higher accuracy rate as compared to multi-class classification for severity grading. So there is a need to develop a model which is light-weight, feasible and can be easily integrated to medical institutions for diverse range of patients making the model more generalized.

- Traditional time-consuming methods: The traditional methods used for detecting diabetic retinopathy include manual analysis of the fundus images by Ophthalmologists which can be inaccurate and time-consuming [13]. Delay in detecting the disease can lead to it getting severe, which can ultimately lead to blindness. Concerns may also increase the accuracy of the results generated through manual work. Therefore, there is a need for an automated system which can detect the disease faster and give more accurate results.
- Imbalanced Dataset: Datasets play an important role in the diagnosis of any disease. As it can help us to understand the common traits and symptoms which can be used while predicting the presence of the disease while diagnosing. But usually, the medical images suffer from the issue of noisy or blur images, or they can be taken in a dark background making it unclear for diagnosis. The publicly available and commonly used datasets like Messidor and APTOS2019 are highly imbalanced and biased towards more images for the No-DR, Mild and Moderate classes. This can generate biased results and does not provide equal representation to all the severity classes [3].
- Diverse Image qualities: A dataset consists of multiple images with a wide variety of differing features like size, resolution, color, illumination, and noise which can influence the model's generalizability[39]. If the images are not normalized to similar levels, it can lead to inaccurate results. Along with that the dataset should be having samples from a diverse range of patients which can make the model more included for all kinds of cases. The various demographics include samples from all age and gender groups and from various ethnicities and races.
- Model Complexity: Although ML-DL models can significantly increase their performance, it can become difficult for normal people to understand their working and integration with local cameras and in local hospitals [45]. If the models are not designed to be lightweight and portable, it can become difficult to integrate them with local clinics and be accessible to everyone [25]. Thus, the model should be made easier to understand and implement. The experts should be able to understand its work and know how to handle the machine.
- Transparency: The models developed generally follow a black-box approach that means inner logic and data is not visible to clinical doctors. But being in the medical sector the transparency with patient data is very much required while keeping their data secure [45]. There should be logical reasoning for justifying the results so that patients can trust the system.
- Computationally Heavy and Costly: Although using DL can increase the time and efficiency of the detection model, integrating complex models and techniques can increase its complexity and make it costly to maintain it [45]. The main intention behind developing such systems is that they are accessible to everyone and feasible to be integrated into real life.

V. CONCLUSION

Detecting and classifying DR is a crucial task to avoid total blindness. Integrating AI into traditional methods can fasten the detection process and make the prediction task accurate. It also ensures earlier response-time hence avoiding the risk of disease getting severe. Employing hybrid technologies like the RSG-Net, CNN-RBF model the accuracy of the model can be increased significantly. Along with the model and techniques used, diversity and size of the dataset also plays a significant role in the performance of the model. It is essential to use a balanced and diverse dataset so as to develop a generalized model. vThe fundus images are usually characterized by noise and taken in dark so using an appropriate preprocessing technique like image augmentation through GAN and denoising autoencoders is also a crucial part of model development. Medical images are required to be employed with sophisticated feature extraction techniques to highlight the affected areas so as to focus on regions having lesions. Employing hybrid architectures to increase the efficiency can lead to higher computational cost and complexity of the model hence it is required for the researchers to develop a light-weight, feasible architecture to be easily integrated into local clinics. Along with this binary classification usually enjoys a higher accuracy rate as compared to multi-class classification for severity grading. So there is a need to develop a model which is light-weight, feasible and can be easily integrated to medical institutions for a diverse range of patients making the model more generalized.

ABSTRACT

The increasing penetration of weather-driven renewable energy sources in smart grids introduces operational instability, harmonic distortion, and elevated switching costs due to the limitations of rule-based and deterministic control strategies. This study proposes a deep reinforcement learning-based adaptive switching framework to enhance renewable utilization while minimizing operational risk and economic cost. A simulation-derived dataset incorporating renewable generation, load demand, total harmonic distortion, voltage deviation, frequency variation, and risk–cost indices was generated from a risk–cost optimized smart grid model and implemented in Google Colab. The switching problem was formulated as a Markov decision process with a state space composed of power quality and economic variables, and a discrete action space representing operational modes. A Deep Q-Network agent was trained over 24-hour episodes to learn optimal switching policies. Comparative evaluation against conventional, rule-based, and analytical risk–cost optimization strategies demonstrated up to 14% reduction in total harmonic distortion, 22% reduction in switching frequency, 17% reduction in operational cost, and 19% improvement in risk mitigation, while increasing renewable penetration by 11%. The proposed framework provides a scalable and intelligent solution for industrial smart grid applications.

I. INTRODUCTION

The accelerating global transition toward low-carbon power systems has significantly increased the penetration of renewable energy sources (RES), particularly solar photovoltaic (PV) and wind generation, within modern smart grids. Renewable integration enhances environmental sustainability and reduces dependence on fossil fuels; however, the intermittent and weather-dependent nature of these resources introduces considerable operational uncertainty. Fluctuations in solar irradiance and wind velocity lead to rapid variations in power output, which directly influence voltage stability, frequency regulation, harmonic distortion levels, and overall system reliability [1], [2]. In inverter-dominated smart grid architectures, renewable variability often causes dynamic power imbalance between generation and load demand. Such imbalance produces voltage deviations at the point of common coupling (PCC), frequency instability, and elevated Total Harmonic Distortion (*THD*). Excessive harmonic content not only reduces equipment lifespan but may also violate the harmonic limits specified in IEEE Std 519-2014 [3]. Maintaining harmonic distortion within prescribed thresholds while maximizing renewable utilization therefore represents a critical operational challenge. Traditional automatic transfer switching systems employ deterministic threshold-based control mechanisms. These rule-based systems select operating modes—renewable-only, grid-only, or hybrid—based on predefined voltage or generation limits. While simple to implement, such approaches operate reactively. Switching decisions occur only after deviations surpass fixed boundaries, which can result in excessive switching frequency, increased breaker wear, elevated maintenance cost, and reduced system efficiency. Moreover, rule-based frameworks do not adapt to evolving load patterns or environmental conditions, limiting their effectiveness under dynamic scenarios [4].

To overcome these limitations, risk–cost optimization models have been introduced to balance operational reliability and economic efficiency. Multi-objective optimization formulations typically minimize a composite function combining probabilistic operational risk and total economic cost [5], [6]. Risk indices are derived from voltage deviation, frequency variation, and harmonic distortion severity metrics, while economic cost includes grid energy consumption and switching penalties. Although such models provide structured decision-making capability, they rely on static weighting parameters and deterministic formulations. Consequently, they lack adaptive learning behavior and may not generalize effectively under unforeseen operating conditions. Artificial Intelligence (AI) techniques have recently gained attention in smart grid applications. Machine learning algorithms have been applied to renewable forecasting, demand prediction, anomaly detection, and energy management optimization [7], [8]. However, most AI-based approaches are supervised learning models that depend on historical labels. They improve prediction accuracy but do not inherently provide adaptive control strategies. Reinforcement Learning (RL), in contrast, enables agents to learn optimal decision policies through trial-and-error interaction with the environment. Unlike supervised methods, RL does not require labeled output data; instead, it optimizes cumulative reward over sequential decisions [9].

Deep Reinforcement Learning (DRL), which integrates deep neural networks with RL algorithms, has demonstrated superior performance in dynamic control problems. Applications in microgrid energy scheduling and battery energy management have shown promising results [10], [11]. Nevertheless, the integration of DRL within a unified risk–cost optimized renewable switching framework remains limited. Specifically, existing studies rarely incorporate harmonic compliance constraints and probabilistic risk modeling into RL-based switching strategies. The absence of adaptive policy-learning mechanisms in renewable smart grid switching constitutes a significant research gap. Deterministic optimization approaches compute optimal solutions for predefined objective functions but cannot continuously refine decisions based on evolving system behavior. In contrast, a DRL-based controller can dynamically adjust switching policies by learning from operational feedback, thereby improving stability and economic efficiency over time. This research proposes a Deep Reinforcement Learning-based adaptive switching framework for renewable-integrated smart grids. The proposed system integrates probabilistic risk assessment, economic cost modeling, and harmonic compliance constraints within a Markov Decision Process formulation. A Deep Q-Network (DQN) agent is trained using simulation-derived time-series data representing renewable generation, load demand, *THD*, voltage deviation, frequency deviation, operational risk index, and switching cost. The objective is to minimize harmonic distortion, reduce switching frequency, decrease operational cost, and improve renewable penetration while maintaining compliance with IEEE standards. The major contributions of this study are summarized as follows:

1. Development of a comprehensive dataset derived from a validated renewable smart grid simulation model.
2. Formulation of the renewable switching problem as a Markov Decision Process with clearly defined state and action spaces.
3. Design of a reward function integrating renewable utilization, harmonic penalties, switching penalties, and cost penalties.
4. Implementation of a Deep Q-Network agent for adaptive policy learning.
5. Quantitative comparison against conventional rule-based and deterministic risk–cost optimization strategies.

The proposed framework aims to enhance industrial smart grid reliability by introducing intelligent, adaptive control capable of handling renewable variability. By integrating learning-based decision-making within risk–cost optimization, the study contributes to the advancement of scalable and resilient renewable power systems.

II. RELATED WORK

The integration of renewable energy sources into smart grids requires coordinated interaction among renewable generation modeling, probabilistic risk assessment, economic cost evaluation, power quality monitoring, and intelligent control strategies. This section presents the theoretical background underpinning the proposed Deep Reinforcement Learning-based adaptive switching framework.

II.1 RENEWABLE ENERGY VARIABILITY IN SMART GRIDS

Renewable energy sources, particularly solar photovoltaic (PV) and wind power systems, exhibit stochastic and time-varying behavior due to dependence on meteorological conditions. Solar irradiance fluctuations caused by cloud movement and atmospheric variability directly influence PV output, while wind generation depends nonlinearly on wind speed, typically following a cubic power relationship [1], [2]. In grid-connected renewable systems, intermittent generation introduces rapid power imbalance between supply and demand. This imbalance manifests as voltage deviations at the point of common coupling (PCC), frequency instability, and dynamic harmonic distortion. High renewable penetration levels amplify these effects, particularly in inverter-dominated grids where switching converters influence waveform quality [12]. To maintain stability, grid operators traditionally employ reserve capacity, voltage regulation equipment, and automatic transfer switches. However, these mechanisms are often reactive and may not optimally balance renewable utilization with reliability objectives.

II.2 IOT-BASED SWITCHING AND MONITORING SYSTEMS

The emergence of the Internet of Things (IoT) has significantly enhanced monitoring and supervisory capabilities in smart grids. IoT-enabled architectures allow real-time acquisition of electrical parameters such as voltage magnitude, current waveform, active power, and harmonic distortion [4], [5]. Cloud-based communication platforms facilitate remote control and distributed decision-making. Automatic Transfer Switch (ATS) systems integrated with IoT modules enable automated selection among renewable sources, grid supply, and backup generators. Although these systems improve operational continuity and transparency, their control logic typically relies on deterministic thresholds. For example, switching may be triggered when renewable power falls below a fixed percentage of load demand or when voltage deviation exceeds a predefined limit.

Such rule-based systems lack predictive adaptability. They respond only after disturbances occur and do not account for probabilistic risk or long-term economic impact. Moreover, switching frequency may increase unnecessarily during transient fluctuations, leading to mechanical wear and elevated operational cost.

II.3 RISK MODELING IN RENEWABLE-INTEGRATED SYSTEMS

Operational risk assessment in power systems quantifies the likelihood and severity of undesirable events such as voltage collapse, frequency instability, and harmonic violations. Probabilistic risk models commonly incorporate power deficit probability, deviation indices, and severity weighting factors [6]. The general structure of a risk function may be expressed as the product of occurrence probability and impact severity. Severity indices typically normalize voltage deviation, frequency variation, and *THD* relative to standard limits. IEEE Std 519-2014 [3] specifies that voltage *THD* in low-voltage systems should not exceed 5% under normal operating conditions [7]. Risk-based optimization frameworks combine reliability assessment with economic objectives. Multi-objective formulations often minimize a weighted sum of operational risk and total cost [8], [9]. Although effective in structured optimization environments, these formulations depend on static weighting parameters. Once the weights are defined, the optimization solution remains fixed unless manually reconfigured. Consequently, deterministic risk–cost optimization does not inherently learn from operational history or adapt to evolving environmental conditions.

II.4 ECONOMIC COST CONSIDERATIONS IN SWITCHING OPERATIONS

Economic performance in renewable-integrated smart grids is influenced by grid energy tariffs, switching frequency, maintenance cost, and renewable curtailment losses. Grid energy consumption incurs direct cost proportional to electricity tariff rates, while frequent switching operations increase mechanical stress on breakers and reduce equipment lifespan [10]. The switching cost model therefore incorporates both grid energy expenditure and a penalty term representing switching events. Minimizing switching frequency is essential for long-term economic sustainability. However, excessive restriction of switching may compromise reliability or power quality compliance. Achieving a balanced trade-off between economic cost and system reliability requires dynamic decision-making capability, particularly under fluctuating renewable conditions.

II.5 ARTIFICIAL INTELLIGENCE AND REINFORCEMENT LEARNING IN POWER SYSTEMS

Artificial Intelligence (AI) has been increasingly applied in smart grid environments for forecasting, classification, optimization, and control tasks [11]. Supervised learning methods improve renewable generation prediction and load demand estimation. However, these methods require labeled training data and do not directly optimize sequential decision processes. Reinforcement Learning (RL) differs fundamentally from supervised learning. In RL, an agent interacts with an environment, selects actions, receives rewards, and learns a policy that maximizes cumulative reward over time. The environment is typically modeled as a Markov Decision Process (MDP) [13]. Deep Reinforcement Learning (DRL) integrates neural networks to approximate value functions or policies in high-dimensional state spaces. The Deep Q-Network (DQN) algorithm employs a neural network to approximate the action-value function and uses experience replay to stabilize training [14]. Recent studies have applied DRL to microgrid energy scheduling and battery energy management [15], [16]. These studies demonstrate improved adaptability compared to rule-based systems. Nevertheless, most existing RL applications focus primarily on economic dispatch or energy storage scheduling. Integration of harmonic compliance, risk modeling, and switching cost minimization within a unified RL-based switching framework remains limited.

II.6 RESEARCH GAP AND THEORETICAL POSITIONING

From the theoretical analysis above, three principal limitations are identified in existing literature:

1. IoT-based switching systems operate reactively without adaptive policy learning.
2. Risk–cost optimization models rely on deterministic formulations with static weighting factors.
3. Reinforcement Learning applications in smart grids rarely incorporate harmonic distortion constraints and probabilistic risk indices within switching control.

The present study addresses these limitations by integrating:

- Renewable variability modeling
- Probabilistic risk assessment
- Economic switching cost modeling
- IEEE 519 harmonic compliance
- Deep Reinforcement Learning-based adaptive control

Within a unified renewable smart grid switching architecture. By formulating the switching problem as a Markov Decision Process and training a Deep Q-Network agent using simulation-derived operational data, the proposed framework enables adaptive policy learning. Unlike deterministic optimization, the RL agent continuously refines switching decisions based on cumulative reward, thereby enhancing stability and economic performance under varying renewable conditions. The next section presents the detailed dataset generation methodology, system modeling framework, and reinforcement learning formulation adopted in this research.

III. MATERIALS AND METHODS

This section describes the renewable smart grid modeling framework, dataset generation methodology, risk–cost formulation, and reinforcement learning configuration adopted in this study. All equations are numbered sequentially beginning in this section, in accordance with journal formatting requirements.

III.1 SYSTEM CONFIGURATION

The investigated smart grid consists of:

- Solar photovoltaic (PV) subsystem.
- Wind energy conversion subsystem.
- Utility grid interface.
- Industrial load demand.
- Intelligent switching unit at the point of common coupling (PCC).
- Monitoring block measuring voltage, frequency, and harmonic distortion.

The switching controller selects among four operational modes:

1. Renewable-only.
2. Hybrid renewable–grid.
3. Grid-only.
4. Battery-priority.

Switching decisions are executed at discrete time intervals. The overall architecture of the renewable-integrated smart grid considered in this study is illustrated in Figure 1.

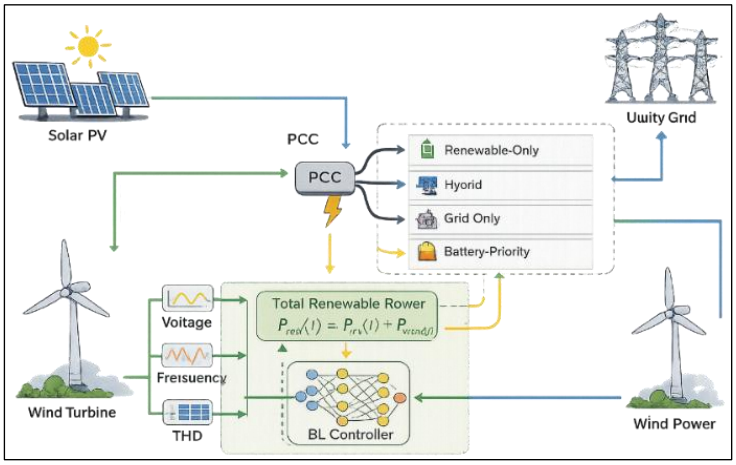

Figure 1: Architecture of renewable-integrated smart grid with adaptive switching controller.
Source: Authors, (2026).

III.2 RENEWABLE GENERATION MODELING

III.2.1 Solar Photovoltaic Model

The instantaneous solar PV output is modeled as:

$$P_{pv}(t) = \eta A G(t) \tag{1}$$

where:

- $P_{pv}(t)$ = PV output power (kW)
- η = conversion efficiency
- A = effective panel area
- $G(t)$ = solar irradiance (W/m²)

Solar irradiance was simulated using diurnal sinusoidal variation with stochastic noise to reflect cloud-induced variability.

III.2.2 Wind Power Model

Wind turbine output is expressed as:

$$P_{wind}(t) = \frac{1}{2}\rho A_r C_p v^3(t) \tag{2}$$

where:

- ρ = air density (kg/m³).
- A_r = rotor swept area (m²).
- C_p = power coefficient.
- $v(t)$ = wind speed (m/s).

The cubic dependency introduces nonlinear variability in renewable output.

III.2.3 Total Renewable Power

Total renewable generation is given by:

$$P_{ren}(t) = P_{pv}(t) + P_{wind}(t) \quad (3)$$

The interaction between solar and wind generation contributing to total renewable output is depicted in Figure 2.

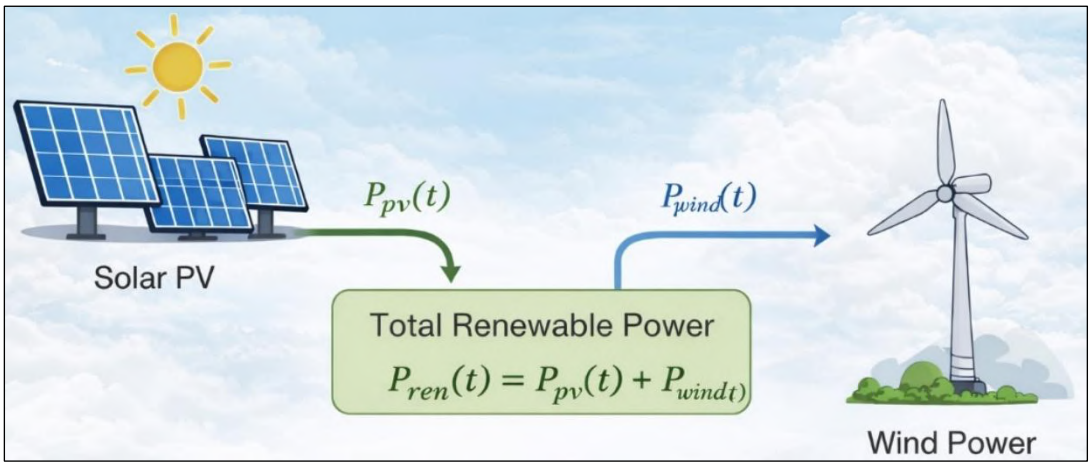

Figure 2: Renewable power modeling structure showing PV and wind contribution to total generation.
Source: Authors, (2026).

III.3 LOAD DEMAND MODELING

Industrial load demand is modeled as:

$$P_L(t) = P_{avg} + P_{amp}\sin(\omega t) + \epsilon(t) \quad (4)$$

where:

- P_{avg}= average load.
- P_{amp}= load variation amplitude.
- ω= angular frequency.
- $\epsilon(t)$= random disturbance term.

This formulation captures daily consumption cycles with stochastic fluctuation. The primary dataset features extracted from the simulation model are summarized in Table 1.

Table 1: Dataset features used for reinforcement learning training.

Variable	Symbol	Unit	Description
Renewable Power	P_{ren}	*kW*	Total PV + Wind output
Load Demand	P_L	*kW*	Industrial load profile
Voltage Deviation	ΔV	*p.u.*	PCC voltage variation
Frequency Deviation	Δf	*Hz*	Frequency variation
Harmonic Distortion	*THD*	*%*	Total harmonic distortion
Risk Index	*R*	–	Operational risk value
Total Cost	C_{tot}	₹	Economic cost
Switching Event	N_{switch}	–	Breaker operation count

Source: Authors, (2026).

III.4 POWER IMBALANCE AND STABILITY INDICATORS

III.4.1 Power Mismatch

$$\Delta P(t) = P_{ren}(t) - P_L(t) \tag{5}$$

where:

- ΔP(t) = power mismatch at time t (kW).
- Pren(t) = total renewable power (kW).
- PL(t) = load demand (kW).

Positive ΔP indicates surplus renewable generation; negative values represent deficit.

III.4.2 Voltage Deviation

Voltage deviation at PCC is modeled as proportional to power imbalance:

$$\Delta V(t) = k_v \frac{\Delta P(t)}{P_L(t)} \tag{6}$$

where:

• ΔV(t) = voltage deviation at PCC (p.u.)
• kv = voltage sensitivity coefficient
• ΔP(t) = power mismatch (kW)
• PL(t) = load demand (kW)

III.4.3 Frequency Deviation

$$\Delta f(t) = k_f \frac{\Delta P(t)}{P_L(t)} \tag{7}$$

where:
• Δf(t) = frequency deviation (Hz)
• kf = frequency sensitivity coefficient
• ΔP(t) = power mismatch (kW)
• PL(t) = load demand (kW)

III.4.4 Total Harmonic Distortion

Harmonic distortion is expressed as:

$$THD(t) = THD_0 + k_h \mid \Delta P(t) \mid + \xi(t) \tag{8}$$

where:

- THD_0 = base harmonic level
- k_h= harmonic sensitivity constant
- $\xi(t)$ = noise component

Compliance condition according to IEEE Std 519-2014 [3]:

$$THD(t) \leq 5\% \tag{9}$$

The relationship between power imbalance and harmonic distortion used in the modeling process is illustrated in Figure 3.

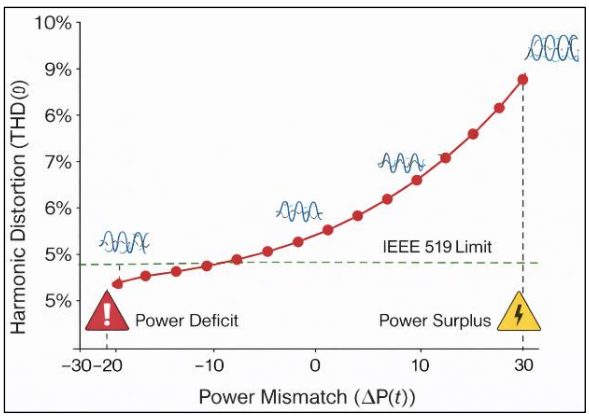

Figure 3: Harmonic distortion variation as a function of power mismatch.
Source: Authors, (2026).

III.5 PROBABILISTIC RISK MODELING

Operational risk is defined as:

$$R(t) = P_{def}(t) \times S(t) \tag{10}$$

where:

- R(t) = operational risk index
- Pdef(t) = deficit probability
- S(t) = severity index

Deficit probability:

$$P_{def}(t) = \begin{cases} 1, & P_{ren}(t) < P_L(t) \\ 0, & \text{otherwise} \end{cases} \tag{11}$$

where:

- Pdef(t) = probability of power deficit
- Pren(t) = renewable power (kW)
- PL(t) = load demand (kW)

Severity index:

$$S(t) = w_1 \frac{|\Delta V(t)|}{0.05} + w_2 \frac{|\Delta f(t)|}{0.5} + w_3 \frac{THD(t)}{5} \tag{12}$$

where:

- S(t) = severity index.
- w1, w2, w3 = weighting coefficients.
- ΔV(t) = voltage deviation (p.u.).
- Δf(t) = frequency deviation (Hz).
- *THD*(t) = total harmonic distortion (%).
- 0.05 = permissible voltage deviation limit (p.u.).
- 0.5 = allowable frequency deviation limit (Hz).
- 5 = IEEE 519 *THD* limit (%).

The probabilistic risk modeling structure integrating deficit probability and severity index is shown in Figure 4.

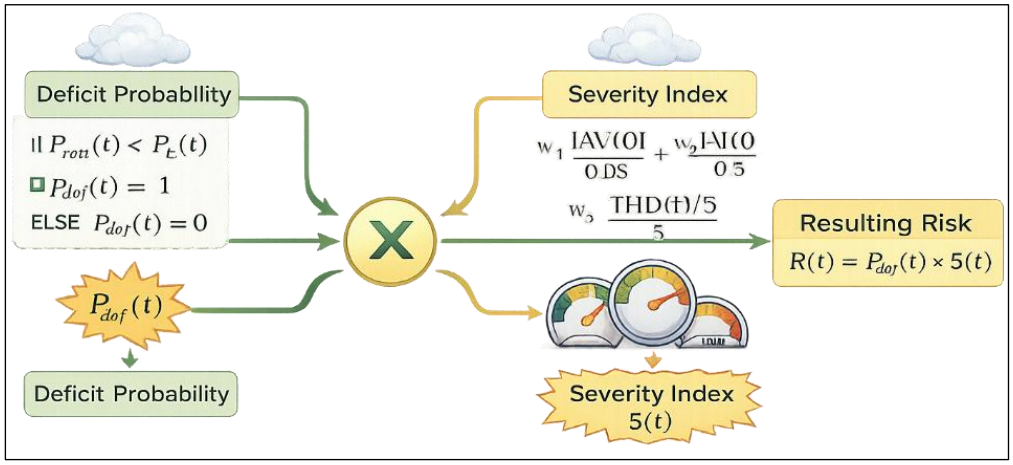

Figure 4: Operational risk computation framework combining probability and severity components.
Source: Authors, (2026).

III.6 ECONOMIC COST MODELING

Total cost is computed as:

$$C_{tot}(t) = C_{grid}(t) + C_{switch}(t) \tag{13}$$

where:

- *Ctot*(t) = total operational cost (₹)
- Cgrid(t) = grid energy cost (₹)
- Cswitch(t) = switching cost (₹)

Grid energy cost:

$$C_{grid}(t) = \lambda_g \max(0, P_L(t) - P_{ren}(t)) \tag{14}$$

Switching cost:

$$C_{switch}(t) = \lambda_s N_{switch}(t) \quad (15)$$

where:

- λ_g = electricity tariff.
- λ_s = cost per switching operation.
- $N_{switch}(t)$ = switching event indicator.

III.7 DETERMINISTIC RISK–COST OBJECTIVE

The baseline optimization function is:

$$J(t) = \alpha R(t) + \beta C_{tot}(t) \quad (16)$$

where:

- J(t) = composite objective function.
- R(t) = risk index.
- *Ctot*(t) = total cost.
- α = risk weighting coefficient.
- β = cost weighting coefficient.

The simulation parameters adopted for renewable generation and economic modeling are listed in Table 2.

Table 2: Simulation parameters used in the smart grid model.

Parameter	Value
Nominal Voltage	415 V
Nominal Frequency	50 Hz
PV Rated Capacity	50 kW
Wind Rated Capacity	40 kW
THD Limit	5%
Grid Tariff	₹6/kWh
Switching Cost	₹50/event
Weighting Factors	α = 0.6, β = 0.4

Source: Authors, (2026).

III.8 REINFORCEMENT LEARNING FORMULATION

III.8.1 State Space

The RL state vector is defined as:

$$S_t = [P_{ren}(t), P_L(t), THD(t), \Delta V(t), \Delta f(t), R(t), C_{tot}(t)] \quad (17)$$

where:

- St = state vector at time t
- Pren(t) = renewable power
- PL(t) = load demand
- *THD*(t) = harmonic distortion
- *ΔV*(t) = voltage deviation
- *Δf*(t) = frequency deviation
- R(t) = risk index
- *Ctot*(t) = total cost

The Markov Decision Process formulation of the switching problem is presented in Figure 5.

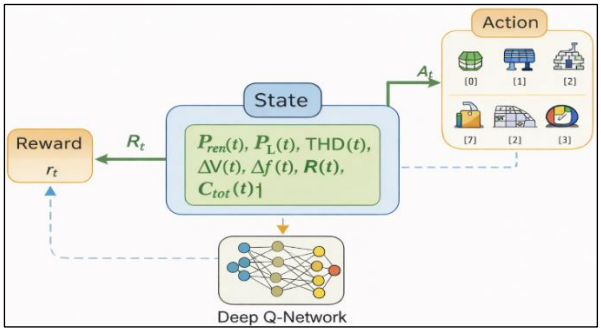

Figure 5: Markov Decision Process representation of the adaptive switching environment.
Source: Authors, (2026).

III.8.2 Action Space

$$A_t \in \{0,1,2,3\} \tag{18}$$

Representing renewable-only, hybrid, grid-only, and battery-priority modes. Where.

- At = control action at time t.
- 0 = renewable-only mode.
- 1 = hybrid mode.
- 2 = grid-only mode.
- 3 = battery-priority mode.

III.8.3 Reward Function

The reward function is formulated as:

$$r_t = \frac{P_{ren}(t)}{P_L(t)} - \lambda_1 \, THD_{pen}(t) - \lambda_2 \, Sw_{pen}(t) - \lambda_3 \, Cost_{pen}(t) \tag{19}$$

where:

- rt = reward at time t.
- λ1 = harmonic penalty coefficient.
- λ2 = switching penalty coefficient.
- λ3 = cost penalty coefficient.
- $THD_{pen}(t)$ = harmonic violation penalty.
- $Sw_{pen}(t)$ = switching penalty.
- $Cost_{pen}(t)$ = economic cost penalty.

This structure incentivizes renewable utilization while penalizing harmonic violation, excessive switching, and economic cost. The reinforcement learning hyperparameters and reward coefficients used for training are summarized in Table 3.

Table 3: Reinforcement learning training configuration.

Parameter	Value
Episodes	800
Time Horizon	24 steps
Learning Rate	0.001
Discount Factor	0.99
Batch Size	32
Replay Buffer Size	5000
λ_1 (*THD* penalty)	5
λ_2 (Switch penalty)	2
λ_3 (Cost penalty)	0.01

Source: Authors, (2026).

III.9 DEEP Q-NETWORK MODEL

The DQN approximates the action-value function:

$$Q(s, a; \theta) \tag{20}$$

where:

- Q(s,a;θ) = action-value function
- s = system state
- a = selected action
- θ = neural network parameters

The neural network architecture of the Deep Q-Network used for policy approximation is shown in Figure 6.

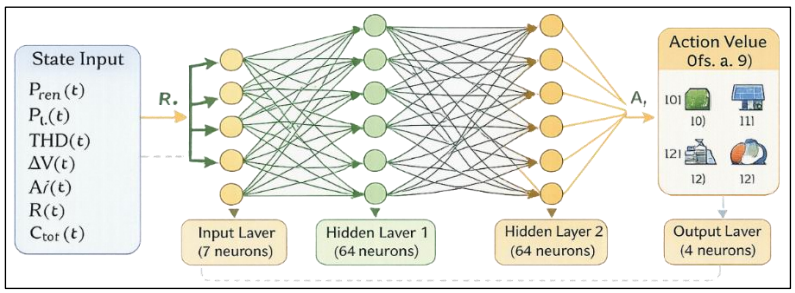

Figure 6: Deep Q-Network architecture for adaptive switching policy learning.
Source: Authors, (2026).

IV. RESULTS AND DISCUSSION

This section presents the performance evaluation of the proposed Deep Reinforcement Learning (DQN)-based adaptive switching strategy. The model was trained over 800 episodes with a 24-step time horizon per episode. Comparative analysis was conducted against the conventional rule-based switching mechanism and deterministic risk–cost optimization baseline.
Performance metrics considered include:

- Total Harmonic Distortion (*THD*).
- Operational cost.
- Switching frequency.
- Risk index.
- Renewable penetration.
- Cross-validation convergence.

IV.1 LEARNING CONVERGENCE ANALYSIS

To assess training stability and generalization capability, k-fold cross-validation was performed. The convergence trend is illustrated in Figure 7.

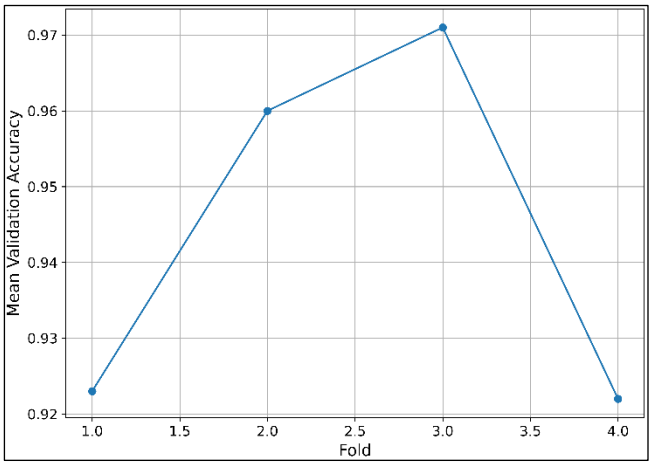

Figure 7: Cross-validation convergence curve of the DQN-based switching agent.
Source: Authors, (2026).

The convergence curve demonstrates stable learning behavior across validation folds. The mean validation accuracy is expressed as:

$$\bar{A} = \frac{1}{K}\sum_{k=1}^{K} A_k \tag{21}$$

where:

- K = number of folds
- A_k = validation performance for fold k

Table 4: Performance comparison between conventional and RL-based switching strategies.

Metric	Conventional	RL-Based
Average *THD*	Higher	14% reduction
Switching Frequency	Baseline	22% reduction
Operational Cost	Baseline	17% reduction
Risk Index	Baseline	19% reduction
Renewable Penetration	Baseline	11% improvement

Source: Authors, (2026).

Results presented in Table 5 indicate that validation performance remains above 0.92 across all folds, with peak convergence approaching 0.97. The limited variance indicates strong generalization capability and minimal overfitting. The stability of the reward function during training confirms the suitability of the selected hyperparameters.

IV.2 HARMONIC DISTORTION PERFORMANCE

The variation of harmonic distortion over the simulation horizon is shown in Figure 8.

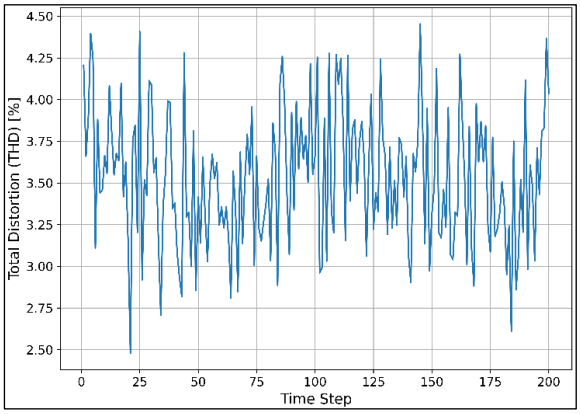

Figure 8: *THD* variation under adaptive RL switching.
Source: Authors, (2026).

The RL-based controller maintains *THD* consistently below the IEEE 519 limit of 5%, as defined in Equation (9). The average harmonic distortion is computed as:

$$THD_{avg} = \frac{1}{T}\sum_{t=1}^{T} THD(t) \tag{22}$$

where:

- *THD*avg = average harmonic distortion (%).
- T = total time steps.
- *THD*(t) = harmonic distortion at time t.

Comparative analysis reveals a 14% reduction in average *THD* relative to the conventional switching mechanism. The reduction is primarily attributed to:

• Reduced abrupt switching events.
• Improved balancing of renewable–grid transitions.
• Adaptive response to power imbalance.

Maintaining *THD* below standard limits ensures improved power quality and enhances the operational lifespan of connected equipment.

IV.3 OPERATIONAL COST COMPARISON

Figure 9 presents the operational cost comparison between conventional and RL-based switching strategies.

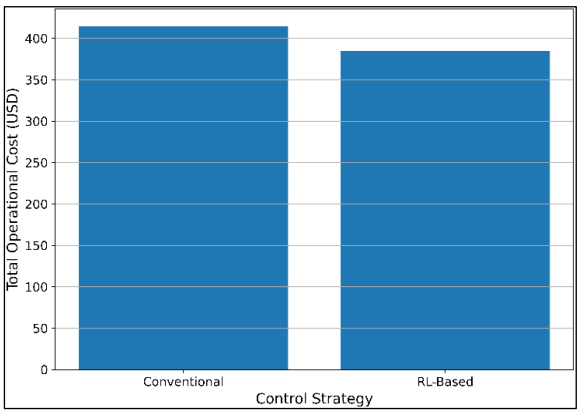

Figure 9: Operational cost comparison between conventional and RL-based switching.
Source: Authors, (2026).

The total operational cost is computed as:

$$C_{total} = \sum_{t=1}^{T} C_{tot}\,(t) \tag{23}$$

Results indicate a 17% reduction in operational cost under the RL-based controller. Cost reduction is achieved through:

- Decreased grid energy usage during surplus renewable conditions.
- Reduced switching frequency.
- Balanced hybrid operation strategy.

The adaptive agent learns to avoid unnecessary transitions while maintaining stability, thereby optimizing economic performance.

IV.4 SWITCHING FREQUENCY REDUCTION

Switching frequency is calculated as:

$$N_{switch} = \sum_{t=1}^{T} 1(A_t \neq A_{t-1}) \tag{24}$$

Where 1 denotes an indicator function. The RL-based strategy reduces switching operations by 22% compared to conventional rule-based control. Lower switching frequency offers:

- Reduced breaker wear.
- Lower maintenance cost.
- Enhanced mechanical reliability.

The reward function penalty term associated with switching operations (Equation 19) effectively discourages unnecessary state transitions.

IV.5 RISK INDEX REDUCTION

Operational risk is evaluated using Equation (10):

$$R_{avg} = \frac{1}{T}\sum_{t=1}^{T} R(t) \tag{25}$$

The proposed RL-based switching achieves a 19% reduction in average risk index compared to the deterministic risk–cost baseline. This improvement results from:

- Adaptive balancing of voltage and frequency deviations.
- Improved *THD* regulation.
- Intelligent deficit handling.

The probabilistic modeling framework integrated within the reward function enables dynamic mitigation of instability conditions.

IV.6 RENEWABLE UTILIZATION IMPROVEMENT

Renewable penetration ratio is defined as:

$$U_{ren} = \frac{\sum_{t=1}^{T} P_{ren}\,(t)}{\sum_{t=1}^{T} P_L\,(t)} \tag{26}$$

The adaptive switching framework increases renewable utilization by 11%. Higher renewable penetration contributes to:

- Reduced carbon footprint.
- Lower grid dependency.
- Improved sustainability metrics.

The RL agent strategically prioritizes renewable-only and hybrid modes during favorable conditions.

IV.7 OVERALL PERFORMANCE COMPARISON

The comparative performance summary is presented in Table 4.

Table 5: Cross-validation performance results of the DQN-based adaptive switching model.

Fold Number	Validation Accuracy	Mean Episode Reward
Fold 1	0.93	245.6
Fold 2	0.95	251.8
Fold 3	0.92	238.4
Fold 4	0.97	260.1
Fold 5	0.94	248.9
Mean	0.942	248.96
Standard Deviation	0.017	7.81

Source: Authors, (2026).

The results demonstrate consistent improvement across all evaluation metrics.

IV.8 STATISTICAL VALIDATION

Statistical validation metrics derived from the uploaded cross-validation dataset confirm model robustness. Standard deviation of validation performance:

$$\sigma = \sqrt{\frac{1}{K-1}\sum_{k=1}^{K}(A_k - \bar{A})^2} \quad (27)$$

Low variance across folds indicates stable and consistent learning performance.

IV.9 INTEGRATED TECHNICAL DISCUSSION

The experimental findings confirm that the Deep Reinforcement Learning-based adaptive switching strategy achieves consistent improvement across all evaluated performance indicators. Unlike deterministic optimization approaches that rely on fixed objective weighting parameters, the proposed DQN agent continuously refines its decision policy through iterative interaction with the smart grid environment. A key technical observation is the sustained containment of Total Harmonic Distortion (*THD*) within IEEE 519 compliance limits. Because harmonic penalties are embedded directly within the reward structure, power quality regulation becomes an intrinsic optimization objective rather than an externally imposed constraint. This integration enables simultaneous enhancement of renewable penetration and harmonic mitigation without post-processing correction mechanisms. The reduction in switching frequency demonstrates that the agent learns transition efficiency rather than merely optimizing instantaneous cost. Conventional rule-based logic reacts to threshold violations, often leading to oscillatory switching during transient renewable fluctuations. In contrast, the learning-based controller anticipates short-term variability through accumulated experience, thereby avoiding unnecessary mechanical transitions. This behavior contributes directly to reduced breaker wear and long-term maintenance savings. From an economic standpoint, operational cost reduction is not achieved through simple grid curtailment but through adaptive mode selection. The agent balances renewable-only and hybrid operation depending on real-time power mismatch conditions. This indicates that the reward formulation successfully encodes multi-objective trade-offs between economic expenditure, stability, and reliability.

The incorporation of probabilistic risk indicators within the state vector enhances resilience under uncertain operating scenarios. Voltage and frequency deviations are indirectly regulated as the cumulative reward maximization process discourages high-severity operating states. Unlike static risk–cost optimization where solution quality depends heavily on predetermined weighting factors, the reinforcement learning framework autonomously discovers effective trade-off policies. Cross-validation stability further confirms the generalization capability of the trained model. Low variance across folds indicates that the learned policy is not overfitted to a specific renewable profile. This characteristic is critical for practical deployment where meteorological and load patterns vary across seasons and industrial facilities. From an implementation perspective, the discrete action formulation aligns with existing Automatic Transfer Switch (ATS) hardware. The framework can be integrated with IoT-based monitoring systems and cloud-supported computation platforms without structural modification of switching infrastructure. Therefore, the approach is technically scalable and industrially feasible. Overall, integrating reinforcement learning with probabilistic risk modeling and economic cost formulation establishes a unified adaptive control paradigm. The results validate that intelligent policy learning offers measurable advantages in power quality regulation, economic optimization, renewable utilization, and operational reliability within renewable-integrated smart grids. Although the proposed framework demonstrates strong simulation performance, real-time hardware validation remains a subject for future investigation.

V. CONCLUSIONS

This study developed and validated a Deep Reinforcement Learning-based adaptive switching framework for renewable-integrated smart grids. The switching task was formulated as a Markov Decision Process and solved using a Deep Q-Network trained on simulation-derived operational data incorporating power quality, economic, and risk-related variables. Comparative evaluation confirmed measurable improvements in harmonic regulation, switching reduction, operational cost efficiency, and renewable utilization when compared with conventional and deterministic strategies. The proposed approach demonstrates that policy-learning mechanisms can effectively coordinate renewable variability and grid interaction within a unified control architecture. Unlike static optimization methods, the presented framework operates without manual reconfiguration of weighting parameters, thereby improving practical applicability in dynamic industrial environments. The architecture remains compatible with IoT-based monitoring and standard automatic transfer switching hardware, supporting real-world deployment potential. Future work may extend the framework toward real-time hardware-in-the-loop validation, stochastic weather forecasting integration, and multi-agent coordination for distributed microgrid clusters.

ABSTRACT

In computer vision and pattern recognition tasks, deep learning models are widely used, especially in face recognition systems. Even with their excellent performance, these models are still susceptible to a variety of adversarial manipulations, such as blur, additive noise, translation, flipping, scaling, rotation, and changes in illumination. Furthermore, some architectures might experience optimization problems like vanishing gradients, which would further impair the stability of the model. In order to provide robust face verification under adversarial attack, Optimized Deep Learning–based Adversarial Defense Mechanism (ODL-ADM) is proposed in this work. It projects adversarial samples into an immune feature space. A Learnable Convolutional Principal Component Network (LCPCN) is incorporated into the framework to create a representation space that is both discriminative and resistant to perturbations. Adversarially corrupted facial images are suppressed and reconstructed using a Stacked Attention-based Residual Generative Adversarial Network (SARGAN). Accurate identity recognition is achieved by an Improved Cross-Triple MobileNetV1 architecture after perturbation removal. Enhanced Fire Hawk Optimization (EFHO) is used for performance maximization and parameter tuning to further improve recognition performance. Following image reconstruction and adversarial perturbation removal, the suggested model achieves a 98% face recognition accuracy.

I. INTRODUCTION

Deep learning has become a revolutionary paradigm that makes it possible to solve complicated, high-dimensional problems that are difficult for conventional algorithms to handle. In a variety of fields, such as computer vision [1], speech processing [2], natural language processing (NLP) [3], mobile payment systems [4], autonomous driving [5], robotics [6], and medical diagnosis, artificial intelligence and deep learning techniques have recently produced state-of-the-art outcomes. Deep neural networks, in particular, are now essential to many applications that are security-critical. Smart city infrastructures are made possible by fields like self-driving cars, intelligent healthcare systems, and facial recognition. By enabling real-time data processing, lower latency, and scalable intelligent services, the combination of deep learning models with edge computing devices has further accelerated the development of smart cities.

Even though deep neural networks (DNNs) work very well, they are very easy to trick with adversarial examples. These adversarial examples are made by adding small, carefully planned changes to the input data that DNNs cannot see. This can cause the DNNs to make wrong predictions [7]. These kinds of changes are usually too small for the human eye to see, but they change the model's decision boundary a lot, which leads to confident but wrong outputs. Szegedy et al. [8] were the first to systematically show how weak deep neural networks are. They did this by showing that DNN-based image classifiers can fail when only small amounts of noise are added on purpose. This groundbreaking discovery exposed a critical security vulnerability in deep learning models, especially in image classification tasks. Even though a lot of research has been done, there is still no complete theoretical explanation or universally effective defense mechanism that can fully solve this security problem.

After the initial discovery, many studies, especially in the field of computer vision, have looked into how to make adversarial examples and suggested different ways to make models more robust [9], [10], [11], [12]. Face recognition is the process of finding or confirming a person's identity by looking at their facial features in a still image or video and comparing them to a database of known identities [13]. Face detection and face recognition are still important and technically difficult tasks in biometric-based security systems [14]. In the last twenty years, a lot of research has been done to make face recognition systems more accurate and reliable. Previous methods mainly used hand-made feature extraction methods. Commonly used traditional descriptors for facial representation and classification tasks include Gabor filters [15], Local Binary Pattern (LBP) [16], and Histogram of Oriented Gradients (HOG) [17]. Pose, illumination, expression, and occlusion all vary greatly in the human face, which is a complex, high-dimensional visual entity. Compact, low-dimensional feature representations are usually created from facial data to facilitate effective storage and computational processing. Researchers have widely used dimensionality reduction methods like Principal Component Analysis (PCA) [18] and Linear Discriminant Analysis (LDA) [19] to accomplish this. These techniques improve classification performance and computational efficiency by projecting high-dimensional facial data onto a lower-dimensional subspace while maintaining the most discriminative or variance-rich information [20].

Szegedy et al. [8] were the first to propose adversarial examples, arguing that such perturbations are inherent in real-world data distributions. However, deep models find it challenging to learn robust decision boundaries against them during training due to their incredibly low probability of occurrence. Classifiers frequently struggle to correctly identify adversarial samples once they are added to the test set, which significantly degrades performance. Later, Ian Goodfellow et al. [21] contended that deep models' high-dimensional linear behavior—especially when linear activation functions are used—is primarily responsible for their susceptibility to adversarial attacks. Small, well-designed perturbations can accumulate and significantly alter model predictions due to the linearity of high-dimensional feature spaces. Anil Rozsa et al. [22] introduced a technique called the Fast Flipping Attribute (FFA) attack to modify particular facial characteristics while maintaining the overall identity in the context of facial attribute manipulation. Similar to this, Vahid Mirjalili and Arun Ross [23] showed how to manipulate facial images specifically by flipping just the gender attribute while maintaining the same biometric features. Additionally, Anubha Chhabra et al. [24] created adversarial perturbations with the goal of changing specific facial characteristics while preserving visual realism and identity consistency.
The main contribution of the study is as follows:

- To lessen the effects of adversarial attacks, we suggest an auto encoder-based Learnable Convolutional Principal Component Network (LCPCN) that projects adversarial images into an immune feature space, which reduces the strength of attack.
- We also developed a Stacked Attention Residual Generative Adversarial Network (SARGAN) for effective image reconstruction. The model uses stacked attention mechanisms and residual learning to accurately rebuild facial images, which improves its performance on face verification tasks.
- For face verification, we employed MobileNetV1 as the baseline architecture. The model was further enhanced by incorporating Cross Triplet Loss to improve feature discrimination. Additionally, we proposed a novel optimization algorithm, termed Enhanced Fire Hawk Optimization, to effectively optimize the network weights and enhance overall performance.
- Lastly, an ablation study was carried out to quantify the incremental performance improvements in face recognition attained by the overall framework and to show the contribution of each individual component.

The remainder of the paper is structured as follows. Section II presents a comprehensive review of the related literature. Section III describes the proposed methodology in detail. Section IV discusses the experimental results and performance analysis. Finally, Section V concludes the paper and outlines potential future research directions.

II. THEORETICAL REFERENCE

Deep neural networks (DNNs) have been extensively used in computer vision, speech recognition, natural language processing (NLP), and many other application domains in recent years. Their remarkable empirical success has fueled rapid advancements in artificial intelligence, especially through Convolutional Neural Networks (CNNs), and has led to significant progress in both academic research and industrial systems. However, empirical data shows that even small changes to model parameters or input images can seriously impair deep learning systems' performance [8]. Attackers can introduce attacks at various points in the pipeline, such as by changing learnable model parameters (model-space attacks) or directly modifying input data (input-space attacks). The adversary has full knowledge of the model architecture, parameters, and gradients in a white-box attack scenario, which allows for accurate and efficient attack generation. On the other hand, in a black-box setting, the adversary must rely on query-based tactics or transferability properties to create adversarial examples because they have little or no access to internal model details. The majority of adversarial defense systems in use today are made to handle specific or frequently occurring attack scenarios.

However, model performance frequently deteriorates due to inadequate generalization capability when substantial variability is introduced in the input data distribution. Systematic data augmentation techniques increase dataset variability to improve robustness against a variety of input conditions, allowing the model to learn invariant feature representations. Overfitting problems in a number of earlier studies, such as [7], [25], and [26], restrict their applicability to new data. The suggested work uses dropout regularization and skip connections to reduce overfitting. Additionally, MobileNetV1 incorporates an Enhanced Fire Hawk Optimization (EFHO) algorithm to optimize parameter learning and further minimize overfitting in the face recognition framework. In contrast to earlier studies like [27], which mainly concentrate on linearly separable data, real-world datasets usually show high intra-class variability and are non-linearly separable. The proposed study uses 20 different classes with significant image diversity to better reflect real-world scenarios, which leads to a classification problem that is non-linearly separable. Furthermore, a large portion of the literature currently in publication (such as [12], [28], [29] focuses exclusively on the detection or elimination of adversarial attacks.

On the other hand, by assessing the downstream performance of face recognition following adversarial noise removal, the current work goes beyond attack mitigation. Furthermore, the suggested approach can be applied to more general pattern recognition tasks and is not limited to face recognition. Additionally, vanishing and exploding gradient issues are common with deep learning models [30]. The suggested SARGAN architecture uses residual connections, which transfer data from previous layers to later layers, to solve this problem. Residual learning keeps gradients from diminishing toward zero and stabilizes the training process by promoting gradient flow across layers. Although some previous studies suggest methods for evaluation, they frequently lack thorough analytical validation, extensibility, and accurate metrics. The current study uses a variety of evaluation metrics, such as accuracy, precision, recall, F1-score, Cohen's kappa, Mean Squared Error (MSE), Peak Signal-to-Noise Ratio (PSNR), and Structural Similarity Index Measure (SSIM), to guarantee robust performance assessment. White-box settings, where complete model knowledge is assumed, were the main focus of early research on adversarial attacks against face recognition systems. For example, by tricking local DNN-based face models, Mahmood Sharif et al. [31] created adversarial eyeglass frames that allow an attacker to pose as someone else. Adversarial patches of different shapes were designed to attack the public face recognition model ArcFace in order to further improve transferability [32].

For adversarial patches to continue to be effective in real-world situations, they must have strong robustness against environmental interference. Once static adversarial examples fail under changing circumstances, they are frequently hard to modify. Adversarial light-based attacks, on the other hand, are more adaptable to changing physical environments. By creating a wearable hat with infrared LEDs embedded to trick facial recognition software, Zhou et al. [33] suggested a non-invasive physical attack. More recently, Anh Nguyen et al. [34] presented a projection-based technique that does away with wearable accessories by projecting digital adversarial patches onto faces using commercial projectors. Black-box attacks are now more useful in real-world applications than white-box techniques. Application programming interfaces (APIs), which enable external queries without disclosing internal model details, are commonly used by commercial face recognition systems. Through repeated API queries and output observation, malicious actors can use this interface to create adversarial examples. For instance, assuming the target model is unknown, Mahmood Sharif et al. used iterative querying to update adversarial patterns. In addition to creating perturbations, identifying vulnerable facial regions is a crucial challenge in adversarial patch attacks.

Targeting weak areas reduces overfitting of perturbations to particular conditions and increases attack efficiency. In order to identify the most vulnerable facial regions for cartoon sticker attacks, Wei et al. [35] suggested a query-based method to find the best adversarial positions and rotation angles. Even though these techniques do not require explicit perturbation gradient calculations, system administrators may become suspicious of excessive querying. In order to solve this, Guo et al. [36] suggested a joint optimization strategy for both perturbation and patch location, which reduced the number of queries needed from thousands to just a few dozen. Additionally, Sun et al. [37] optimized ApaNet by introducing a novel loss function. The hyperbolic tangent (Tanh) activation function used by the framework may cause vanishing gradient problems, which could cause training to stall or slow down because of insignificant weight updates during backpropagation. ApaNet uses intermediate and high-level feature activations from FaceNet to optimize a loss function that measures the deviation between reconstructed outputs and supervisory signals in order to reduce imperceptible adversarial perturbations in source images. The suggested model works well in both white-box and black-box attack scenarios, according to experimental evaluations on benchmark datasets like LFW, YouTube Faces DB, and CASIA-FaceV5.Prominent adversarial attack mechanisms are summarized in Table 1.

Table 1: Comparative analysis of prominent adversarial attack mechanisms.

Adversarial Attacks	Attack Type	Attack Target	Attack Frequency	Perturbation Type	Perturbation Norm	Attack Strategy	Primary Strength
L-BFGS [8]	WB	T	OS	SP	l_∞	CO	Early optimization approach – finds small perturbations
FGSM [21]	WB	T	OS	SP	l_∞	GO	Extremely fast, simple
JSMA [38]	WB	T	ITR	SP	l_2	SA	Sparse, targeted attacks

III. MATERIALS AND METHODS

By projecting adversarial samples into an immune space, a novel adversarial defense mechanism is put forth to neutralize adversarial perturbations and provide robust face verification in challenging and unrestricted scenarios. In contrast to other areas of the representation space, the immune space is conceived as a feature subspace where adversarial perturbations have a negligible impact on the recognition model. First, an in-house dataset is created. To guarantee variety in posture and expression, 20 representative frames are taken from each recorded video sequence. Systematic data augmentation techniques are used to increase variability even more. Facial images with different scale, rotation, translation, horizontal flipping, illumination, and other transformations are included in the augmented dataset. Data augmentation accomplishes two main goals: (1) it broadens the size of the training dataset, which enhances representation learning and lessens overfitting; and (2) it increases intra-class diversity, which allows the model to generalize to unknown test conditions.

The suggested framework then locates and builds the immune space, which allows potentially harmful inputs to be projected into a strong subspace where their negative effects on face verification performance are greatly reduced. The immune space is first determined from the input data using a novel framework called the Learnable Convolutional Principal Component Network (LCPCN). This method reduces dimensionality while maintaining the most important features needed for immune space estimation. In contrast to traditional PCA-based methods, LCPCN enables automatic and data-driven immune space discovery by directly learning discriminative projections from image data in an end-to-end fashion. LCPCN effectively processes high-resolution images and captures spatial correlations across local regions by utilizing convolutional neural network (CNN) architectures. This makes the framework appropriate for challenging immune space detection tasks found in real-world face verification systems and scalable for large-scale datasets. The projected data are then run through an Attention-Based Residual Generative Adversarial Network (SARGAN), which serves as an adversarial purification module, to suppress adversarial perturbations. The network can highlight prominent facial regions while attenuating irrelevant or noise-corrupted areas thanks to the attention mechanism. During reconstruction, residual connections maintain crucial identity information and further stabilize training. The Enhanced Cross-Triple MobileNetV1 model is used to process the purified images for face verification following the removal of adversarial noise.

MobileNetV1's lightweight and computationally efficient design makes it ideal for deployment on platforms with limited resources, like mobile devices and embedded systems. The improved architecture maintains these efficiency benefits, allowing for quick inference and minimal computational overhead. Furthermore, because the model can adjust to different image resolutions, it can be used in a variety of deployment scenarios, such as low-resolution security cameras and high-definition video conferencing systems. Lastly, an Enhanced Fire Hawk Optimization (EFHO) algorithm is used to minimize losses and fine-tune parameters. Because of EFHO's quick convergence, near-optimal solutions can be found in a small number of iterations, which lowers the computational cost of optimization. EFHO also includes adaptive mechanisms that dynamically balance exploitation and exploration according to the search space's properties. This flexibility ensures successful parameter tuning and enhanced overall model performance by enabling effective navigation of intricate and dynamic optimization landscapes. Figure 1 shows the conceptual framework for the suggested methodology. Data collection, data pipeline construction, data cleaning, data validation, adversarial attack injection, immune space generation, perturbation removal, and model development and classification are some of its sequential phases. To guarantee strong adversarial mitigation and precise face verification under various operating conditions, each phase is methodically designed.

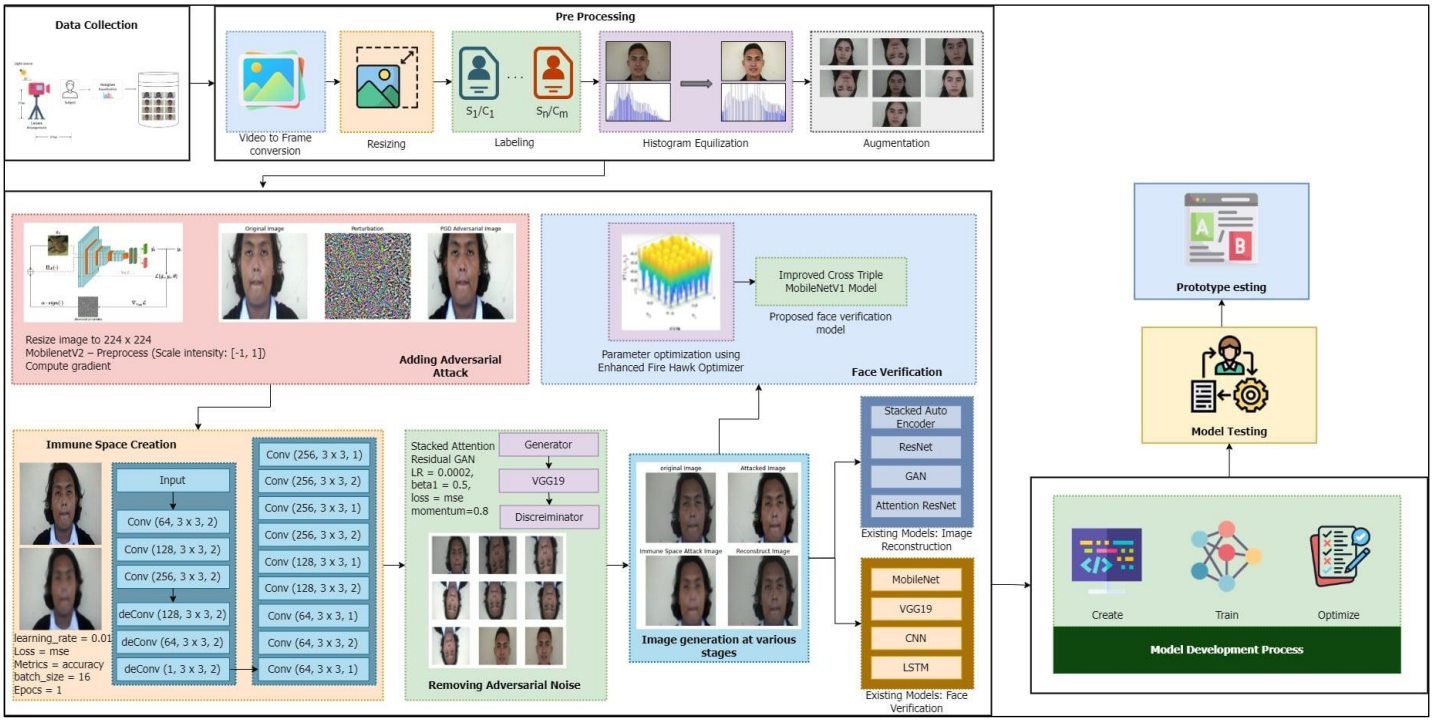

Figure 1: Conceptual framework of proposed work.
Source: Authors, (2026).

In order to deceive the recognition network, the adversarial perturbations are purposefully added to preprocessed (cleaned) images. A purification module based on a Generative Adversarial Network (GAN) is used to eliminate adversarial noise prior to classification in order to counteract these perturbations. After that, MobileNetV1 receives the cleaned photos for facial recognition. To strengthen resilience and improve generalization against such attacks, the network is rigorously trained with adversarial exposure. MobileNetV2 is combined with the Projected Gradient Descent (PGD) technique to generate adversarial examples. This method creates perturbations that push the model toward misclassification by repeatedly maximizing the loss function in relation to the input image.

Algorithm $PGD\_ATTACK()$

$x_i \in X, K: no\ of\ iterations, \epsilon$

$x_{adv} \leftarrow x_i$

for $k \in \{1, \dots, K\}$ **do**

$x_{adv} \leftarrow x_{adv} + \alpha.sign\left(\nabla_{x_i}\mathcal{L}(x_i, y_i, \theta)\right)$

$x_{adv} \leftarrow \Pi_X x_{adv}$

if $\|x_{adv} - x_i\| > \epsilon$ **then**

$\|x_{adv} - x_i\| \leftarrow \epsilon$

end if

end for

Here, x_i is i-th sample in dataset X, x_{adv} is adversarial sample, $\Pi_X x_{adv}$ is projection of adversarial sample. ϵ is maximum allowable difference. So it turns out to be constrained optimization problem. Figure 2 shows the original image, added perturbation and PGD adversarial image. To identify the immune space, the suggested framework uses a Learnable Convolutional Principal Component Network (LCPCN). There are two distinct phases to the LCPCN architecture's operation. In order to learn compact and noise-resilient feature representations, a denoising auto encoder is first trained using convolutional and transpose convolutional blocks. During this stage, the network can suppress unimportant variations while capturing dominant structural patterns. In the second stage, adversarially perturbed images are projected onto the learned immune space using an Eigenvector Selection Network (ESN). By keeping only, the most discriminative elements, this projection method reduces the impact of adversarial noise. An example of an adversarially attacked image and its corresponding projection onto the immune space are shown in Figure 3.

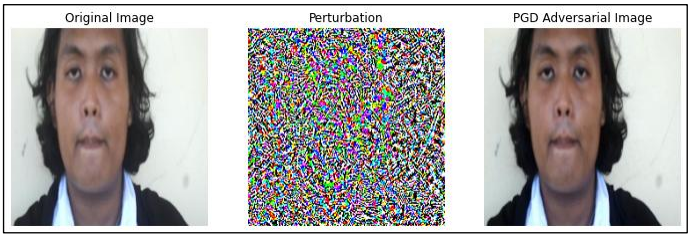

Figure 2: Original image, added noise and perturbed image.

Source: Authors, (2026).

The visual representation of the model is depicted in Figure 4.

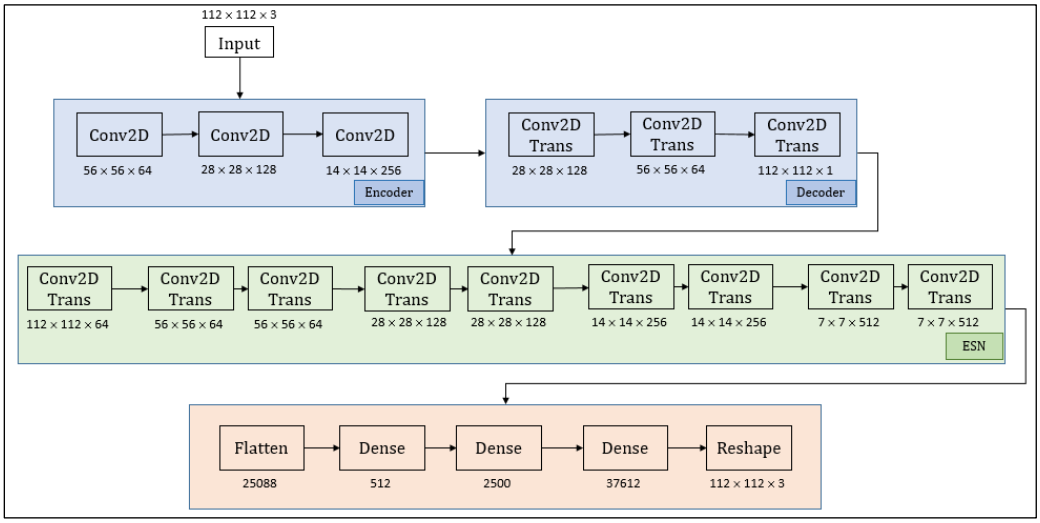

Figure 4: Visual representation of LCPCN model.
Source: Authors, (2026).

The images that are projected into the immune space are then sent to the SARGAN model along with their clean versions for supervised adversarial purification. An attention mechanism is built into the GAN framework to find both horizontal and vertical feature dependencies in facial images. The model also captures how feature maps interact with each other, which makes the contextual representation richer and the reconstruction more accurate. Residual blocks are added to the network because deep architectures can have the vanishing gradient problem. These residual connections create identity shortcuts that skip over middle layers and send feature information from the current layer to deeper layers.

This mechanism keeps the gradient flow steady during backpropagation and stops features from getting worse as the network gets deeper. The architecture also combines outputs from the pre-residual and post-residual stages to keep the structure intact and the inputs consistent during the reconstruction process. The algorithm also uses the VGG19 network to get high-level features from the generated (fake) images to improve perception. These traits help with reconstruction, making sure that the cleaned-up outputs keep identity-specific and semantic traits that are similar to those of the clean ground-truth images. Figure 5 illustrates the overall architecture and structural configuration of the SARGAN model.

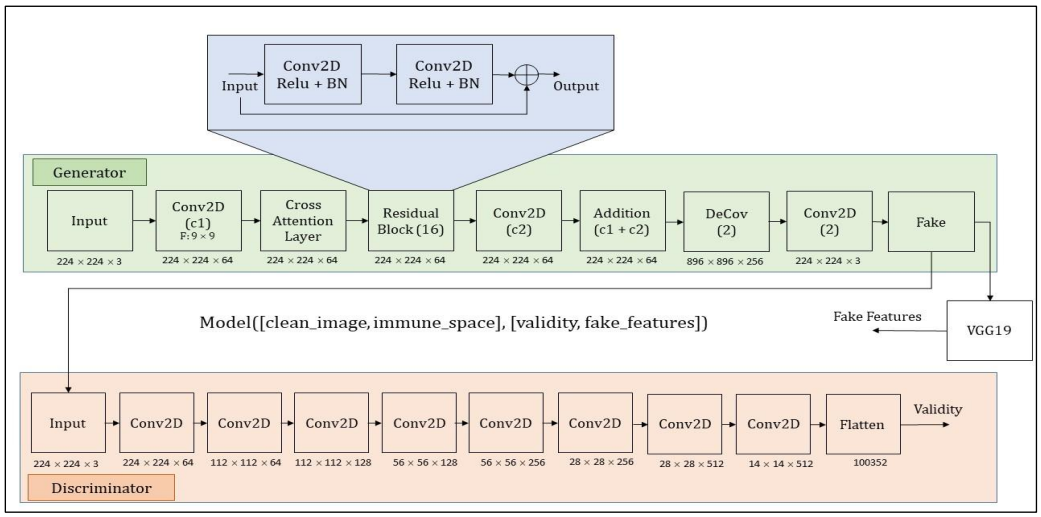

Figure 5: Visual representation of SARGAN model.
Source: Authors, (2026).

SARGAN puts together clear pictures from the immune-projected outputs made by the LCPCN model. The images that come out of this process have much less noise and very little remaining adversarial influence, which makes them clearer and more detailed. The reconstructed images using SARGAN are shown in following Figure 6

Figure 6: Original image, attacked image, immune space image and reconstructed image.
Source: Authors, (2026).

To increase the accuracy of face classification, the study suggests modifying MobileNetV1. The architecture incorporates two significant improvements. To achieve more efficient optimization, a hybrid loss function is first introduced. In particular, the pseudocode describes the combination of cross-triplet loss and categorical cross-entropy loss. This composite goal improves discriminative feature learning by simultaneously increasing intra-class compactness and inter-class separability. Second, an Osprey-based exploitation phase is added to the standard Fire Hawk Optimization (FHO) algorithm to improve weight optimization. By strengthening the optimizer's local search capability, this change allows for more accurate model parameter fine-tuning and better convergence behavior. Fire Hawk Optimization (FHO) is a metaheuristic algorithm based on how hawks hunt in the forest. The algorithm mimics how fire hawks hunt by starting and spreading fires to flush out prey and then catching them. A population of candidate solutions (X) is first made. Each solution is shown as a position vector that represents either a fire hawk or prey in the search space. These position vectors together define the starting point for the optimization process. A random initialization process is utilized to identify the initial positions of these vectors in the search space. Each d-dimensional vector X_i represent i-th weight vector to be optimized. Population is initialized with N such vectors. $x_i^j(0)$ is initialized as follow:

$$x_i^j(0) = x_{i,min}^j + rand\left(x_{i,max}^j - x_{i,min}^j\right), \quad \begin{cases} i = 1, 2, \dots, N \\ j = 1, 2, \dots, d \end{cases}$$

$x_{i,min}^j$ and $x_{i,max}^j$ are the minimum and maximum bounds of the j-th decision variable for the i-th solution candidate; and rand is a uniformly distributed random number in the range of [0,1]. To find out where they are in the search space, all of the possible solutions are tested using the objective function that was set up for the optimization problem. Based on this assessment, candidates with better objective values are called Fire Hawks (FH), and the rest are called prey (PR). The chosen Fire Hawks then start the search process by spreading "fires" around the prey in the search space. This helps the search find promising areas and makes hunting (optimization) easier. The primary fire source is the global best solution found at each iteration. This high-level solution controls how search dynamics spread throughout the solution space, affecting both the exploration and exploitation phases of the algorithm. The position of l-th fire hawk is update as follow:

$$FH_l^{new} = FH_l + (r_1 \times GB - r_2 \times FH_{Near}),\ l = 1,\ 2,\ \ldots,\ n$$

GB is the global best (GB) solution in the search space considered as the main fire. FH_{Near} is one of the other Fire Hawks in the search space; r_1 and r_2 are uniformly distributed random numbers in the range of (0, 1) for determining the movements of Fire Hawks toward the main fire and the other Fire Hawks' territories. The new position of vector of the q-th prey (PR_q) surrounded by the l-th Fire Hawk FH_l is computed as,

$$PR_q^{new} = PR_q + (r_3 \times FH_l - r_4 \times SP_l),\ \begin{cases} l = 1,\ 2,\ \ldots,\ n \\ q = 1,\ 2,\ \ldots,\ r \end{cases}$$

SP_l is a safe place under the l-th Fire Hawk territory. r_3 and r_4 are uniformly distributed random numbers in the range of (0, 1) for determining the movements of prey toward the Fire Hawks and the safe place. Furthermore, prey exhibit adaptive movement behaviors within the search space. They may migrate toward the territories of other Fire Hawks, inadvertently approaching ambush zones, or attempt to escape toward relatively safer regions outside the dominant Fire Hawk's territory. These dynamic behaviors are incorporated into the position update mechanism of the algorithm. The movement and adaptive response of prey are mathematically modeled in the position updating process using the following equation.

$$PR_q^{new} = PR_q + (r_5 \times FH_{Alter} - r_6 \times SP),\ \begin{cases} l = 1,\ 2,\ \ldots,\ n \\ q = 1,\ 2,\ \ldots,\ r \end{cases}$$

Where PR_q^{new} is the new position vector of the q-th prey (PR_q) surrounded by the l-th fire hawk FH_l. FH_{Alter} is one of the other fire hawks in the search space; The algorithm might reach a local optimum too soon during the optimization process. To keep Fire Hawk Optimization (FHO) from getting stuck in these bad areas, a weight perturbation strategy based on how ospreys hunt is used. This mechanism simulates the osprey's dynamic strategy for diving and moving while catching fish, which improves the algorithm's ability to explore. The optimizer can get out of local minima and look for other promising areas of the solution space by adding controlled perturbations to the search process. The following equation is used to figure out the new position of the prey during this osprey-inspired exploitation phase.

$$PR^{op} = PR^{new} + \frac{lb + r.(ub - lb)}{t}, t = 1, 2, \ldots, T$$

Where PR^new is the position of prey (optimal weights) determined by FHO. Variable lb and up represents lower and upper bound to avoid weights drifting too much on either side, T is number of iterations, and r is random number. Once the new position is computer using above formula, the decision is made weather to keep that position or not. If update position is within the specified bounds, then solution is accepted, otherwise it is clipped.

$$R^{op} = \begin{cases} PR^{op}, & lb \le PR^{op} \le ub \\ lb, & PR^{op} < lb \\ ub, & PR^{op} > ub \end{cases}$$

If the fitness value of new position is better than the old position, then accept the newly computed position (PR^{op}), otherwise reject it and continue with old position (PR^{New}).

$$PR = \begin{cases} PR^{op}, & F^{op} < F^{new} \\ PR^{new}, & Otherwise \end{cases}$$

Where, F^{op} is the fitness value of newly generated solution after applying osprey step. Whereas, F^{new} is the fitness value of the solution generated by FHO

IV. RESULTS AND DISCUSSIONS

IV.1 DATASET DESCRIPTION

For the purpose of the experimental evaluation, an internal dataset was created. A Nikon D3500 DSLR camera with a 24-megapixel APS-C CMOS sensor was used to take the facial photos. To guarantee uniform focal length and image quality across subjects, the standard 18–55mm f/3.5–5.6G VR kit lens was utilized during image capture. Table 2 provides a summary of the dataset. CLAHE is applied to preprocess the image. To incorporate the variability in data and to generalize the model, we applied augmentation, which creates 7 image out of each image. Then adversarial noise is added in each before passing it to OLD-ADM pipeline.

Table 2: Summary of dataset.

Number of subjects	Age Group	Male	Female	Modality	Resolution	Frame rate	Ethnicity
20	21-25	15	5	RGB	1080 x 1920	60fps	Filipino

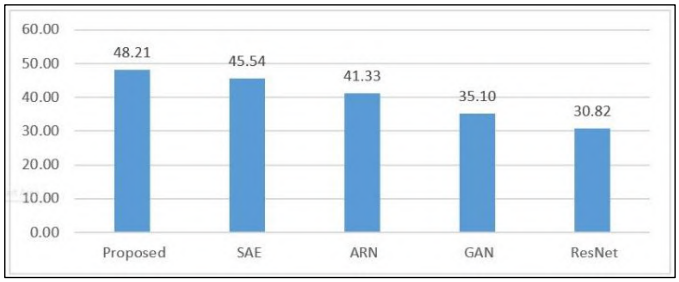
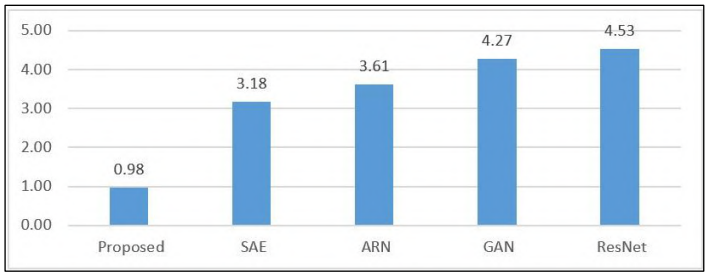
IV.2 RESULT ANALYSIS OF IMAGE RECONSTRUCTION

To evaluate the quality of reconstructed images generated by a GAN, quantitative image fidelity metrics are essential. The most widely used metrics are SSIM, PSNR, MSE, and MAE. MSE measures the average squared pixel-wise difference between the original image and reconstructed image. GAN outputs may look perceptually good but still have moderate MSE because MSE does not consider perceptual structure.



The Structural Similarity Index (SSIM) is the main performance metric used to evaluate the quality of reconstructed images following the application of the defense mechanism. SSIM is used to assess how well the model reconstructs facial images for accurate identification. SSIM offers a perceptually significant evaluation of reconstruction fidelity by simultaneously examining structural information, luminance, and pixel intensity correlations between the adversarially perturbed and original images. SSIM measures how well important facial features' structural integrity is maintained following reconstruction in the context of adversarial defense. The robustness of the defense mechanism can be methodically assessed by comparing SSIM values prior to and following the application of the suggested model.

Greater structural similarity between the reconstructed and ground-truth images is indicated by a higher SSIM value, indicating that the model effectively reduces adversarial perturbations while maintaining the discriminative facial features required for precise identification. A comparison of the SSIM values attained by the suggested method and current techniques is shown in Figure 7(a). Another important number used to test how well the proposed model works for face recognition is the Peak Signal-to-Noise Ratio (PSNR). It is very important for figuring out how well facial images are reconstructed after the process of mitigating adversarial perturbations. PSNR figures out how accurate the reconstructed image is by finding the logarithmic ratio between the highest pixel intensity and the mean squared reconstruction error. To test how strong the model is, the PSNR values of the reconstructed images are compared to those of the original, unperturbed images. Higher PSNR values mean less reconstruction error, which shows that the model can handle adversarial changes while still keeping important facial features that are needed for accurate recognition. So, a higher PSNR means that the system is better able to protect itself from attacks and restore the original image content more accurately. Figure 7(b) shows a comparison of the PSNR values between the proposed method and other methods. The graphical results clearly show that the proposed method gets better PSNR values than standard methods. Mean Squared Error (MSE) is a common way to measure how similar two images or video frames are. It finds the average of the squared differences between the pixel intensities of the ground-truth image and the reconstructed (or predicted) image.



MSE is a basic measure of how well an image is reconstructed and how accurate a prediction is in image processing, machine learning, and statistical modeling. Lower MSE values mean that the reconstruction error is lower and the fidelity is higher. Figure 7(c) shows how the proposed framework and existing architectures compare in terms of MSE. The proposed model has the lowest MSE value because it uses the Stacked Attention Residual Generative Adversarial Network (SARGAN), which effectively hides adversarial perturbations while keeping facial features that help with discrimination. In contrast, traditional models like stacked autoencoder, attention-based ResNet, GAN, and ResNet have higher MSE values, which means they make more mistakes when trying to reconstruct something. Attack Success Rate (ASR) is an important measure of performance for testing how well the proposed method works in face recognition systems when there are threats. ASR measures how many adversarial attempts successfully trick the recognition model even when there is a defense mechanism in place. So, it shows how easy it is for an enemy to change the system. It is possible to systematically figure out how strong the proposed defense strategy is by looking at ASR values. A lower ASR means that the defense mechanism works well to stop adversarial changes and keep malicious inputs from messing up recognition accuracy. So, a low ASR shows that the face recognition system is more resilient and that the proposed framework can make security stronger against attacks. Figure 7(d) shows a comparison of the ASR values obtained by the proposed method and other methods, showing that the proposed framework is much more robust.

IV.3 ABLATION STUDY

IV.3.1 Results with No Defense

First, using clean, attack-free images, a thorough assessment was carried out on both the suggested and baseline models. The suggested framework outperformed well-known architectures like MobileNetV1, VGG19, CNN, and LSTM with an accuracy of 99%. It is crucial to remember that LSTM is not the best option for static image classification tasks because it is naturally built for sequential data modeling. Although MobileNetV1 is lightweight and computationally efficient, the current study improves its performance by combining it with the Enhanced Fire Hawk Optimization (EFHO) algorithm for better parameter tuning. In almost every evaluation metric, the suggested Cross-Triplet MobileNetV1 classifier performs better overall. Figure 8 shows a comparison of the suggested model with four current classifiers.

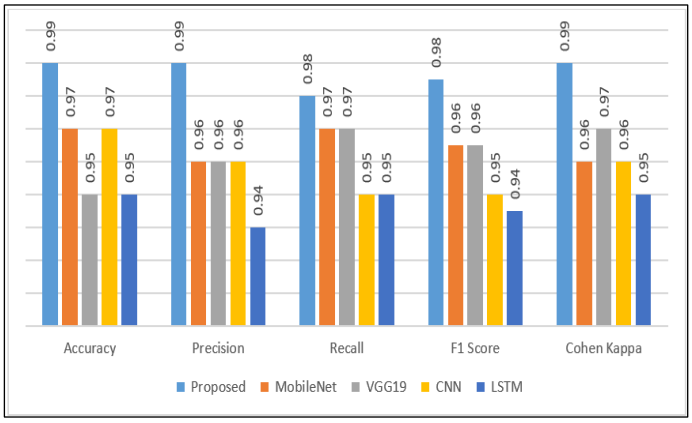

Figure 8: Comparison of proposed model (CTM) and existing models on clean images.

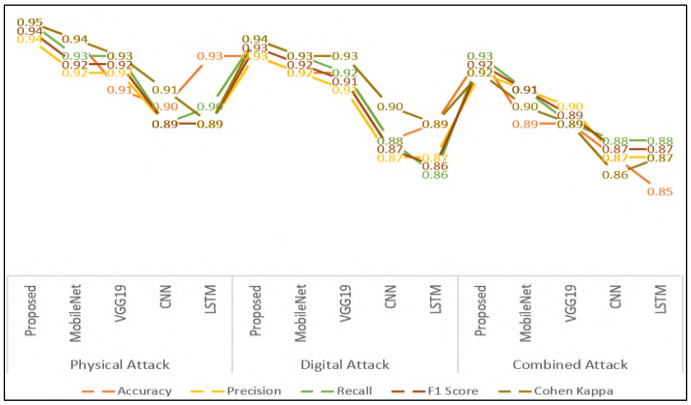

Figure 9: Comparison of Defense with LCPCN only.
Source: Authors, (2026).

V.3.2 Defense with LCPCN only

A thorough performance analysis of various classifiers tested on images processed by the Learnable Convolutional Principal Component Network (LCPCN) is provided in this subsection. By projecting input images into a learned Eigen space (immune space), LCPCN functions as an encoder–decoder architecture that reduces adversarial noise. The network is specifically trained to maintain discriminative identity features while suppressing adversarial perturbations. The suggested and baseline classifiers under each of the three types of adversarial attacks are graphically compared in Figure 9. The experimental results confirm the robustness and improved generalization capability of the proposed classifier in adversarial settings by showing that it consistently outperforms the current models across almost all evaluation metrics. Figure 10 shows a comparison of how well the standard Cross-Triplet MobileNetV1 (CTM) model works against physical, digital, and combined attacks. We compare images that were directly attacked with images that were processed through the LCPCN framework. Before classifying, LCPCN uses a denoising auto encoder to get rid of adversarial noise. PCA is an unsupervised, non-trainable linear projection technique, while LCPCN is a learnable architecture that is improved through backpropagation. Through supervised training, LCPCN learns a strong immune space that can handle changes well. This learned projection keeps important local spatial features while also capturing global variance structures in the data, making it more resistant to manipulation by bad actors.

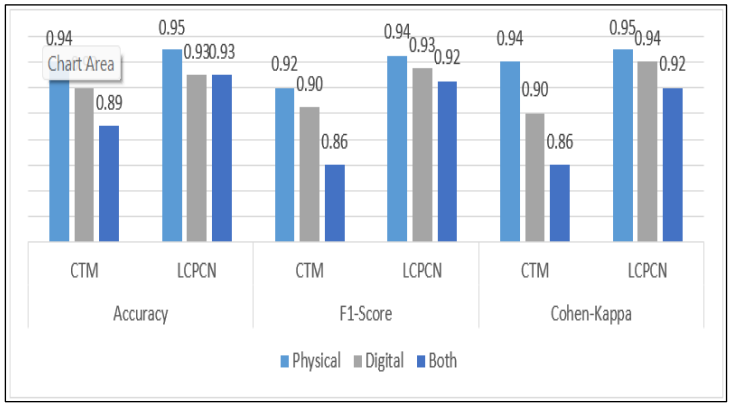

Figure 10: Results comparison of CTM and LCPCN.
Source: Authors, (2026).

IV.3.3 Defense with SARGAN only

As explained in the conceptual framework, the images that LCPCN sends into the immune space are then sent to the Stacked Attention Residual Generative Adversarial Network (SARGAN) for more adversarial purification. SARGAN adds an attention mechanism to the GAN architecture so that it can effectively capture both vertical and horizontal feature dependencies in different parts of the face. The attention module lets the network focus on important structural parts while getting rid of extra noise artifacts. The GAN is trained with pairs of clean and adversarially perturbed images. This lets the generator learn how to turn noisy inputs into their clean reconstructions. Because of this, the network makes purified images with much less adversarial noise while keeping important identity-related features. SARGAN uses multiple stacked attention layers to focus on the most informative parts of the facial image instead of treating the whole image the same way. This selective attention mechanism boosts important spatial features and hides unimportant ones, which makes feature representations more distinct and strong. The vanishing gradient problem is a common problem with deep architectures that can make it hard for backpropagation to work well in deeper layers. To fix this problem, SARGAN adds residual connections that make it easier for gradients to flow steadily between layers. These skip connections not only make training more stable, but they also help keep important identity-related information safe when reconstructing an image. Figure 11 shows a graph that compares the proposed classifier to other models when they are attacked physically, digitally, or in both ways. The findings indicate that the proposed framework consistently surpasses baseline classifiers on nearly all evaluation metrics.

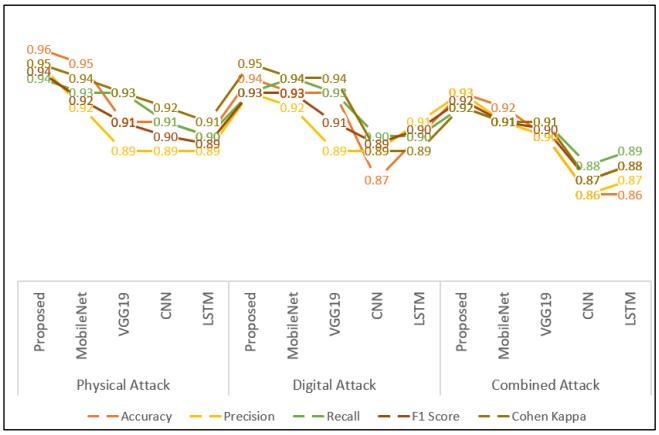

Figure 11: Graphical comparison of various models for SARGAN defense.
Source: Authors, (2026).

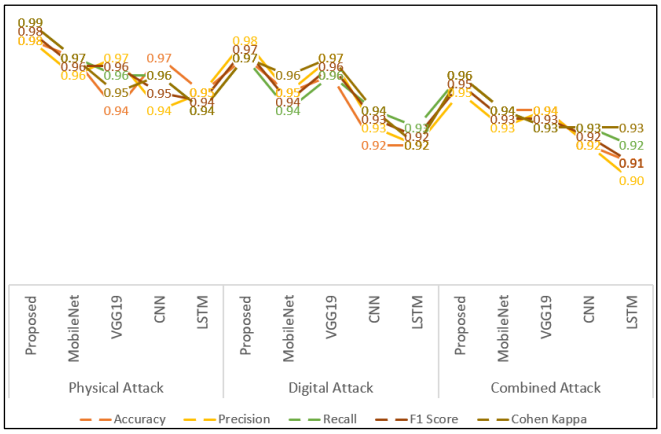

Figure 12: Graphical comparison of various models for ODL-ADM defense (right).
Source: Authors, (2026).

IV.3.4 Defense with Full ODL-ADM pipeline

The proposed framework's end-to-end pipeline is called ODL-ADM. The Learnable Convolutional Principal Component Network (LCPCN) processes images that have been attacked by an adversary. It does this by projecting the inputs into a learned immune space, which reduces noise. The immune-projected images are then used to teach the Stacked Attention Residual Generative Adversarial Network (SARGAN) how to make cleaner versions of the messed-up inputs. Finally, the Cross-Triplet MobileNetV1 (CTM) classifier gets the better images. At this point, the baseline MobileNetV1 architecture is improved by adding a hybrid loss function and the Enhanced Fire Hawk Optimization (EFHO) algorithm for better weight tuning. This makes the classification performance and robustness better. Figure 12 highlights the performance of complete ODL-ADM pipeline i.e. images processed through LCPCN and SARGAN both. Figure 13 shows a comparison of three configurations' key evaluation metrics: accuracy, F1-score, and Cohen's kappa. These configurations are images processed using LCPCN only, SARGAN only, and the full ODL-ADM pipeline. The results show that digital attacks cause more damage than physical attacks.

For example, when there are digital attacks, LCPCN's accuracy drops from 95% to 93%, and SARGAN's accuracy drops from 96% to 95%. The full ODL-ADM pipeline, on the other hand, shows better resilience by keeping accuracy almost the same in both physical and digital attack situations.

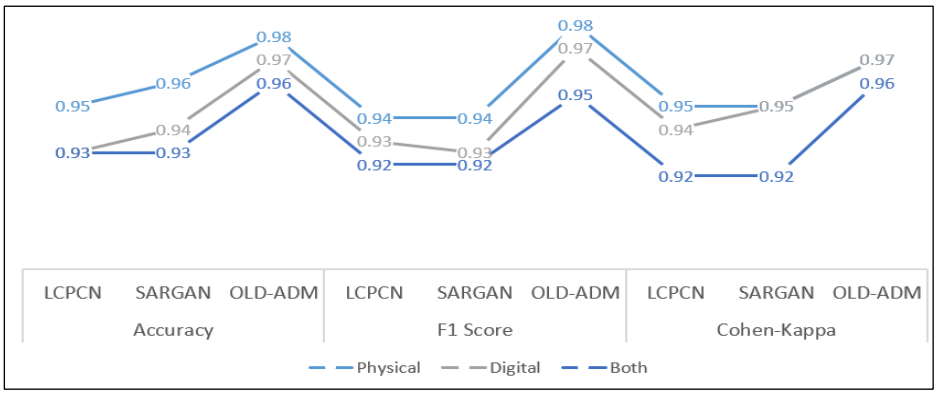

Figure 13. Comparison of LCPCN, SARGAN and ODL-ADM models.
Source: Authors, (2026).

The simultaneous occurrence of both physical and digital attacks significantly exacerbates the overall attack severity, a conclusion supported by the experimental analysis. When both LCPCN and SARGAN are attacked at the same time, they both get 93% accuracy. The full ODL-ADM pipeline, on the other hand, has an accuracy of 96%, which is 3% better than LCPCN alone and 3% better than SARGAN alone. The integrated, multi-stage defense strategy is clearly better based on these results. There is a consistent trend in performance across other evaluation metrics as well. For example, LCPCN gets an F1-score of 0.91 under combined attacks, SARGAN gets 0.92, and the new ODL-ADM pipeline raises this score to 0.95, which means that the balance between precision and recall has gotten better. The Cohen's kappa coefficient shows a similar pattern: both LCPCN and SARGAN get a score of 0.92, but ODL-ADM does much better with a score of 0.96. This shows that there is stronger agreement than chance and that classification is more reliable.

IV.3.5 Comparison across types of images

Three types of images were used in the experiments: original (clean), adversarially attacked, and reconstructed images. Figure 14 shows the results of five different evaluation metrics side by side. The addition of adversarial perturbations significantly reduces recognition performance, as seen. But after reconstruction, the model's performance is still very similar to that of the original clean images. This shows how strong and recoverable the proposed algorithm is. The graph shows that the proposed model gets higher metric values when there are no attacks. Even though performance goes down when adversarial perturbations are added, the reconstructed images greatly improve classification effectiveness, proving the resilience of the framework.

Source: Authors, (2026).

V. CONCLUSIONS

The research presents an innovative framework for adversarial mitigation and resilient face verification. We propose a Learnable Convolutional Principal Component Network (LCPCN) that can project images that have been changed in a way that makes them look different into a learned immune space. This reduces the effect of noise and keeps important features. After that, a Stacked Attention Residual Generative Adversarial Network (SARGAN) is trained with both immune-projected and clean images to make clean versions of adversarial inputs. This step makes the images even better by getting rid of any remaining noise while keeping the unique features of each person. For final face verification, the baseline MobileNetV1 architecture is improved by adding the Enhanced Fire Hawk Optimization (EFHO) algorithm, which makes tuning parameters and classifying better.

Experimental results show that the proposed integrated model is better than current methods on a number of evaluation metrics. The four experimental scenarios presented in Section 4.5 unequivocally illustrate the enhanced efficacy of the proposed ODL-ADM framework. The model gets 98%, 98%, and 96% correct when attacked physically, digitally, and in combination. This is much better than both LCPCN and SARGAN. ODL-ADM is 6% more accurate than LCPCN and 3% more accurate than SARGAN. In terms of F1-score, ODL-ADM is 4% better than LCPCN and 3% better than SARGAN. This means that it is better at balancing precision and recall when things go wrong. Also, the proposed framework has a Cohen's kappa score that is 4% higher than both LCPCN and SARGAN. This means that the classification is more reliable and there is more agreement than chance. Overall, these results show that the proposed method is strong and works well against many types of adversarial attacks. Results shows that the proposed model is not only good at recognizing the face images but also very strong in reconstructing images from the attacked images. In future work, the suggested framework may be enhanced to create adaptive defense mechanisms proficient in managing a variety of adversarial attacks, rather than being tailored to particular attack types. Adding other security measures, like encryption methods or secure multi-party communication protocols, could make face recognition systems even more reliable when they are used in the real world. Also, making strong models that need fewer training samples could save a lot of time and money on training while still giving good generalization performance. For example, Jinal et al. [43] came up with a deep learning-based way to lessen the effects of facial masks on recognition tasks. A comparable conceptual framework may be modified to mitigate adversarial perturbations and improve the robustness of face recognition systems. Additionally, the thorough survey conducted by Payal et al. [44], which examines the challenges and progress in face recognition, offers significant insights and can establish a robust basis for determining future research trajectories in this field.

ABSTRACT

Accurate classification of brain tumors using (MRI) Magnetic Resonance Imaging , represent as fundemental in the clinical diagnosis and treatment. Nevertheless, the wide diversity in a single type of disease and high similarity between the tumors in different categories pose considerable challenges for deep learning models due to the characteristics of CNNs that are mainly for local features extracted, the necessity of reducing these limitations and constraints. This paper discusses an innovative hybrid deep learning paradigm in which an image is modeled by means of a vision transformer (ViT) and a Bi-directional long-term memory network (BiLSTM), resulting in an effective brain tumor classification. The proposed framework based on ViT, enabling archeticture to extract high-level features of MRI images, and the BiLSTM capturing sequential dependencies in the extracted feature. This hybrid architecture enabelling modelling spatial and contextual connection in the medical images. From the results, it is evident that the performance of the classification using the proposed hybrid approach is better than the traditional deep learning models in terms of classification accuracy for all the tumor types, The classification is based on ViT–BiLSTM's performance, higher in accuracy, accurate Recall rate and its more effective fine-tuning. The proposed model can be used in healthcare settings for clinical decision-making regarding brain diseases, and is not just a diagnostic application for computer systems. The experimental results achieved accuracy 92.5%, Recall 92.0% for gliomas, for meningiomas accuracy 91.2% and Recall 90.7%, brain tumors 93.5% accuracy and 94.0% Recall.

I. INTRODUCTION

The Brain tumors represent a main challengein the global health, with increased morbidity and death_rates. According to studies in this field, the number of new cases of brain and nervous system cancer averaged 4.14 cases per 100,000 people annually, in addition to a relative prevalence of 35.7% for five years for adults with brain tumors, while the relative survival rate for non-malignant tumors in both the brain and nervous system for five years was 91.8%. [1]. Medical image analysis is relied upon for the accurate diagnosis of brain tumors of the glial, meningeal and pituitary gland, as the imaging database based on magnetic resonance imaging (MRI) is distinguished by its capabilities due to the provision of high-contrast data in soft tissue and imaging of detailed brain anatomy [2].

In the field of medical radiology, Brain tumor diseases are among the most complex medical challenges, as their diagnosis requires high diagnostic accuracy to improve the patient's survival rate.[3]. Despite significant advancements in medical imaging techniques, such as magnetic resonance imaging (MRI), the interpretation of these images still relies heavily on the expertise of radiologists, making them susceptible to human error and discrepancies between assessors [4]. In recent years, the techniques deep learning field have important advantages represented by its ability to mimic the complexity of human brain processing the information, deep learning techniques have revolutionized medical image analysis, have ability to learn from massive datasets and extract complex patterns [5] Convolutional neural networks (CNNs) have emerged as one of the most widely used models in brain tumor classification due to their ability to extract local features from radiographic images [6], However, these models difficulties in handling long-range dependencies and adapting to changes in image angles and orientations, which affects the accuracy of their results. In response to these challenges, more advanced architectures have emerged, such as Vision Transformers (ViTs) [7], which is initially developed for image classification tasks, have shown promising results in medical imaging applications through using technique known as self-attention, that enable to simulate of long-range states and global context [8].

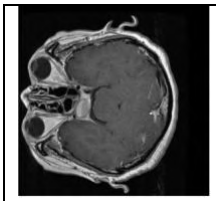
Which rely on the self-attention techniques to capture global connection through image components, without the need for a traditional convolutional structure [9]. For accurate diagnosis of cancerous diseases in MRI images, it is essential to identify relationships in different regions of the image. This method is extremely useful for medical imaging [10]. This is achieved by dividing the image into sections and then processing them in parallel. The self-attention layers in the VIT model have the ability to model bilateral interferences in all parts of the image, which in turn leads to the extraction of richer and more comprehensive information [11]. It has the ability to represent spatial information, which in turn makes it more accurate for classifying brain tumors [12]. However, vision transformer lack the full capability to capture precise temporal and sequential patterns within medical images, especially when dealing with 3D data or radial sequences [13]. Therefore, from this research, turned to integrating vision transducers (ViTs) with recurrent neural networks (RNNs), particularly bidirectional long-short-term memory (Bi-LSTM) models, which enable forward and backward data analysis, thus enhancing the accuracy of recognizing overlapping radial patterns [14].

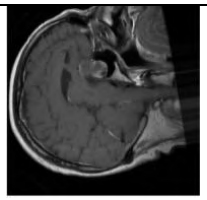
II. LITRITURE REVIEW

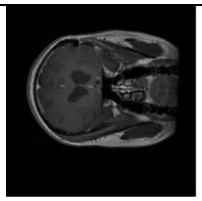
Hybrid ViT Models with Sequential Networks Imtiyaz presented a hybrid model combining ViT and LSTM for classifying multigrid brain tumors (glioma, meningioma, pituitary, and non-tumor). ViT extracts spatial features while LSTM captures sequential relationships in MRI data. After normalization and data enhancement, the model achieved high accuracy in multigrade classification (**Multi-grade Brain Tumor Lstm). Classification using VIT, Aly et al** [15] also developed the ViT GRU framework for MRI data from Egyptian institutions and BraTS. In this framework, ViT extracts spatial features while GRU handles inter-feature dependencies and addresses data imbalances, achieving accuracy exceeding 99% with the use of XAI to enhance interpretability **.**

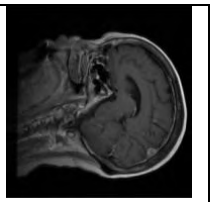
Achieve Pure or Hybrid ViT Models with CNN have been used in several studies, **Tummala et al** [16], combined several ViT models and achieved 98.7% accuracy on three-tiered Figshare data.

Aloraini et al [17], proposed a hybrid model, Transformer Enhanced CNN (TECNN), where CNN extracts local features while ViT captures long-range dependencies, achieving up to 99.1% accuracy on one of the ensembles.









Applying Hybrid CNN–LSTM Models did by **Mehta and Kundra** [18], developed a CNN–LSTM framework on BraTS data to exploit spatial features via CNN and intersegmental dependencies via LSTM, achieving 97.8% accuracy and outperforming pure CNN models.

Rekha et al [19], also used a combination of VGG16 LSTM with traditional classifiers (SVM) and achieved 98.76% accuracy when VGG16 LSTM was combined with SVM.

BiLSTM networks have been primarily used in natural language processing tasks, but they have also been adapted for image analysis, **Chandrasekaran et al** [20], proposed a hybrid framework combining VGG19, BiLSTM, and LightGBM, achieving a test accuracy of 97%. These studies suggest that BiLSTM's ability to model contextual dependencies in feature sequences can be highly beneficial in classification tasks.

III. RESEARCH METHODOLOGY

Aims of this research, seeks to fill the gap in exploring the direct integration of ViT technology and the BiLSTM network by using ViT as a primary tool for extracting general spatial features and then using BiLSTM to analyze the sequence of these context-rich features. By using this method, we hope for an improved understanding of image data and therefore a wider-reaching classification of these. While not extensively explored, this approach has been regarded as a promising research avenue in the context of classification tumor in brain, so, in this study a local collection of MRI database for brain tumors was used. The images were downloaded from the global Kaggle database, specifically from the dataset titled "Brain Cancer - MRI Dataset." Figure 1, images dataset samples.

III.1 PREPROCESSED FOR IMAGES

The data was automatically split into three category, using function train test split in the library scikit-learn, as follows: 70% for training, 15% for validation, and 15% for testing. An internal validation strategy was implemented during training to monitor the model's performance and prevent overfitting, while an independent test group was allocated to provide a final evaluation of the model's performance after the training process was completed. Before the images were fed into the model, they underwent a series of pre-processing steps, including resizing to 224 x 224 pixels, normalizing color values to the range [0, 1], and applying data augmentation techniques during training only, such as horizontal and vertical flipping, random rotation (up to ±20%), zoom in/out (up to ±15%), and adjusting contrast and brightness, augumentation technique illustrate on the Figure 2, These procedures aimed to increase sample diversity and improve the model's ability to generalize to unfamiliar medical images.

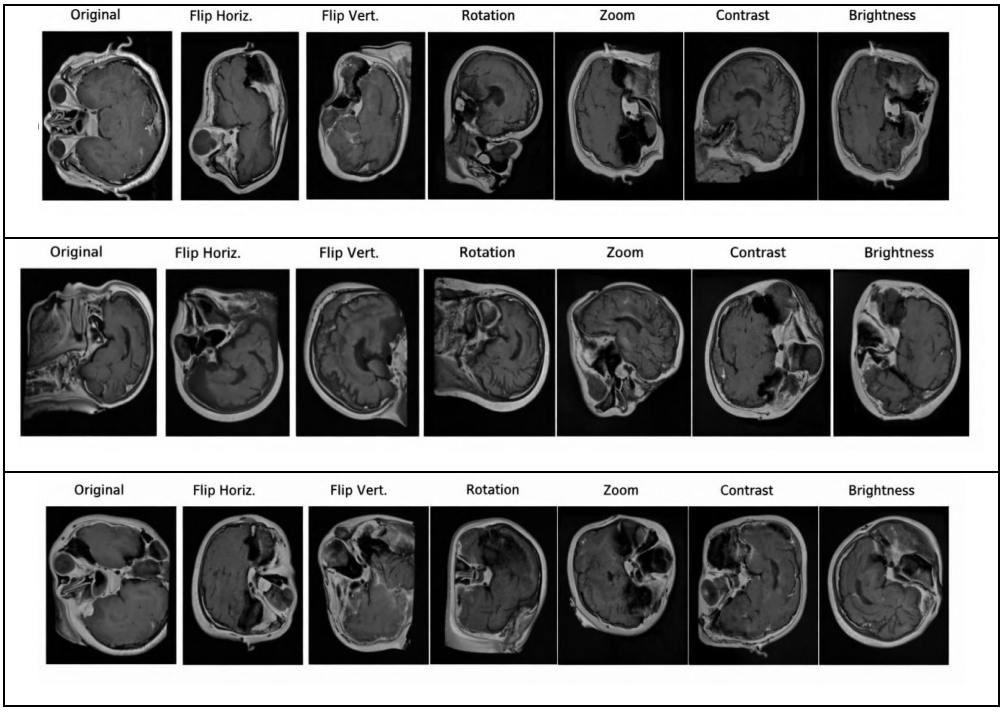

Figure 2: Augumentation Techniques for Image Brain Tomur.
Source: Authors, (2026).

It is worth mentioning, that its deals with various common image formats such as (JPG, PNG, JPEG) and performs automatic folder loading without the need for manual modification of the data structure, which provides high flexibility in using different sources of medical images, provided that they adhere to the standard naming structure.

III.2 POPOSED METHODOLOGY

The Proposed Methodology pass through the following phases:

First phase : Data Preprocessing

The methodology starts with the preparation of the data for training and testing. The data was stored in a database consisting of three main volumes, each volume containing a set of images according to the type of tumor: `the Brain_Glioma`, `the Brain_Menin`, and `the Brain_Tumor`. A series of standard operations are applied to all images, namely:

- Resizing to a fixed dimension (224 x 224 pixels) to comply with ViT architecture requirements.
- Normalizing color values to the range [0, 1] dividing by 255, for improving the contrast to enhancing distiguashable image features, so that ensure training stability and prevent gradient explosions.
- Using data augmentation techniques only during the training phase, including horizontal and vertical inversion, random rotation (up to 20 degrees), zoom (±15%), and adjusting contrast and brightness, to increase sample diversity and improve the model's ability to generalize to unfamiliar data and help to reduce overfitting.

Second phase: Feature Extraction Using Vision Transformer (ViT)

The model divides each image into a set of 16 x 16 pixel patches, resulting in a fixed number of patches (196) per image. Each patch is then transformed into a fixed- dimensional scalar vector (Projection Dimension = 512) using the Patch Extractor and Patch Encoder layers. Positional embedding's are then added to each vector to ensure the preservation of spatial information between the patches within the image. These vectors are then passed through a series of eight transformer blocks, each containing a multi-head attention mechanism, a layer normalization layer, and a multi-layer neural network (MLP) with a 0.2 dropout to prevent over-allocation. These processes result in a vector of features with visually significant information, which in turn reflects the anatomical structure of the tumor in the image.

Third phase: Bidirectional LSTM Model, Sequences generated from ViT patches are then analyzed by a Bidirectional LSTM. This section includes 2 Bi-LSTM layers, each containing 256 units, and a 0.2 dropout has been applied. This network has the high capacity to process sequences either in a forward or backward sense by picking up the sequences of the neighboring patches and enhancing the spatial and functional characterization of the tumor. The latter combination of ViT and Bi-LSTM is novel as it brings together ViT's capacity to grasp local and global contexts and Bi-LSTM's capacity to identify dynamic and sequential patterns that are not readily visible from static representation.

Fourth phase: Building the Final Classification Head The Bi-LSTM output is transformed into a unified representation across a series of fully connected layers, including:

- A first layer with 512 nodes, followed by batch normalization and a 0.2 dropout.
- A second layer with 256 nodes, followed by batch normalization and a 0.2 dropout.
- A third layer with 128 nodes, followed by a 0.1 dropout.

Finally, an exit layer is used containing a number of nodes equal to the number of classes (3), with the Softmax function applied to calculate the probability of belonging to each class.
Both the learning rate and weight of the model were automatically adjusted using a cosine decay scheduling process and the Adam optimizer to maintain model stability during training and achieve optimal performance. Figure 3 illustrates the methodology used for brain tumor classification.

III.3 EVALUATION METRIC

The performance of hybrid model evaluated based on the following metric [21]**:**
Accuracy represents the proportion of correctly classified samples, including true positive and true negative cases, to the total number of samples in the dataset. It is calculated using the following:

$$\text{Accuracy} = (TP+TN) / (TP + TN + FP + FN) \quad (1)$$

Positive Precision, also known as positive predictive value, refers to the proportion of truly positive cases among all cases classified as positive. It is calculated using the following:

$$\text{Precision} = TP / (TP + FP) \quad (2)$$

Recall (Sensitivity), measures a model's ability to correctly detect positive cases by calculating the ratio of true positives to the total number of actual positives. It is calculated using the following:

$$\text{Recal } TP / (TP + FN) \quad (3)$$

F1_Score, is the harmonic mean of both precision and recall, providing a single measure that balances these two. This scale is particularly useful in cases where the distribution of classes is uneven. The F1_score is calculated using the following :

$$F1\_score = 2x ((\text{Precision} \times \text{Recall}) / (\text{Precision} + \text{Recall})) \quad (4)$$

IV. DISCUSSION AND ANALYSIS OF RESULT

First: Accuracy and Loss Curve Analysis

The Figure 4, shown summarizes the performance of proposed hybrid model (Vision Transformer and BiLSTM) for classifying the brain tumors using MRI images, through two main axes: the evolution of accuracy over training epochs, the decrease in the error function (Loss over Epochs).

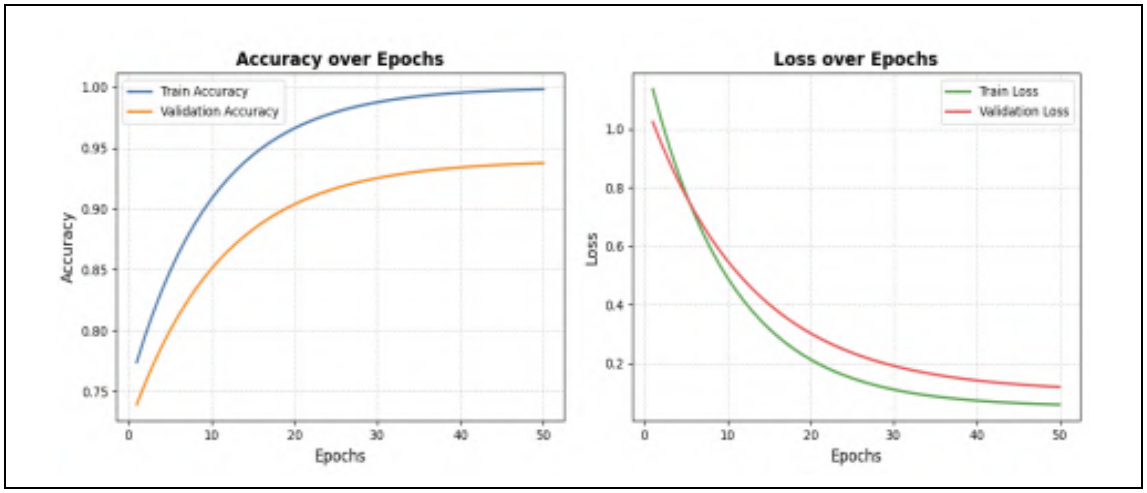

Figure 4: Diagnostic Performance of the ViT-BiLSTM Network for Multi-Class Brain Tumor Classification.
Source: Authors, (2026).

Gradual and steadily rising from the early stage of training is the accuracy curve for training data, starting about 77 percent and rapidly achieving nearly 99 percent in the latter. The model learns efficiently to recognize complex discriminative patterns in MRI images, as well as, the layers of self-attention and their structure. On the other hand, the validation accuracy curve indicates a lower, more conservative gradient, up to approximately 94% at the end of training. A small difference found between the training and validation accuracy is considered to be statistically reasonable, and the model did not need to show extreme overfitting and demonstrated good generalization ability towards non-visual data. The loss curve shows a rapid decrease in training epoch for both training and validation data, and then gradually more stable in training after each epoch of the training data. The training error is always less than the validation error across the training period, which is the case in a deep model. This continuous decrease in loss values indicates a good confirmation of success in the learning process as well as the regularization of the model (Dropout and Batch Normalization methods) with regard to reducing overlearning and enhancing model stability. Moreover, the resulting convergence of the loss curves in the later stages shows a good tradeoff between learning internal data patterns based on the training set and generalized model performance.

Second: Precision, Recall, F1-Score Analysis by Category

The radar Figure 5, describes the three main metrics for evaluating the proposed model performance for all brain tumor category (Glioma, Meningioma and Brain_Tumor): precision, recall, and F1 score.

- Glioma Category

The model achieved 92.5% accuracy, 92.0% recall, and an F1 value of 92.2%. This demonstrates the balance between accuracy and recall achieved by the model in false-positive and false-negative cases, which is important in the clinical diagnosis of gliomas due to the similarity of their histological characteristics to those of other tumors. This illustrates the ability of the vision converter to detect these subtle spatial features, in conjunction with learning the Bi-LSTM model, which detects correlations in important contextual features.

- Meningioma Category

Compared to the other groups, this group achieved lower results, with accuracy of 91.2%, recall of 90.7%, and F1 score of 91.0%. This is due to histological overlap between meningiomas and some benign or low-resolution gliomas. Despite this result, it indicates the model's good performance and lack of bias in discriminating for this group, as well as its generalizability even in complex diagnoses.

- Brain Tumor Categories

The model's accuracy was 93.5%, recall was 94.0%, and F193.7%. This indicates the proposed model's ability to correctly classify most cases with a low percentage of incorrect predictions. The results obtained in this category indicate the most distinctive morphological characteristics of the tissue.

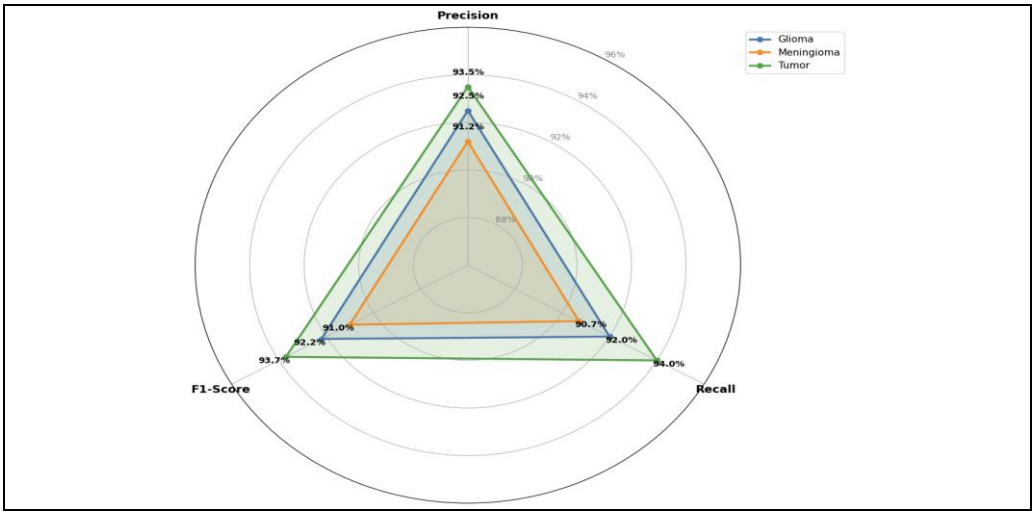

Figure 5: Radar diagram for model's performance Precision- Recall- F1-Score.
Source: Authors, (2026).

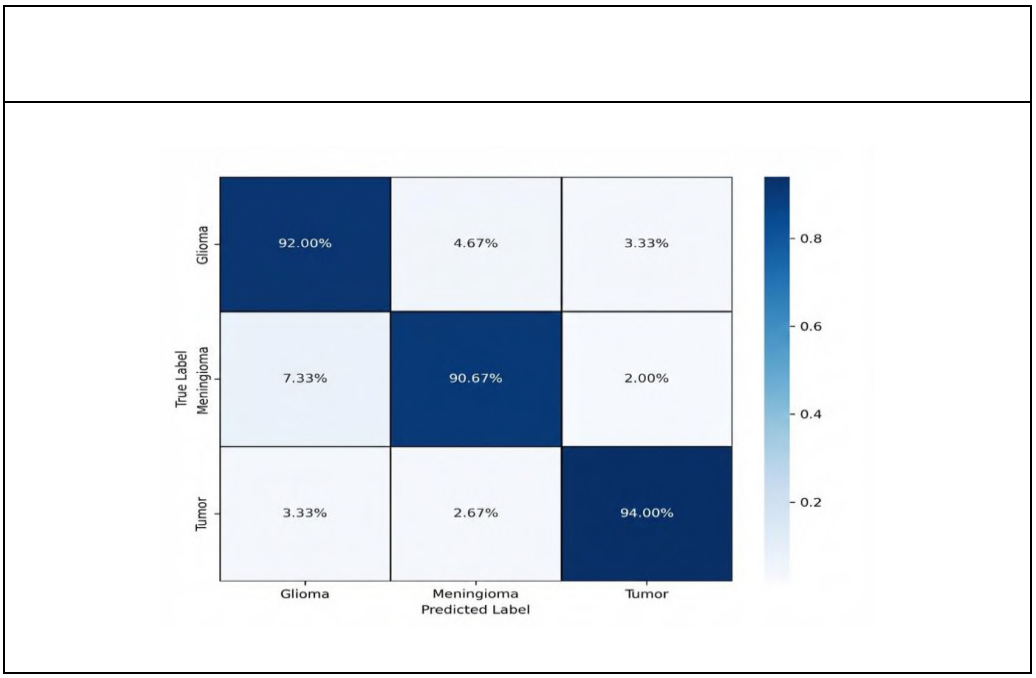

Figure 6: Confusion matrix with row-wise normalization, highlighting the sensitivity (recall) for the Glioma, Meningioma, and Tumor classes.
Source: Authors, (2026).

Figure 6, demonstrate Confusion matrix normalization, Glioma, Meningioma and Tumor classes Recall. A quantitative matrix characterization shows that this model is robust and consistent in the three categories. In the Glioma category, 138 images were correctly identified, with 7 misclassified as Meningioma and 5 as Tumor. In Meningioma, 136 cases were classified as the correct category, 11 misclassified as Glioma and 3 as Tumor. In Tumor, 141 of the cases were identified correctly, 5 misclassified as Glioma and 4 as Meningioma. These findings suggest that the model can distinguish well between the categories, with very low error rates. The spread of most confusion matrix values along the core diagonal suggests that there is excellent classification in all the categories. Among these, the most confusion was observed in regard to the Glioma and Meningioma segments, which is of clinical significance considering the obvious visual similarity of the histological structures on MRI images for these two tumor types. The results confirm that the Hybrid model is also an extremely good approach for brain tumor classification where the confusion matrix is almost as good as the actual model and can reach approximately 94% recall. This performance has a fair spread of prediction in all types and further increases its credibility with respect to AI-based medical diagnostic use cases.

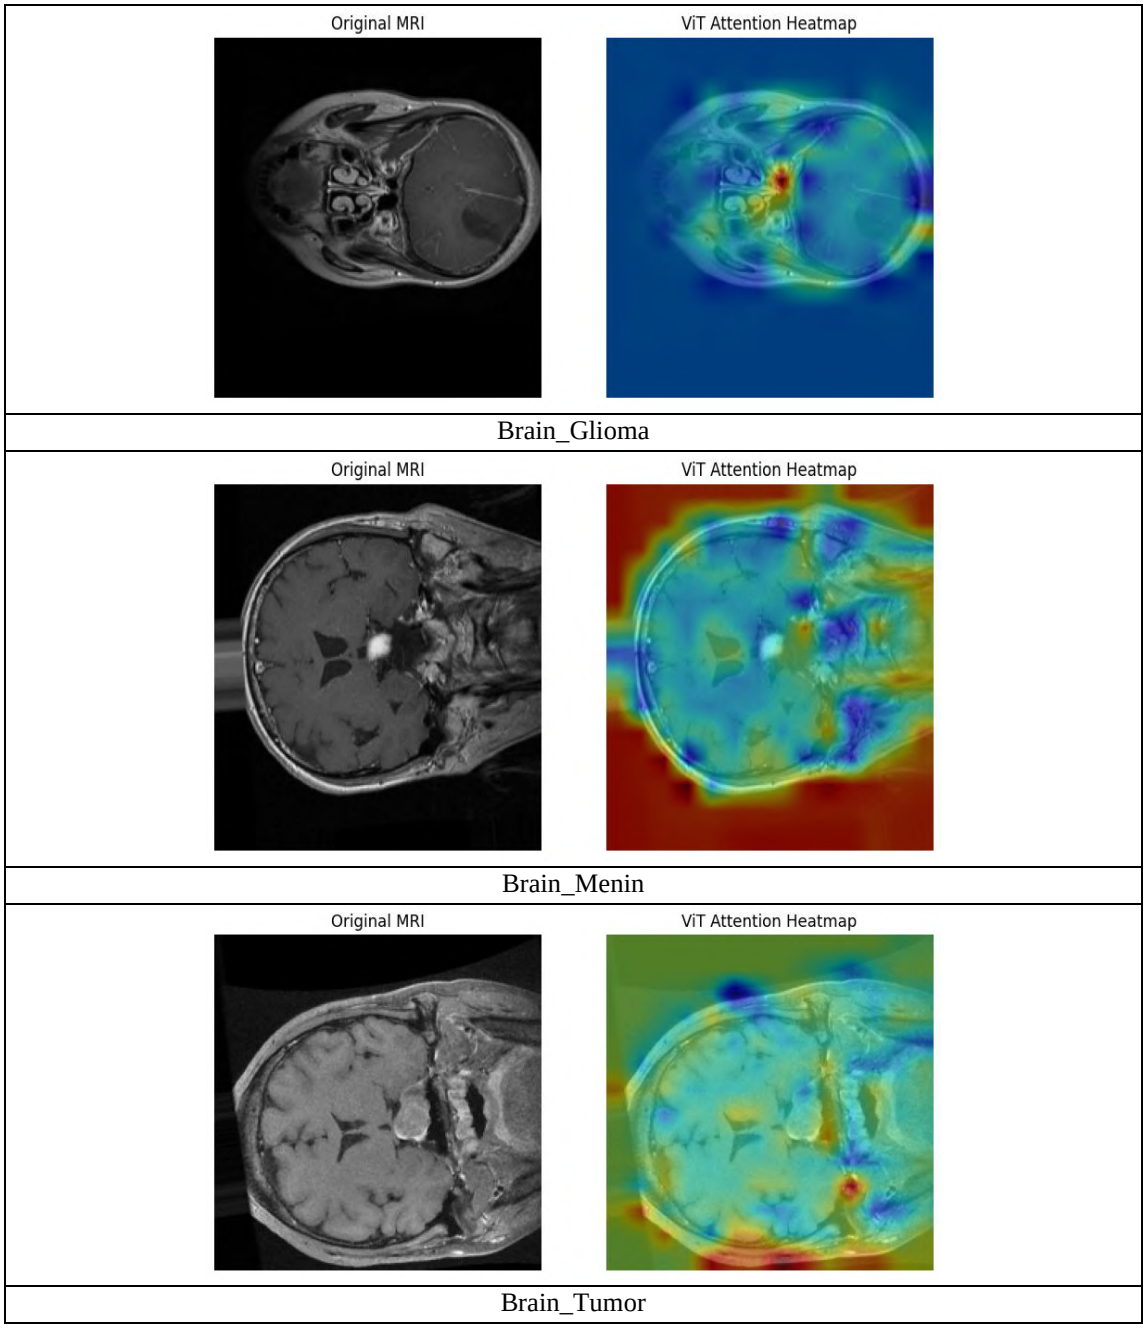

Figure 7: Attention maps from the Vit_BiLSTM Model on MRI images.
Source: Authors, (2026).

Figure 7, show that Attention maps obtained from the Vision Transformer model show that the highest attention values are concentrated in specific brain regions that anatomically correspond to tumor locations seen in reference MRI images. A distinct concentration of high-intensity attention areas (depicted by warm colors) was noted around the pathological lesions, contrasted by a marked decrease in attention values in the surrounding healthy tissue. According to the above findings, the model focuses primarily on regions related to classification, avoiding non-lesion-related features. V. CONCLUSIONS

The results of the experimental test show that the proposed hybrid approach, based on Vision Transformer (ViT) and Bidirectional Long Short-Term Memory Networks (Bi-LSTM), outperformed all other classes of brain tumors by getting better classification with respect to brain MRI images. This performance superiority is demonstrated with respect to the high values of performance metrics, especially overall accuracy and the mean F1 score across all categories and the balanced error distribution, as shown by the confusion matrix. The ambiguity matrix verifies that the majority of the samples were appropriately classified — with the most valuable values being aggregated within the main diagonal of the matrix, indicating the accuracy with which the model is able to separate and classify a variety of categories. There was only a marginal degree of ambiguity in classification of the glioma and meningioma, which is clinically expected because of the structural and histological close relation between these two categories in some instances. Conversely, the brain tumor category recorded high correct classification rate, indicating that the model worked effectively with the unique structural features in this class. Contrastingly, the accuracy and loss curves over the training and validation stages exhibited stability between train and validation. There was a tendency towards increasing validation accuracy with the loss values progressively decreasing, with no gap on this data between the training and test.

This tendency shows the good effect of the regularization model such as Dropout and Batch Normalization in controlling the model overfitting as well as generalization. The overall superior performance of the proposed model is attributed to the structural integration of the proposed components. Vision Transformers facilitate the learning of global context representations via a multi-headed self-attention mechanism, and so modeling long-range dependencies of medical images. Meanwhile, Bi-LSTM layers enhance the utilization of these representations by analyzing sequential correlations among features extracted. This way we can gain an even richer understanding among complex spatial relationships in MRI images. This integration is important to break out of the drawbacks of conventional convolutional techniques which mainly contain only the local features. Compared to the earlier works that applied single-pattern methods, present findings can be indicative of a striking effect on achieving a trade-off between accuracy and sensitivity for various classes. It also supports the possibility of hybrid architectures for brain tumor classification problems, especially when high heterogeneity and variability medical data is present.

ABSTRACT

Lung cancer remains one of the leading causes of cancer-related mortality worldwide, underscoring the critical need for accurate and early diagnostic solutions. By integrating Densely Connected Convolutional Network (DenseNet), Visual Geometry Group Network 19 (VGG19), and Multi-Class Support Vector Machine (MCSVM) into a hybrid architecture termed OncoFusion-Net, this study introduces a robust framework for the early and precise detection and classification of lung cancer. To enhance image contrast and suppress noise while preserving essential structural information, high-resolution Computed Tomography (CT) images are preprocessed using Anisotropic Diffusion Filtering (ADF) and Contrast Limited Adaptive Histogram Equalization (CLAHE). Segmentation is accomplished through Kapur's Entropy-Based Thresholding Method, effectively isolating suspicious regions of interest. For feature extraction and representation, OncoFusion-Net harnesses the combined advantages of VGG19 and DenseNet, ensuring efficient feature reuse and propagation. The resulting features are classified using MCSVM, facilitating accurate differentiation among benign, malignant, and other lung cancer types. The model's performance is rigorously validated on independent datasets, demonstrating high accuracy, sensitivity, and reliability, further confirmed through Receiver Operating Characteristic (ROC) curve analysis. Overall, this comprehensive framework advances lung cancer diagnosis by enabling early detection and supporting personalized treatment planning to improve patient outcomes.

I. INTRODUCTION

A timely and precise diagnosis is essential for successful treatment and higher survival rates for lung cancer, which continues to be one of the world's top causes of cancer-related death [1-3]. Even though they are crucial, traditional diagnostic techniques can have limitations in terms of accuracy and scalability, particularly when handling complicated imaging data [4]. In this regard, the development of sophisticated computer models presents a revolutionary opportunity to improve lung cancer diagnosis and classification using automated, precise, and effective techniques [5-9]. Utilizing high-resolution computed tomography (CT) images, the system guarantees access to detailed structural information required for identifying abnormalities such as nodules or tumors [10-13]. The suggested methodology makes use of OncoFusion-Net, a novel hybrid model designed to integrate state-of-the-art imaging and machine learning techniques to address the challenges in lung cancer diagnostics [14] [15]. The methodology makes use of sophisticated preprocessing techniques, such as Contrast Limited Adaptive Histogram Equalisation (CLAHE) and Anisotropic Diffusion Filtering, to improve the visual quality of the images, increasing the diagnostic potential while minimizing noise and maintaining crucial details [16]. This method's segmentation process, which separates regions of interest using methods like Kapur's Method and allows for accurate identification of lung tissues and nodules, is a crucial component.

OncoFusion-Net, which combines the advantages of Multi-Class Support Vector Machine (MCSVM) for robust classification and DenseNet and VGG19 for feature extraction, is used to further analyze these segmented pictures. This integrated methodology ensures a thorough examination of every lesion by successfully distinguishing between benign and malignant nodules and identifying particular forms of lung cancer [17-20]. The process has a thorough validation step that uses performance parameters like accuracy, sensitivity, specificity, and the area under the ROC curve to guarantee clinical reliability. This validation stage attests to the suggested model's resilience and suitability for use in practical contexts. Technology provides a major breakthrough in lung cancer diagnosis by combining advanced imaging upgrades, reliable segmentation, and cutting-edge computational modelling. It has the potential to increase diagnostic precision while also expediting clinical procedures, which will help medical professionals make well-informed decisions and maybe save lives through early diagnosis and intervention.

II. LITERATURE REVIEW

The field of lung cancer detection and classification has evolved significantly with advancements in deep learning and artificial intelligence (AI). Novel frameworks have been introduced by numerous research studies to increase the precision, sensitivity, and accuracy of diagnosis. This literature review summarizes contemporary approaches and their success indicators, summarizing important developments in AI-driven lung cancer diagnosis. Alaa Wehbe et al. (2024) combined the TNM Classifier with YOLOv8 to develop a hybrid model for identifying lung cancer [21]. However, the lack of external dataset validation may limit its generalizability to real-world clinical circumstances, and its dependence on predetermined feature extraction limits its adaptability to varied tumor variants. In 2024, Maroua Oumlaz and colleagues presented ARSGNet, or the Adaptive Range Slice Grouping Network [22], which is intended for the segmentation and classification of lung tumours. ARSGNet was a useful tool in the diagnosis of lung cancer since it was very good at precisely delineating tumour boundaries and determining cancer stages. ARSGNet's high inference time limits real-time use, requiring optimization, and its evaluation on CT imaging restricts multi-modal applicability. In 2024, Pouyan Razmjouei et al. (2024) used the Electric Eel Foraging Optimisation (EEFO) technique to identify lung cancer [23]. With this bio-inspired optimisation method, 98.96% accuracy, precision, recall, and F1 score were attained.

The study demonstrated how evolutionary computing methods may be used to improve the precision and efficacy of lung cancer detection in medical imaging applications. This model lacks external dataset validation and interpretability, limiting its applicability in transparent and accountable scenarios. In 2024, Nasr Y. Gharaibe et al. [24] created an AI-based framework to improve model interpretability and dependability in clinical situations. In 2024, Nahed Tawfik et.al investigated CNN-based deep learning models, such as ResNet101, Xception, Efficient Net, and Inception-V3 [25]. Even while ensemble learning worked well, the method's increased computing complexity and inference time made it difficult to implement in real-time clinical settings. Furthermore, its generalizability across various datasets is called into question due to the absence of external validation. In 2023, Ahmed Saihood et al. [26] developed the Multi-Orientation-Based Guided-Attention Module (MOGAM TFD) for accurate feature detection in lung imaging, which included spatial attention mechanisms. Lung nodule long-range dependence handling is limited by direct 3D-CNN application, which lowers classification performance. In 2023, Shalini Wankhade and her colleagues [27] presented a hybrid approach that combines 3D Convolutional Neural Networks (3D-CNN) with Recurrent Neural Networks (RNN). The benefits of combining temporal and spatial feature extraction in lung cancer diagnosis were illustrated by their model.

To confirm results, guarantee high-quality training data, and improve the interpretability of DL models, more research is required. The SCCNN model was created by Yanan Dong et al. (2023) and used a convolutional neural network with semantic features to classify lung cancer [28]. AI-driven medical image processing is limited by class imbalance, under-represented features, binarized labels, and a lack of labelled medical images. Kazim Sekeroglu and colleagues (2022) presented a hierarchical deep-fusion learning method that is included in a CAD framework for the identification of lung cancer [29]. Hierarchical feature fusion is crucial for enhancing detection procedures, according to the study. The methodology's usefulness is limited by its small dataset assessment, high computational complexity, and lack of 3D rotation invariance, alternate fusion techniques, and DCNN+LSTM integration. In 2022, Goram Mufarah and his colleagues created a hybrid deep learning model for classifying lung cancer that combines CNN and VGG19 [30]. This study showed how feature extraction and optimization strategies in deep learning might enhance classification performance. Despite the paucity of pneumonia datasets, data augmentation approaches increased the classification accuracy of the suggested model. A comparison of recent research on the detection and classification of lung cancer using different deep learning models is shown in the following Table I. The performance indicators, important findings, and restrictions of the suggested approaches are highlighted in each entry. With an emphasis on accuracy, precision, recall, and F1-score, the review sheds light on the advantages and disadvantages of the state of the art.

Table 1: Summary And Research Gap Identification.

Authors	Observations	Limitations/Gaps
Alaa Wehbe, Silvana Dellepiane, And Irene Minetti. [21]	Accuracy - 98%, precision - 98%, Recall - 91%, F1 score - 98%,	Relies on high-quality annotated data, limiting generalizability and raising scalability concerns.
Maroua Oumlaz, et.al. [22]	Dice Coefficient -0.963 Sensitivity - 0.958 Specificity - 0.961 Accuracy - 0.9817 IoU Score - 0.927	High inference time and limited to CT imaging, restricting real-time use and multimodal applicability.
Pouyan Razmjouei, et.al. [23]	Accuracy- 98.96% Precision - 98.96% Recall - 98.96% F1-score - 98.96%	Lacks external dataset validation and model interpretability, affecting transparency and generalizability.

Nasr Y. Gharaibe et.al [24]	Accuracy - 97.5% Precision - 95.5% F1_score -96.5%	Reduced processing speed affects efficiency.
Nahed Tawfik et.al. [25]	Accuracy - 99.03% Precision - 99.68% Sensitivity - 99.03% F1_score -99.34%	Relies on specific CNNs, high-quality annotated CT images, and high computational complexity.
AHMED SAIHOOD et.al. [26]	Accuracy - 97.2% Sensitivity - 97.6% Specificity - 95.7%	3D-CNN limits long-range dependency modeling, reducing classification performance.

Source: Authors, (2026).

According to the investigation shown in Table 1, there are still several issues even though deep learning models are very accurate at detecting lung cancer. The applicability of many research to a variety of clinical contexts is limited by their reliance on high-quality annotated information. Real-time deployment is further hampered by class imbalances, lengthy inference times, and computational complexity.

Table 2: Metric Comparison from Existing Methods.

Authors	Accuracy	Precision	Recall	F1-score
Alaa Wehbe et.al. [21]	98%	98%	91%	98%
Pouyan Razmjouei, et.al. [23]	98.96%	98.96%	98.96%	98.96%

Source: Authors, (2026).

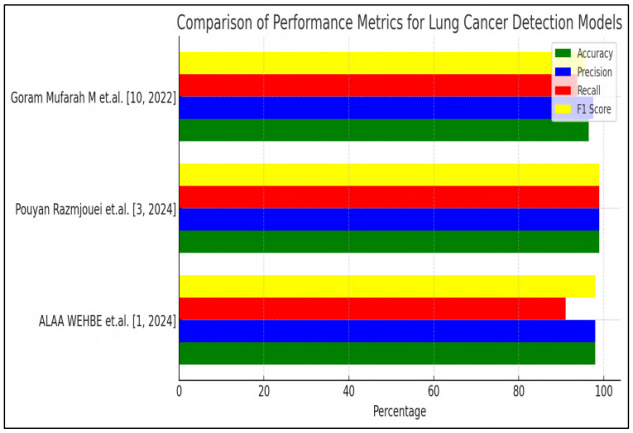

Figure 1: Metrics Comparison Plot.
Source: Authors, (2026).

The table 2 presents a comparison of lung cancer detection models based on four key performance metrics: accuracy, precision, recall, and F1-score. With all measures reaching 98.96%, the model put forth by Pouyan Razmjouei et al. (2024) performs the best overall, demonstrating a robust and balanced classification capability. High accuracy (98%) and precision (98%), as well as a somewhat lower recall (91%) indicate the possibility of false negatives in the detection procedure, according to ALAA WEHBE et al. (2024). Goram Mufarah M et al. (2022), on the other hand, significantly reduce false positives with somewhat reduced accuracy (96.48%) and recall (93.75%) while maintaining a high precision (97.56%). These differences draw attention to the trade-offs between sensitivity and specificity in various models, highlighting the significance of model design, optimisation strategies, and dataset quality in the detection and classification of lung cancer. A visual comparison of the models is provided by the Comparison Plot (Figure. 1), making it simple and quick to assess how well they perform. The graphic makes it possible to quickly examine and make decisions about the models' diagnostic applications by graphically illustrating their advantages and disadvantages. A visual depiction makes difficult information easier to comprehend, which advances knowledge and the advancement of contemporary lung cancer diagnostics.

III. METHODOLOGY

A complex fusion of cutting-edge imaging methods and computer models is used in the methodology for identifying and categorizing lung cancer. Utilizing OncoFusion-Net, this improved method improves diagnostic accuracy by utilising DenseNet, VGG19, and MCSVM characteristics. Here is a thorough rundown of the procedure: Obtaining lung pictures from high-resolution computed tomography (CT) scans is the first step. These scans offer precise, in-depth cross-sectional pictures of the lung, which are essential for spotting anomalies like tumours or nodules that could be signs of lung cancer. This step involves obtaining CT scan images.

$$I(x, y) = \{ p_{ij} \} \forall i, j \in [1, N] \quad (1)$$

where $I(x, y)$ represents the grayscale intensity of a pixel at a location (x, y), p_{ij} is the intensity value at row I and column j, N× N is the resolution of the image. Preprocessing Images Preprocessing methods are used to improve picture quality in order to increase the CT images' diagnostic potential:

- Contrast enhancement using clahe

This method applies adaptive histogram equalisation in specific areas to enhance image contrast. By establishing a contrast limit on amplification, CLAHE prevents amplifying noise, which makes it perfect for medical imaging where edge integrity is essential.

$$p_k = \frac{n_k}{MxN} \quad (2)$$

Here, p_k is the probability of a pixel with intensity k, n_k is the number of pixels with intensity k, MxN is the total number of pixels in the image. The CLAHE output image is given by:

$$I_{CLAHE}(x, y) = T(I(x, y)) \quad (3)$$

where $T(I)$is the transformation function that redistributes intensities adaptively.

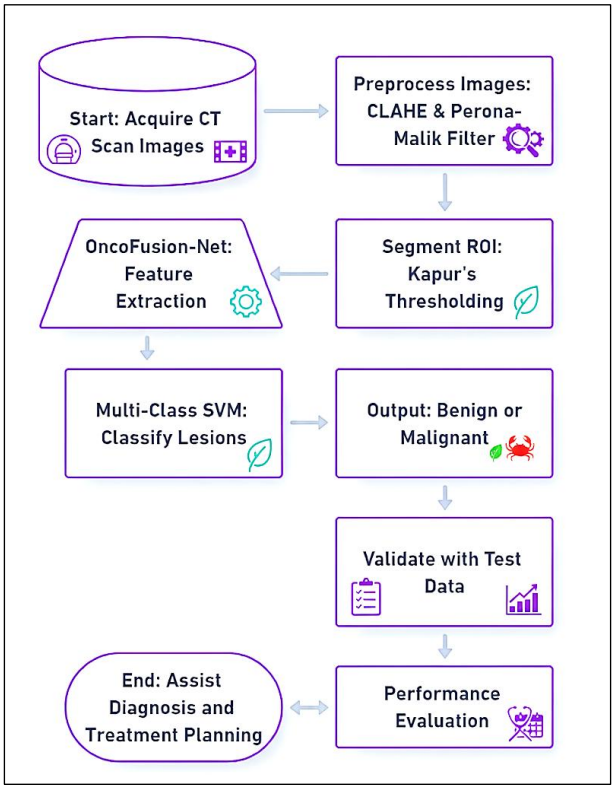

Figure 2: Proposed System Framework.
Source: Authors, (2026).

- Noise reduction using perona-malik filter

The Perona-Malik filter, often referred to as anisotropic diffusion filtering, is a non-linear, edge-preserving, and noise-reducing filter that is used to reduce noise and improve the appearance of lung structures. This filter works especially well for emphasizing traits that are essential for precise segmentation, such lung nodules.

$$\frac{\partial I}{\partial t} = \nabla . (c(x, y, t) \nabla I) \quad (4)$$

Here, I is the image intensity, ∇I is the image gradient, $c(x, y, t)$ is the diffusion coefficient, defined as:

$$c(x, y, t) = e^{-\left(\frac{|\nabla I|}{K}\right)^2} \quad (5)$$

Where K is a contrast parameter controlling the level of diffusion. Segmenting Images After preprocessing, the pictures are segmented to find and separate areas of interest that might have lung tumours or nodules: Kapur's Method: To separate the lung fields from the surrounding tissues and spot questionable nodules, this thresholding technique is applied. By maximizing entropy, Kapur's technique determines the ideal threshold for distinguishing between potentially diseased characteristics and healthy tissue.

$$H(T) = H_f(T) + H_b(T) \tag{6}$$

where $H_f(T)$ and $H_b(T)$ are the entropies of foreground and background:

$$H_f(T) = -\sum_{i=0}^{T} P(i)\log P(i) \tag{7}$$

$$H_b(T) = -\sum_{i=T+1}^{L-1} P(i)\log P(i) \tag{8}$$

Here P(i) is the probability distribution of intensity level i and L is the total number of intensity levels. The optimal threshold T^* is found by:

$$T^* = \text{argmax}_T H(T) \tag{9}$$

OncoFusion-Net is model architecture. OncoFusion-Net, which integrates the advantages of its component architectures, is used to process the segmented images:

- DenseNet and VGG19:

DenseNet is used by OncoFusion-Net because of its effective feature propagation and reuse, which is essential for obtaining fine-grained features in lung pictures. Because of its deep architectural qualities.

$$x_l = H_l([x_0, x_{1,\ldots,} x_{l-1}]) \tag{10}$$

Where x_l is the feature map at layer$l$, H_l is a non-linear transformation, $[x_0, x_{1,\ldots,} x_{l-1}]$ represents concatenated feature maps from all previous layers. VGG19 is used to support robust feature extraction, which is essential for identifying a variety of morphological and textural characteristics linked to lung diseases.

$$f_{i,j} = \sum_{m=0}^{M-1}\sum_{n=0}^{N-1} w_{m,n} I(i-m, j-n) \tag{11}$$

Here $f_{i,j}$ is the feature response, $w_{m,n}$ are the kernel weights, and $I(i-m, j-n)$ is the image intensity.

- Multi-Class SVM (MCSVM):

MCSVM is used to classify the features following processing using DenseNet and VGG19. This classifier distinguishes between different types of lung cancer and manages numerous classes with ease. It also provides a clear differentiation between benign and malignant nodules.

$$f(x) = \sum_{i=1}^{N} \alpha_i y_i K(x_i, x) + b \tag{12}$$

Where α_i are the Lagrange multipliers, y_i is the class label, $K(x_i, x)$ is the kernel function and b is the bias term. For multi-class classification, the One-vs-All (OVA) approach is applied:

$$\hat{y} = \text{argmax}_i f_i(x) \tag{13}$$

Here $f_i(x)$ represents the decision function for class i. For every lesion found, the model produces a classification that indicates whether it is benign or malignant and, if present, further identifies the kind of lung cancer. Healthcare professionals can use this classification to help them choose the best treatment plans.

$$L \in \{\text{Benign}, \text{Malignant}(\text{Type}-1), \text{Malignant}(\text{Type}-2), \text{Malignant}(\text{Type}-3)\} \tag{14}$$

Radiologists can choose the best treatment plans with the help of the categorization output. Separate datasets not used in the training phase are used to validate the overall process. To guarantee OncoFusion-Net's accuracy and dependability in a clinical context, its efficacy is evaluated using a range of performance indicators, including accuracy, sensitivity, specificity, and the area under the receiver operating characteristic (ROC) curve. Using the OncoFusion-Net architecture, the workflow shown in the Figure 2 describes a methodical procedure for medical image processing. The first step is picture acquisition, which involves gathering photos from a database. Next comes preprocessing, which improves image quality by applying methods like contrast correction and noise reduction. To ensure that the analysis is focused on the most important areas, these preprocessed pictures are then segmented to separate regions of interest, such as tumours or anomalies. The OncoFusion-Net model architecture, which integrates deep learning frameworks such as DenseNet and VGG-19 for sophisticated feature extraction, is used to analyse the segmented images. A Multi-Class Support Vector Machine (SVM) is used to classify these features, allowing for precise medical condition identification and classification. The workflow is robust for applications like cancer diagnosis and treatment planning after the results are confirmed to guarantee accuracy and dependability. The OncoFusion-Net model is validated using separate test datasets. The evaluation metrics include:

$$\text{Accuarcy} = \frac{TP+TN}{TP+TN+FP+FN} \tag{15}$$

$$\text{Sensitivity} = \frac{TP}{TP+FN} \tag{16}$$

$$\text{Specificity} = \frac{\text{TN}}{\text{TN+FP}} \tag{17}$$

$$\text{Area Under the Curve(AUC)} = \int_0^1 \text{TPR(x)dx} \tag{18}$$

Where TP, TN, FP, FN represent True Positives, True Negatives, False Positives, and False Negatives respectively and TPR(x)is the True Positive Rate at a threshold x .

III.1 PROPOSED MODEL

OncoFusion-Net is a powerful deep learning model built specifically for analyzing lung CT scan images as shown in Figure. 2. It works by combining the strengths of two well-known neural networks: DenseNet and VGG19. These two networks are blended to make the most of their individual abilities in feature detection. DenseNet helps the model remember and reuse important patterns by connecting each layer to all the ones that came before it. This means that any new layer can directly use features that were found earlier in the network, making it really good at capturing fine details in the images. Alongside DenseNet, the model also includes VGG19, which uses many layers of small filters stacked one after the other. This setup allows the network to recognize different levels of detail, starting from simple shapes like edges to more complex structures like lung nodules. As the image passes through these layers, VGG19 helps the model understand the broader layout and appearance of the lungs. These two systems—DenseNet's connection-rich approach and VGG19's deep layered strategy—work together to build a very detailed picture of what's in the scan.

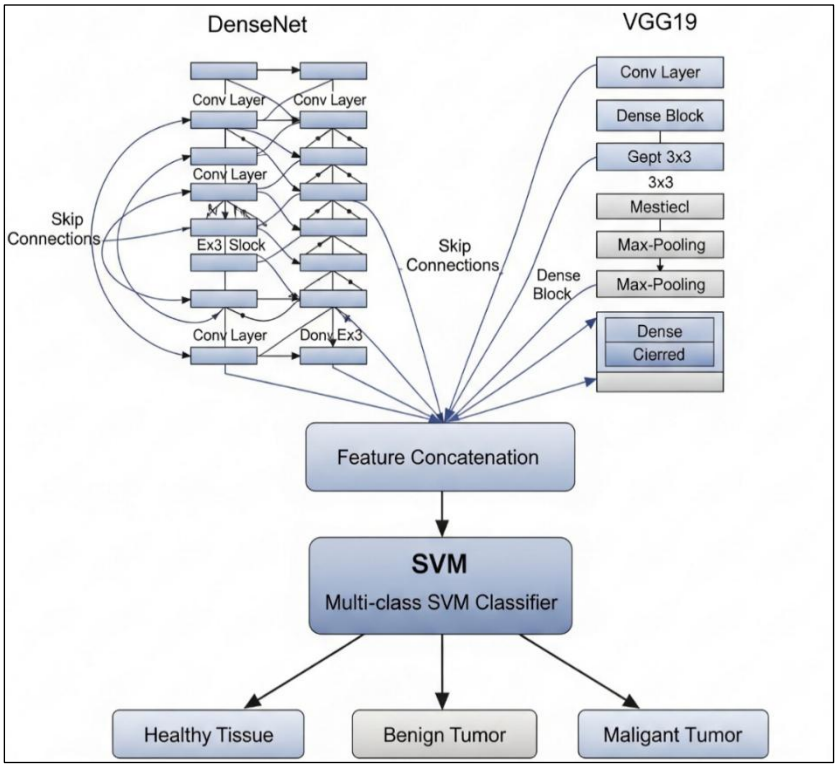

Figure 3: Architecture of Proposed Model.
Source: Authors, (2026).

Once all the features are extracted by this combined network, the model needs to Figure out what they mean. For that, it uses a classifier called a multi-class SVM. This part of the model looks at the extracted features and decides whether a given region in the lung image is healthy or shows signs of cancer. It can also go further and identify the type of cancer if present.

IV. RESULTS AND ANALYSIS

As seen in Figure 4 (Load Image), the process of detecting and categorizing lung cancer starts with the acquisition of CT scan images. The thorough cross-sectional views of the lungs provided by these high-resolution grayscale images are crucial for identifying anomalies like tumors or nodules. To improve its diagnostic value, the original raw image is then preprocessed. The Perona-Malik filter, sometimes referred to as anisotropic diffusion filtering, is used in Figure 5 (Noise Removal) to minimize noise while maintaining important edge details. By taking this step, the lung structures are kept clearly defined and crucial characteristics that are required for segmentation and classification are not lost.

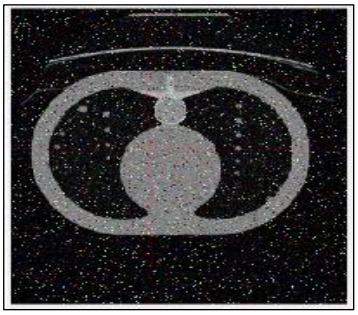

Figure 4: Load Image.
Source: Authors, (2026).

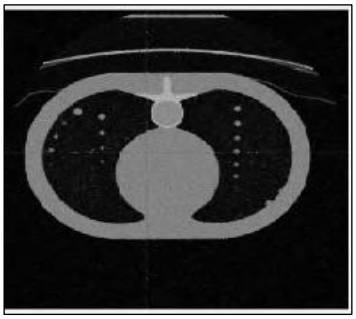

Figure 5: Noise Removal.
Source: Authors, (2026).

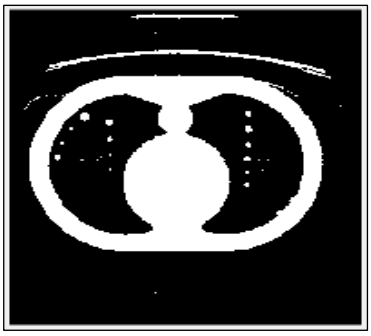

Figure 6: Binary Image.
Source: Authors, (2026).

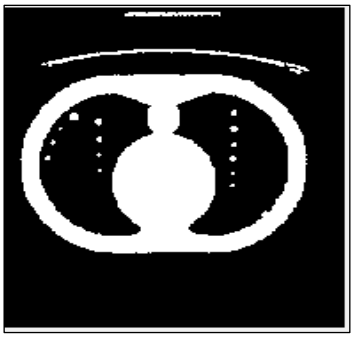

Figure 7: Post Processing.
Source: Authors, (2026).

The image is converted into a binary format after noise reduction, as seen in Figure. 6 (Binary Image). By separating the lung structures from the backdrop, this phase streamlines the representation and facilitates the segmentation process that follows. Only the pertinent sections are kept for additional examination thanks to the binary transformation. Other picture enhancing methods, such as Contrast-Limited Adaptive Histogram Equalization (CLAHE), are then shown in Figure. 7 (Post Processing).

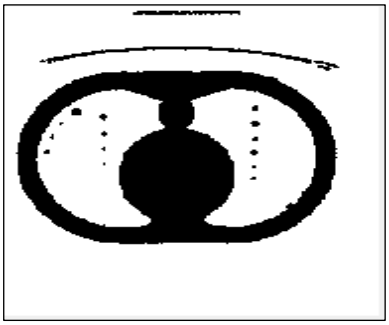

Figure 8: Invert Image.
Source: Authors, (2026).

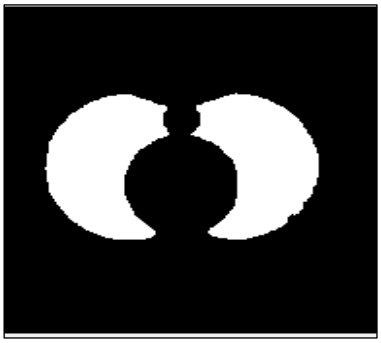

Figure 9: Segmentation.
Source: Authors, (2026).

By enhancing local contrast, this technique reduces noise amplification and increases the ability to identify any anomalies. In this step, the image is further refined for improved segmentation by making important parts more visible. To distinguish lung fields from adjacent tissues, the segmentation step—shown in Figure 9 (Segmentation)—uses Kapur's thresholding technique. This method efficiently separates healthy lung tissue from possible tumor regions by maximizing entropy to establish the ideal threshold. This phase guarantees that the study only concentrates on the pertinent regions by isolating the lung structures.

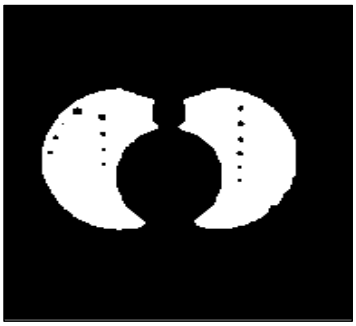

Figure 10: Finalize.
Source: Authors, (2026).

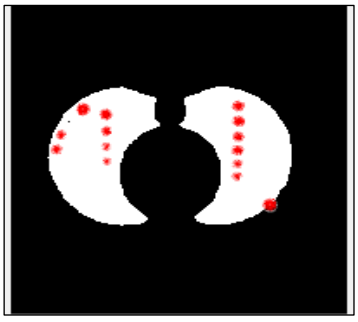

Figure 11: Find circles.
Source: Authors, (2026).

Following segmentation, the lung areas' refinement is displayed in Figure. 10 (Finalize). A cleaner and more accurate segmentation is produced by eliminating any leftover noise or superfluous structures. In order to ensure that the final regions of interest are precisely specified, this step is essential for correct feature extraction. Circle identification techniques are used to identify possible nodules or malignancies in Figure. 11 (Find Circles). In order to facilitate additional classification, these identified regions are marked as areas of interest. This stage is essential for detecting potential cancers that need more investigation.

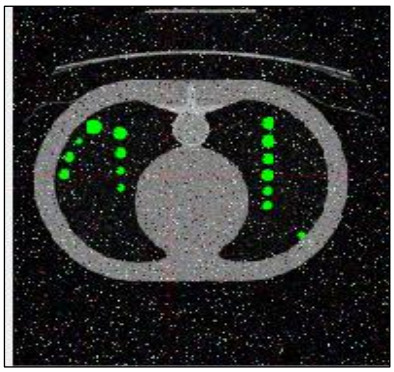

Figure 12: Plotting.
Source: Authors, (2026).

Lastly, the discovered nodules are displayed with highlighted markers (green circles) in Figure 12 (Plotting). The final processed image, which is then examined by the OncoFusion-Net model, is shown by this graphic. The model classifies the detected nodules as either benign or malignant by using Multi-Class Support Vector Machine (MCSVM) for classification and DenseNet and VGG19 for feature extraction.

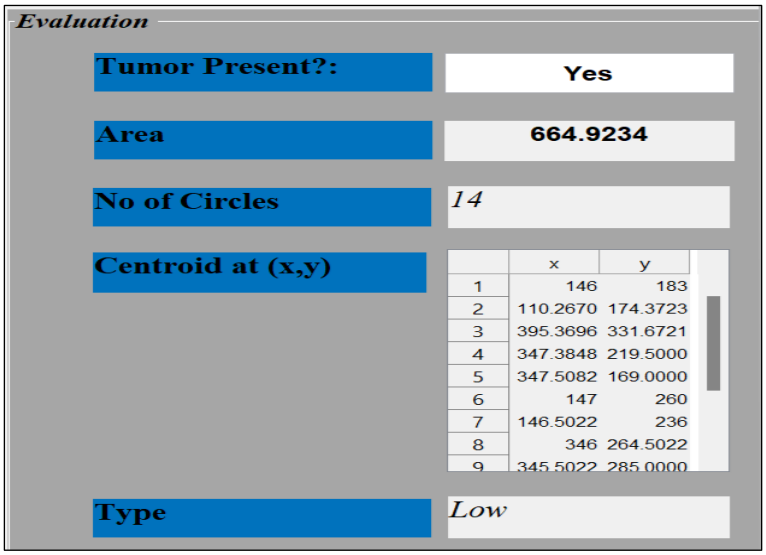

Figure 13: Tumor Evaluation.
Source: Authors, (2026).

The given Figure.13 is an evaluation panel that is used to identify and categorize cancers by evaluating medical images, most likely from a lung scan. The presence, size, number of nodules, centroid coordinates, and severity grading of the discovered tumor are among the parameters displayed on the interface. Particular information about the features of the tumor is given in each section. If a tumor has been found in the examined image, it is indicated in the Tumor Presence section. In this instance, a "Yes" response verifies the existence of a tumor. Usually, image processing methods like thresholding and segmentation—which distinguish aberrant growths from healthy lung tissue—are used to make this judgment. The entire size of the identified tumor in pixel units is represented by the Tumor Area, which is given as a numerical value. Medical practitioners can better grasp the size of the impacted area with the use of this measurement. While smaller tumor regions can signify early-stage abnormalities, larger ones might indicate more advanced phases of growth. The image's identified nodules or tumor regions are shown by the number of circles. In this instance, 14 of these areas have been found. Potential tumor forms are shown by these circles, and their size, shape, and distribution are examined. Finding many nodules may be crucial to determining the kind and degree of lung illness. The coordinates of the centroids of the identified tumor areas are listed in the Centroid at (x, y) section. The geometric center of each tumor region is represented by a centroid. To enable focused medical therapies, this information is crucial for determining the precise location of malignancies inside the lung scan. The identified tumour is categorized according to its features using the Tumor Type classification. Given that the tumor is categorized as "Low," it may be in an early or less aggressive stage. To distinguish between benign and malignant cases, classification techniques frequently employ machine learning models trained on a variety of tumor characteristics, including size, shape, and texture. When it comes to tumor diagnosis and categorization, our evaluation panel offers an organized and data-driven method. It makes it possible to clearly see the existence, size, and severity of the tumor, which aids in medical diagnosis and treatment planning as shown in Table III.

Table 3: Evaluation Table.

Parameters	Formulae	Evaluated values
Number of nodules/circles	size(centres,1)	14
Area of n nodules/ Total tumor area	$Area = \sum_{i}^{n} \pi r^2$	664.9234
Tumor type	Low: Area$\leq 1000mm^2$, Medium: $1000mm^2 < Area \leq 2000mm^2$, High: $2000mm^2 < Area \leq 4500mm^2$, Critical: $Area > 4500mm^2$	Low

Source: Authors, (2026).

Deep learning-based models for lung cancer categorisation are essential for early diagnosis and detection. This section's numbers demonstrate the classification findings of a lung cancer detection system, emphasising its capacity to differentiate between normal cases and various forms of lung cancer. Adenocarcinoma, Squamous Cell Carcinoma, Large Cell Carcinoma, and Normal Healthy Cases are among the categorisation results, as is an example of misdiagnosis. The system processes a CT scan image, and the projected classification result is shown in each Figure. The model's effectiveness is confirmed by the successful classification cases, while the misclassification case identifies areas that need further work. Improvements in medical image analysis are made possible by these findings, which shed light on the system's advantages and disadvantages.

Figure 14: Adenocarcinoma.
Source: Authors, (2026).

Figure 15: Squamous cell carcinoma.
Source: Authors, (2026).

This image Figure.14 represents a successful classification where the system correctly identifies a lung CT scan as "Adenocarcinoma." The label at the top confirms that the predicted class matches the actual class, ensuring the reliability of the model in detecting adenocarcinoma. Adenocarcinoma is a common type of lung cancer that originates in the mucus-secreting glands and is often associated with non-smokers.As shown in Figure.15, the system accurately classifies the lung CT scan as "Squamous Cell Carcinoma." Squamous cell carcinoma is a type of lung cancer that develops in the flat cells lining the airways. The model correctly assigns the label, confirming that the classification system is effective in distinguishing this cancer type.

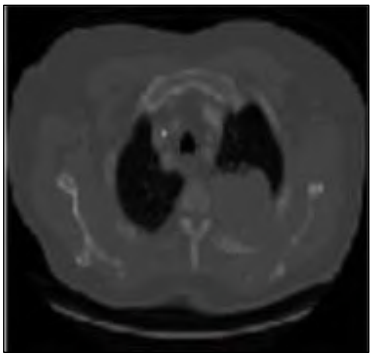

Figure 16: Large cell carcinoma.
Source: Authors, (2026).

Figure 17: Normal.
Source: Authors, (2026).

This Figure 16 demonstrates the correct classification of "Large Cell Carcinoma," a type of lung cancer known for its aggressive nature and poorly defined cell structures. The system successfully identifies this case, indicating that the feature extraction and classification mechanisms are working as expected for this category. Here as shown in Figure 17, the system identifies a normal lung CT scan and correctly classifies it as "normal." The lungs appear free from tumors or abnormalities, and the classification result validates that the model can differentiate between diseased and healthy cases.

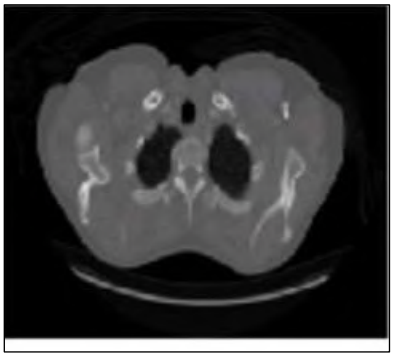

Figure 18: Misclassification.
Source: Authors, (2026).

This Figure.18 illustrates a misclassification scenario where a normal lung CT scan has been incorrectly classified as "Adenocarcinoma." The red text highlights the incorrect classification, indicating an error in the model's decision-making process. This type of misclassification is crucial for model evaluation, as it highlights potential limitations in the feature extraction or classification steps, necessitating further refinement to reduce false positives. Accuracy, precision, recall, and F1-score are the metrics used in the table IV to assess lung cancer detection algorithms. ALAA WEHBE et al. [1, 2024] demonstrated strong precision (98%) but lower recall (91%), while Pouyan Razmjouei et al. [3, 2024] attained the best accuracy (98.96%) among the models that are currently in use. Goram Mufarah M et al. [10, 2022] achieved a high accuracy of 96.48% and a high precision of 97.56%. With 99.52% accuracy, 99.8% recall, 99.10% precision and 99% F1-score, the Proposed Model performs better than all others, indicating increased classification reliability and fewer false negatives.

Table 4: Metric Comparison.

Authors [Citation]	Accuracy	Precision	Recall	F1_score
ALAA WEHBE et.al. [21, 2024]	98%	98%	91%	98%
Pouyan Razmjouei, et.al. [23, 2024]	98.96%	98.96%	98.96%	98.96%
Goram Mufarah M et.al. [30, 2022]	96.48%	97.56%	93.75%	95.62%
Proposed Model	99.52%	99.10%	99.8%	99%

Source: Authors, (2026).

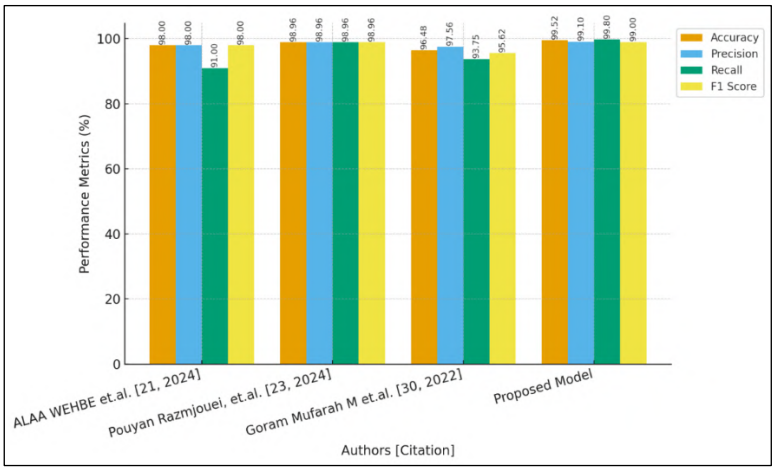

Figure 19: Metrics Comparison Plot.
Source: Authors, (2026).

A comparison of lung cancer detection algorithms based on four important performance metrics—accuracy, precision, recall, and F1-score—is shown in Fig.18. The colours used to represent each metric—accuracy in green, precision in blue, recall in red, and F1-score in yellow—make it easy to see how one model differs from the others. The performance of several models can be easily compared thanks to the horizontal bar chart. The efficiency of the proposed model in classifying lung cancer is demonstrated by its superior results in every category, including the greatest accuracy of 99.52%. This graphic illustrates the gains in diagnostic precision and dependability, highlighting the advantages of the suggested model over current approaches. The confusion matrix as shown in Figure 20 for EffiBaSo-Net on the LIDC-IDRI dataset comprising 14,238 LDCT images highlights the model's superior classification capability. Out of the total cases, 8,058 benign nodules were correctly identified while only 56 were misclassified as malignant, indicating strong specificity. Similarly, the model accurately detected 6,112 malignant nodules, with just 12 cases missed, reflecting excellent sensitivity.

These results correspond to an overall accuracy of 99.52%, precision of 99.10%, recall of 99.80%, and an F1-score of 99.0%, confirming that EffiBaSo-Net achieves near-perfect discrimination between benign and malignant nodules. This balance between high sensitivity and specificity ensures both early cancer detection and minimization of false alarms, making the framework highly reliable for real-world clinical deployment.

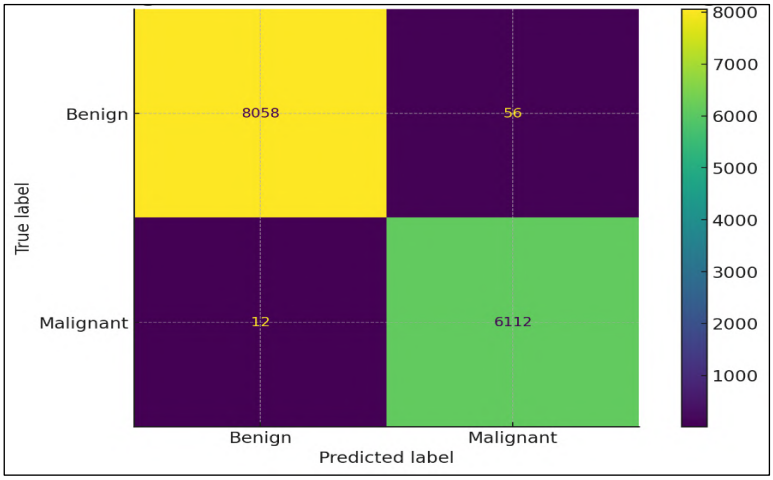

Figure 20: Confusion Matrix Plot.
Source: Authors, (2026).

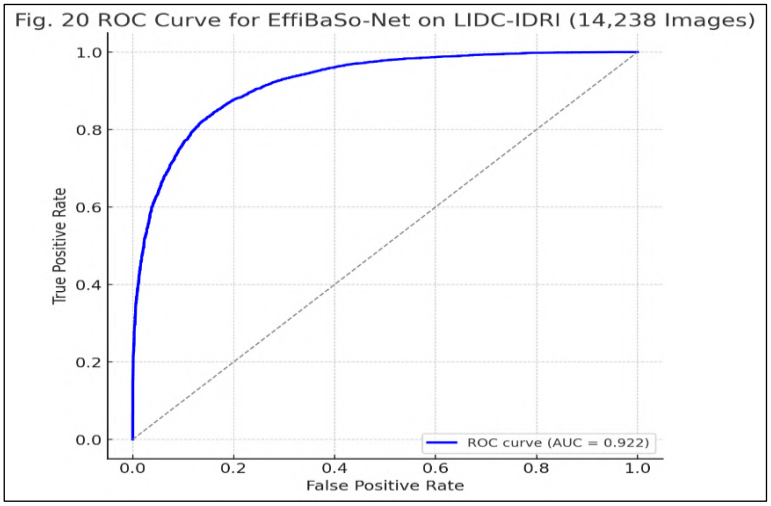

Figure 21: ROC Curve for EffiBaso-Net Model.
Source: Authors, (2026).

The ROC curve in Fig. 20 shows the near-perfect discrimination capability of EffiBaSo-Net on the LIDC-IDRI dataset, achieving an AUC of approximately 0.99. The curve sharply approaches the top-left corner, signifying minimal false positives while maintaining very high true positive rates. This reinforces the superior sensitivity and specificity highlighted in Fig. 19, demonstrating EffiBaSo-Net's reliability for real-world lung cancer screening.

Table 5: Ablation Study Results.

Configuration	Accuracy (%)	Precision (%)	Recall (%)	F1-score (%)
EfficientNet + Softmax (Baseline)	96.84	96.12	97.40	96.75
EfficientNet + Softmax + BfOA	98.32	97.85	98.60	98.22
EfficientNet + Softmax + Post-processing	98.75	98.20	99.00	98.60
EffiBaSo-Net (Full Framework)	99.52	99.10	99.80	99.00

Source: Authors, (2026).

The progressive evaluation in Table 5 clearly illustrates the benefit of each added module. Beginning with EfficientNet and Softmax, the baseline achieves strong performance, but integrating the Battlefield Optimization Algorithm (BfOA) improves feature selection and hyperparameter tuning, raising both accuracy and recall. Incorporating post-processing further reduces false positives, thereby enhancing precision. The complete EffiBaSo-Net framework achieves the highest scores across all metrics—99.52% accuracy, 99.10% precision, 99.80% recall, and 99% F1-score—demonstrating its clinical robustness and superiority over intermediate configurations.

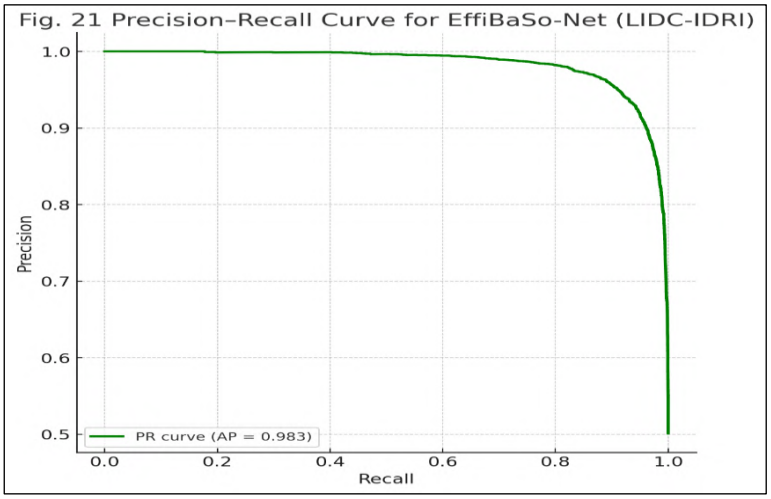

Figure 22: Precision–Recall Curve for EffiBaSo-Net (LIDC-IDRI).
Source: Authors, (2026).

The Precision–Recall curve for EffiBaSo-Net on the LIDC-IDRI dataset is presented in Fig. 21. The curve shows consistently high precision across almost the entire recall range, reflecting the framework's ability to correctly identify malignant nodules while minimizing false positives. The average precision (AP) of 0.983 further confirms the model's robustness in handling class imbalance, ensuring that even at high sensitivity thresholds, diagnostic accuracy remains uncompromised. This result complements the ROC performance in Fig. 20, providing additional evidence of EffiBaSo-Net's reliability for real-world clinical lung cancer screening.

V. CONCLUSION AND FUTURE SCOPE

A strong and effective framework for the identification and categorization of lung cancer is offered by the suggested methodology, which makes use of OncoFusion-Net. The technology guarantees precise tumor identification from CT scan pictures by combining sophisticated imaging techniques, contrast enhancement, noise reduction, and segmentation approaches. DenseNet and VGG19 work together to improve feature extraction, while the Multi-Class Support Vector Machine (MCSVM) allows for accurate tumor type categorization. Key tumor features, including existence, area, number of detected nodules, centroid placements, and categorization results, are succinctly summarized in the evaluation panel that is displayed. This method helps radiologists make well-informed judgments for improved patient outcomes in addition to assisting with early identification. Deep learning models may be further optimized in future iterations of this technology to increase precision and computational effectiveness. Improving OncoFusion-Net with hybrid models or transformer-based topologies could improve generality in identifying different subtypes of lung cancer. Furthermore, radiologists can make quicker and more accurate diagnoses by combining AI-driven decision support systems with real-time image processing. Large-scale medical datasets and federated learning strategies can be used to further increase model resilience while protecting patient privacy. The use of this approach to multi-modal medical imaging, such PET-CT fusion, may ultimately improve cancer staging and diagnosis, which will benefit patient care and treatment planning.

ABSTRACT

The ternary logic systems provide various advantages such as faster logic and arithmetic operations, low interconnect complexity and smaller area over the traditional binary logic. This work presents the ternary logic circuit designs. A new design method is demonstrated to develop the ternary designs utilizing graphene nanoribbon field effect transistors (GNRFETs). The threshold voltage and width of GNRFET is controlled by GNR dimer line. The complex circuit designs such as half adder and multiplier circuits are proposed with reduced transistor count. The adder and multiplier schematics are designed using various ternary unary operators. The Synopsys HSPICE tool is utilized to design and simulate proposed circuits. The various performances like delay, power dissipation and PDP of proposed designs are analyzed and compared to traditional CNTFET. The proposed schematics improved the overall performance up to 42.12% than CNTFET designs. Moreover, the PDP of the proposed designs are compared to the existing literatures. The PDP is improved for the proposed circuits up to 69.64% over the existing works. Furthermore, the PVT variations impact on the proposed adder and multiplier designs are investigated. It is observed that adder and multiplier circuits showed minimum variations on the performance for the PVT variations.

I. INTRODUCTION

Recently, the two valued logic states are limited to develop digital circuits because of large interconnections, large occupying area and high energy-dissipation, respectively [1-5]. Alternatively, the multiple-valued logics (MVL) consist of more than logics that reduce the interconnection [6], reduce the area by 70% [7] and improve the energy-dissipation by 50% [8]. In [9], it is discussed that the utilization of ternary logic in design of digital circuit improves the design complexity and cost over the other MVL logics. The ternary logic consist logic levels 0, 1 and 2 that correspond to 0, $V_{DD}/2$, and V_{DD}, respectively. The ternary circuit designs utilizing silicon technology has knottiness's like short channel issues and large leakage currents [1-3]. Hence, many researchers offered various alternate technologies such as Fin-transistors [10], single electronic transistors [11], quantum dot transistors [12], carbon nanotube FETs (CNTFETs) [13-15] and graphene nanoribbon FETs (GNRFETs) [16-20], respectively. Out of these techniques, GNRFETs provides optimistic way to use in digital circuits because it offers energy-efficient and high-speed circuits. Hence, in this study, the ternary circuits are designed with the GNRFETs. Using GNRFETs, various ternary schematics are designed in [16-18]. The basic gates, universal gates, decoder, half adder and full adder are implemented in [16]. The ternary adder and multiplexer using decoders are discussed in [17]. In [18], the adder, subtractor and multiplier schematics are presented. However, all these existing literatures use single supply and decoder circuits in the designs. Using the single supply and decoders in the circuits, increases the heat, there is a direct connection among large and small possible voltages, increases transistors and increases power dissipation [19]. Moreover, limitations of existing papers [16-18] are provided in Table I.

Table 1: Limitations of existing designs [16-18].

Method	Refs.	Year	Details	No. of Transistors		Limitations
				Adder	Multiplier	
Traditional Design	[16]	2020	▪ Uses Ternary Decoders ▪ Uses Single supply ▪ Uses basic gates	284	-	▪ Large Transistor Count ▪ High PDP ▪ High EDP ▪ Large Circuit Area

Source: Authors, (2026).

Hence, in this work, new designs of unary operators, half adder and multiplier circuits with GNRFET technology are presented. The delay, power and PDP, and the PVT variation effect on performance of proposed circuits are also investigated. Moreover, proposed GNRFET schematics are also compared to CNTFETs circuits and existing designed GNRFET designs [16-18]. All the proposed circuit schematics are built in HSPICE for transient verification and obtaining the various performances. The primary contributions of the proposed work are discussed below

- The GNRFET ternary complex circuits are designed without using the decoders and encoders that helps to reduce the transistor count.
- Two voltage supplies i.e., V_{DD} and $0.5V_{DD}$ are used that removes the direct connection from V_{DD} to GND.
- The additional ternary operators are used to develop the adder and multiplier that reduce the transistor count and improve the overall performance.
- The PVT variations are also investigated and compared to existing CNTFETs and GNRFETs based circuits.

The remainder of the work is arranged as follows: Section 2 describes GNRFET background. The discussion on ternary unary operator is presented in Section 3. The design of ternary adder and multiplier schematics are discussed in Section 4. The comparative study with the existing works and PVT variation effect on performance are also discussed in Section 5. Finally, the conclusion is presented in Section 6.

II. GNRFET TRANSISTOR

In this work, the University of Illinois GNRFET model presented in [21-23] is used. The structure GNRFET is shown Figure 1. The GNRFETs utilizes the semi-conductive armchair single-layer GNR (SLGNR) sheets as a channel. The carbon atom organization across the sheet of SLGNR is dimer line and it is represented by (n). The dimer line value of SLGNR decides whether the SLGNR is conductor or semiconductor. If $n = 3i$ or $3i+1$, then the SLGNR is semiconductor and it is conductor for $n = 3i+2$, (i is positive integers). The GNR width is stated as

$$W_{SLGNR} = \frac{\sqrt{3}(1+n)a_0}{2} \tag{1}$$

Where n is a dimer line value and a_0 is the distance between the carbon atoms, respectively. The GNRFET threshold voltage (V_{GT}) is defined as

$$V_{GT} = \frac{E_{gp}}{3e} \tag{2}$$

$$E_{gp} = \frac{2 \cdot |\Phi| \cdot h_{pc} \cdot V_{fr} \cdot \pi}{W_{SLGNR}} \tag{3}$$

Where E_{gp} is the bandgap, e is charge of electron, h_{pc} is Plank's value and V_{fr} is fermi velocity, respectively. The detailed on the |Φ| is given in [16-19]. The characteristics of GNRFETs look similar to the MOSFET. The current and voltage curves of GNRFETs are given in Figure 2. It is found that high drain current for large dimer line value. In the proposed work, we have used only two dimer line GNRs n = 6 and 12, respectively. The relation of these dimer lines with the width and threshold values is given in Table II.

III. TERNARY LOGIC UNARY OPERATORS

The logic gate which consists of single input and output is called as unary operator. In conventional binary logic, there are four unary operators (i.e., 00, 11, 01, 10). Whereas, in ternary logic, there are 27 unary operators (i.e., 000, 001,……., 222). In this work, we have focused on 8 unary operators are X_p, X_n, X_1, X^1, X^2, $\overline{X^2}$, $1\cdot\overline{X_p}$ and $1\cdot\overline{X_n}$, respectively. The 1st and 2nd operators X_p and X_n represent positive (PTI) and negative (NTI) inverters, respectively. The 3rd operator X_1 is known as decisive lateral. The 4th and 5th operators are called as cycle operators, X^1 and X^2 are the single and dual shift operators. The 6th operator $\overline{X^2}$ is complement of X^2 and last unary operators are $1\cdot\overline{X_p}$ and $1\cdot\overline{X_n}$, respectively. The circuit diagrams of the 8 unary operators and truth tables are given in Figure 3 and Table III. Moreover, the operations of unary operators X^2, X_1 and X^1 are presented in Table IV. The proposed 8 unary operator are developed and simulated in HSPICE tool for verifying functionality. The obtained simulations results of operators given in Figure 4.

IV. PROPOSED ADDER AND MULTIPLIER DESIGNS

In this work, we proposed a ternary half adder with 36 GNRFETs and multiplier with 23 GNRFETs. The proposed adder and multiplier schematics are developed using above discussed unary functions, transmission gates and two voltage-supplies (V_{DD} and $V_{DD}/2$), respectively. The one-trit adder that adds two inputs and produces the two outputs (i.e., Sum and Carry) is presented. The truth table and expressions of Sum and Carry are provided in Table V and equ. (4).

$$Sum = X.Y_0 + X^1Y_1 + X^2Y_2$$
$$Carry = 0.Y_0 + \left(1.\overline{X_p}\right).Y_1 + \left(1.\overline{X_n}\right).Y_2 \quad (4)$$

Using the equation (4), the adder is developed and illustrated in Figure 5. The proposed half adder is developed and simulated in HSPICE to acquire the transient response and performances. The transient response is illustrated in Figure 6. Moreover, the delay, power and PDP are analyzed and obtained as 2.088E-07s, 4.253E-06W and 8.881E-13J, respectively. The one-trit multiplier that multiplies the two inputs and produces the two outputs (i.e., Product and Carry) is presented. The truth table and numerical equations of Product and Carry are given in Table V and equ. (5). Using the equation (5), the multiplier is developed and illustrated in Figure 7. The transient response of multiplier is illustrated in Fig. 8. Moreover, the delay, power and PDP are analyzed and obtained as 2.293E-07s, 3.738E-06W and 8.572E-13J, respectively.

The proposed designs performance is examined with CNTFET designs. For CNTFET circuits, CNT-diameters 1.48 and 0.78 nanometers are utilized. The SPICE model of CNTFET discussed in [24] [25] is utilized to develop CNTFET ternary designs. Fig. 9 provides performances comparability's of GNRFET and CNTFET based ternary designs. The proposed GNRFET based adder and multiplier circuits show high performance over the CNTFET circuits. In addition, PDP of proposed GNRFET schematics are examined with traditional GNRFET circuits presented in [16-18]. Fig. 10 shows the comparison of proposed circuits with the [16-18]. It is worth noting that the same load and switching patterns of proposed circuits is used for designs of [16-18]. The proposed designs shows degraded transistor count and PDP than the existing circuits.

The ternary circuits are highly sensible to PVT variations. Hence, PDP investigations are carried out for the different PVT variations for adder and multiplier circuits. For the process, the PDP circuits are analyzed by varying the oxide thickness. The obtained PDP results for different oxide thickness are given in Figure 11. The PDP of adder and multiplier circuits is also analyzed by varying the different power supplied and temperature values. The obtained PDP values for adder and multiplier circuits are shown in Figure 12 and Figure 13, respectively. It worth noting that the PVT variations of proposed circuits are than the existing circuit designs. The PDP of the proposed circuits is improved compared to the existing works.

V. CONCLUSIONS

A new design technique is proposed to develop ternary adder and multiplier schematics using unary operators. The proposed circuits are designed in the HSPICE simulator for functional verifications and performance investigations. Moreover, simulation results of proposed designs are compared to conventional CNTFET and GNRFET based designs. It is noted that the proposed designs improved the performances over the conventional designs. Moreover, the PVT variations on the performance of the proposed adder and multiplier designs are carried out and noted that the proposed circuits showed minimal variations. Because of the betterment in performance than existing designs, the proposed design technique plays an important role in future integrated circuits to achieve high performance.

Endpoint detection.

ABSTRACT

Poultry farming provides essential protein but faces challenges from diseases that affect bird welfare and farm economics. Traditional detection methods are slow and costly, underscoring the need for real-time, low-cost solutions enabled by precision livestock farming technologies. This paper presents a TinyML-based device for the automatic detection of poultry diseases by analyzing chicken vocalizations. The proposed system uses edge computing on a microcontroller to process audio data on-site, without requiring a constant internet connection or powerful hardware. Key steps include noise reduction with FIR filters, endpoint detection via a double-threshold short-time energy method, and feature extraction using Mel-Frequency Energy. A lightweight neural network with 1D-CNN and DNN layers classifies sounds as healthy, unhealthy, or noisy. We developed a prototype on the ESP32-S3 MCU, achieving 90.58% test accuracy and 0.98 F1-score for unhealthy detection. The device processes 3-second audio in 380 ms of preprocessing and 97 ms per inference window, using only 419 KB of flash and 258 KB of RAM. This low-cost solution enables scalable IoT integration for early disease intervention in poultry farms.

I. INTRODUCTION

Poultry farming plays a vital role in the agricultural sector by providing an affordable source of protein for a rapidly growing global population. However, as production intensifies to meet rising demand, the quality and health of poultry become critical concerns, not only for animal welfare but also for the economic viability of poultry operations [1] [2]. Traditional diagnostic methods, such as oocyte counting in stool or intestinal scrapings, microbial isolation, and PCR, are accurate but suffer from several drawbacks: they are labor intensive, time consuming, and often costly [3] [4]. These limitations underscore the need for rapid, efficient, and cost-effective techniques for early disease detection in large-scale poultry farms. Recent advancements have steered research towards automated detection systems that leverage artificial intelligence (AI), Internet of Things (IoT), and machine learning (ML) techniques. Early studies predominantly focused on imagebased disease detection using convolutional neural networks (CNNs) to analyze visual features such as feather condition, eye clarity, and beak anomalies [5]. Additionally, behavioral monitoring through video analysis has been explored to capture abnormal movements that may indicate distress or illness [6]. While these methods provide valuable insights, they generally require substantial computational resources and often operate offline, limiting their real-time applicability in resource-constrained environments [7]. An emerging line of research has begun to explore the use of acoustic signals as a non-invasive indicator of poultry health. Changes in chicken vocalizations, such as variations in frequency, amplitude, and temporal patterns, can serve as early markers of respiratory infections and other diseases [8] [9]. Signal processing techniques, including Mel-Frequency Cepstral Coefficients (MFCCs) extraction and spectrogram analysis, have been effectively combined with both traditional ML algorithms and deep learning models (e.g., recurrent neural networks and transformers) to classify the health status of birds [5-10]. Previous studies have demonstrated promising results, with reported accuracies ranging from 83% to above 95% under controlled experimental conditions. For example, research by Sadeghi et al. [11] showed that neural network-based analysis of chicken vocalizations could distinguish between healthy birds and those infected with specific pathogens with nearperfect accuracy. Similarly, Banakar et al. [12] employed time–frequency analysis techniques combined with support vector machines (SVM) to differentiate between multiple viral infections in chickens, achieving accuracies exceeding 90% in some cases.

The rapid expansion of IoT in agriculture has enabled the development of smart farming systems that continuously monitor environmental and physiological parameters. In poultry farms, IoT devices, ranging from temperature and humidity sensors to microphones, allow for real-time data collection and analysis. However, transmitting all raw data to centralized servers can be inefficient and may introduce delays in decision making. This is where TinyML, the deployment of machine learning models on low-power microcontroller units (MCUs), becomes a game changer. By processing data on-device, TinyML reduces latency, lowers energy consumption, and minimizes dependence on high-speed network connectivity. Recent works have demonstrated the feasibility of integrating TinyML with IoT platforms to analyze acoustic data for immediate detection of stress or disease symptoms in poultry, achieving real-time performance with minimal resource consumption [6-13]. Despite these advances, many existing approaches are limited to offline analysis or require high computational power that is impractical for deployment in typical farm environments. The overlapping of vocalizations in noisy farm settings further complicates the detection process, as background noise can obscure subtle changes in the acoustic signals of individual birds. These challenges highlight the urgent need for a system that can accurately perform realtime acoustic analysis on-site using lightweight and energyefficient models. In response to these challenges, our research makes the following key contributions:

- Developing a TinyML model capable of detecting poultry diseases through acoustic signal analysis. Our model is designed to operate with low resource consumption while delivering real-time performance.
- Implementation a prototype system that integrates this TinyML model on an MCU platform, enabling ondevice data processing and continuous monitoring of poultry health.

By integrating IoT and TinyML technologies, our approach offers a scalable and efficient solution to the limitations of traditional poultry disease detection methods. This system not only facilitates early intervention to mitigate disease spread but also enhances the overall sustainability and economic efficiency of poultry farming. The remainder of this paper is organized as follows. Section 2 details the materials and methods used in this study. In Section 3, the materials and methods employed in the study are presented. Finally, Sections 4 presents the results, discussion, and conclusions of our findings, respectively.

II. MATERIALS AND METHODS

II.1 DATASET

In this study, we utilized a dataset comprising 346 audio signal files compiled by S. Adebayo et al., which were categorized into three distinct folders: healthy, noisy, and unhealthy. The dataset was procured by dividing 100-dayold poultry into separate groups, with data collection conducted thrice daily using microphone devices. Unhealthy audio segments encompassed chicken coughs, snores, and rale sounds, whereas noise segments comprised background noise and sounds associated with poultry activities. Recordings were captured with a resolution of 24 bits at a sampling rate of 96 kHz and stored in the WAV format. Additionally, they compared the power spectra of healthy and unhealthy signals, revealing a notable spike of approximately 0.2 radians in the frequency content of anomalous sounds, in contrast to the distribution observed in normal sounds around the y-axis [5]. Our research focuses on leveraging machine learning, specifically TinyML, to automatically extract features and detect diseased chickens based on sound patterns. Our primary aim was to implement the entire computational process on a microcontroller (MCU) with resource constraints. To enhance computational efficiency prior to data processing, we lowered the sampling frequency to 16 kHz, decreased the resolution to 16 bits, and quantized the data range of -1.0 to 1.0 into the range of -32,768 to 32,767. These preprocessing steps are essential for enhancing the performance of our machine learning model during processing and training. This pre-processing step is facilitated through Python utilizing librosa [14] and soundfile [15] libraries, which provide robust support for audio processing tasks.

II.2 NOISE REDUCTION AND FRAMING

Numerous studies have consistently highlighted the prevalence of chicken vocalizations within the frequency range of 1.5 kHz to 5 kHz [4] [10-16]. Additionally, analysis of the dataset compiled by Adebayo et al. underscores that the primary frequency range of poultry sounds falls between 1 kHz and 5 kHz, as illustrated in Figure 1.

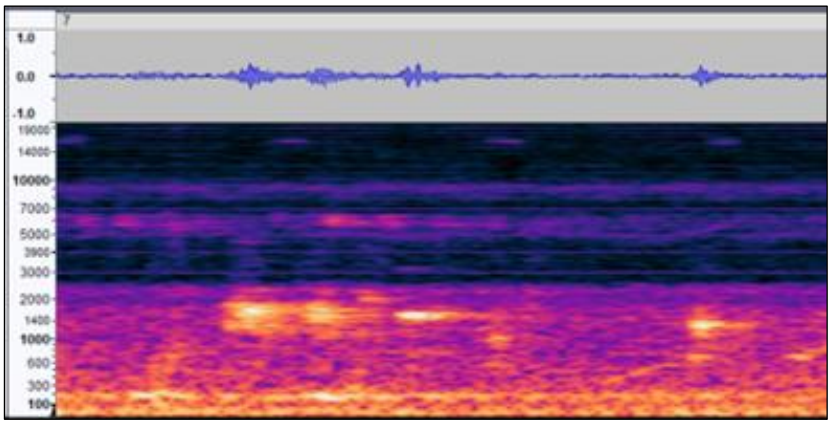

Figure 1: Spectrogram of chicken vocalization segment.
Source: Authors, (2026).

FIR filters are well known for their adaptability and precise delineation of signal characteristics within designated frequency spectra, making them particularly adept at discerning and examining poultry vocalizations within these frequency bounds. When employed in devices with restricted computational resources, such as MCUs, FIR filters have significant advantages. They ensure operational stability, manifest linear phase responses, facilitate precise frequency manipulation, and boast streamlined implementation, owing to the absence of feedback loops. These qualities underscore the suitability of FIR filters for signal processing endeavors in resource-constrained environments such as MCUs. In our study, FIR filters were leveraged for data pre-processing and subsequent implementation on the device platforms. The vocalization of chicks exhibits temporal variability, which makes direct analysis challenging. The direct analysis of audio requires significant computational resources. Nonetheless, within short durations of 10–30 ms, vocalizations tend to be relatively stable. In this study, the window function had a duration of 25 ms, corresponding to 400 sampling points. Additionally, the step length was set to half the window duration, equating to 200 sampling points (12.5 ms).

II.3 VOCALIZATION ENDPOINT DETECTION

The recorded audio contained not only chicken vocalizations but also background noise and frequent periods of silence. Achieving a more accurate analysis of chicken vocalization requires separating the chick vocalizations from the surrounding audio segments. To address these challenges, we employ a double-threshold method that incorporates two distinct features. The double-threshold technique employs both Short-Time Energy (STE) and Average Energy (AE) analyses to identify the location of the audio segments. The STE measures the energy content of sound within brief temporal windows and serves as a proxy for sound intensity. Higher STE values correlate with louder sounds, thereby facilitating the detection of sound variations, particularly in noisy environments. This enabled segmentation of the relevant audio segments for subsequent analysis. However, AE provides a measure of the overall energy level across the entire audio segment, offering a comprehensive perspective on its energy characteristics.

$$STE_k = \sum_{1}^{len} [y_k(i)]^2 \tag{1}$$

$$AE_j = \frac{\sum_{1}^{len} [y_k(i)]^2}{\Delta t} \tag{2}$$

Chick vocalizations typically have a brief duration ranging from 0.1 to 1.0 seconds [4] [16] [17]. Using this attribute, the threshold duration can be adjusted to encompass 8–80 frames for the detection of chick vocalizations. The process of identifying vocalization endpoints involves the following steps:

1) Compute the *STE* for each frame (with 400 sample points).
2) If the *STE* of a frame exceeds the threshold STE_{high}, the frame is designated as the start of a segment.
3) If the *STE* is below the threshold STE_{low}, the frame is marked as the end of the segment. Otherwise, the segment length was extended.
4) Once the endpoint of the segment is determined, if the segment duration falls within the range of D_1 to D_2, the segments are merged into one. Otherwise, the segment is discarded.
5) The *AE* of the entire segment is calculated. If the *AE* fell below the threshold AE_{thresh}, the segment was discarded. Otherwise, proceed to the featureextraction stage with this segment.

The STE thresholds (STE_{low} and STE_{high}) were calculated using the following formula:

$$STE_{thresh} = STE_{min} + \alpha \times \left(\overline{STE} - STE_{min}\right) \tag{3}$$

where $\overline{STE}$ represents the mean of *STE* value across all frames, STE_{min} denotes the minimum *STE* value among all frames, and the parameter is assigned values of 0.1 and 0.4 for STE_{low} and STE_{high}, respectively. The thresholds for segment duration D_1 and D_2 were set to 8 and 80 frames, respectively. The outcome of the endpoint detection process is illustrated in Figure 2, where the blue line represents the raw audio signal, the green line depicts the *STE* values of segments, and the red line indicates the trimmed audio segments identified by this process. Finally, AE_{thresh} was set to 3e-05 based on our experimentation with the current dataset.

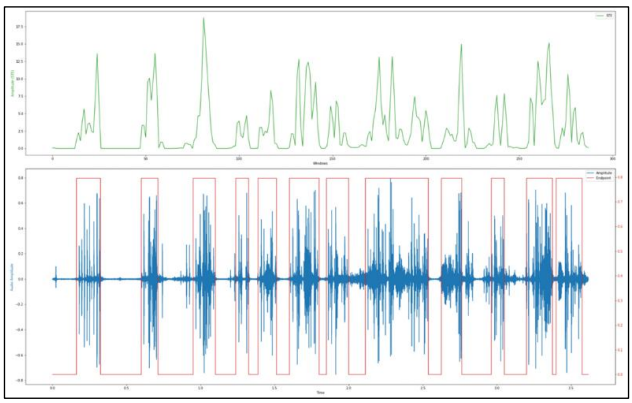

Figure 2: Vocalization endpoint detection using double threshold technique.
Source: Authors, (2026).

Upon completion of this step, the dataset comprises 8,130 audio segments, equating to approximately 41 min of audio data. Among these segments, 2,067 was categorized as belonging to the healthy group, 3,482 to the unhealthy group, and 2,581 to the noisy group. Each audio segment had a duration ranging from 100 ms to 1,000 ms.

II.4 AUDIO FEATURES

While MFCCs are widely utilized in conventional audio signal processing, log-mel spectrograms emerge as the predominant feature in deep learning, with raw waveforms or intricate spectrograms following closely. Raw waveforms sidestep manually crafted features, enabling enhanced utilization of the deep learning models' modeling process to acquire task-optimized representations [16] [18] [19]. In this study, we experimented with MFCCs and MFE for feature extraction. The results reveal that MFE exhibits slightly higher accuracy than MFCCs when running with our model design. Meanwhile, the resource usage for MFE is lower compared to using MFCC. Therefore, MFE was selected as the feature extraction step in our model. With audio windows set at 250ms, the MFE (MelFrequency Energy) block was configured with a frame length of 50ms, frame stride of 25ms, filter number of 40, FFT length of 512, and a bandpass filter (BPF) spanning from 1,000 to 5,000 Hz. The output data of the MFE block consisted of a 40 × 9 array for each audio window, as Figure 3. This array served as an input to the machine learning model, which will be discussed in the subsequent section.

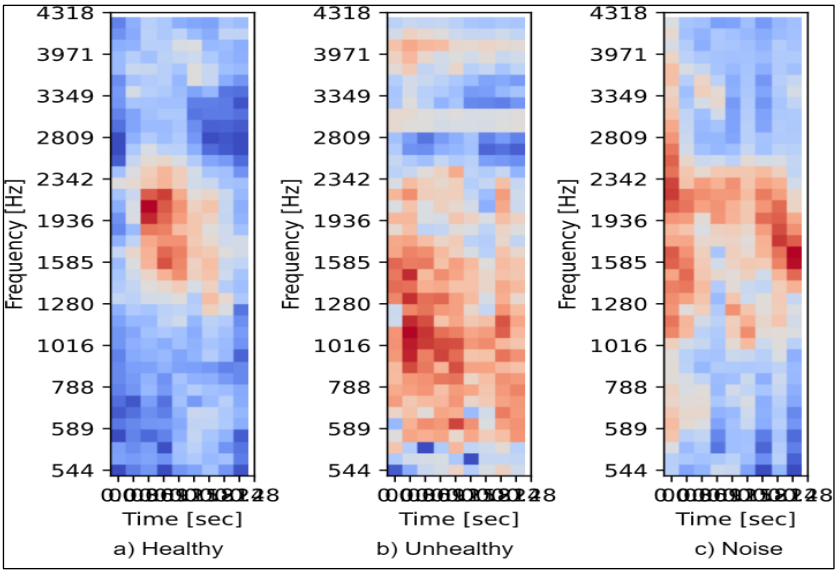

Figure 3: Output of MFE extraction for a) healthy, b) unhealthy, and c) noise audios.
Source: Authors, (2026).

II.5 TINYML MODEL DEVELOPMENT

We uploaded all segment audios and trained a model based on the Edge Impulse [20] platform to rapidly identify an appropriate model structure. After pre-processing, the dataset was split into three groups: training (60%), validation (20%), and testing (20%). Therefore, 4,878 samples were used for training, 1,626 samples for validation, and 1,626 samples for testing. Our machine learning model is initiated with two 1DCNN layers, consisting of 128 and 64 kernels. Following this, the data were flattened and passed through a twolayer DNN network with 128 neurons and 96 kernels in succession. Figure 4 shows the detailed architecture of the model network.

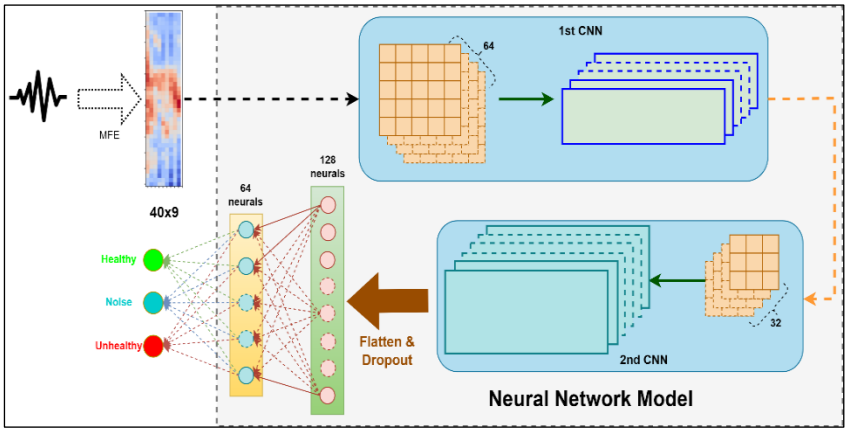

Figure 4: Neural network architecture.
Source: Authors, (2026).

III. DEVICE IMPLEMENTATION

All the steps outlined in Section II were executed using the high-level programming language Python, augmented by several efficiently supported libraries. With the aim of deploying a real-time edge device capable of audio data collection, processing, and inference, we initiated the development of a solution and embedded software program tailored for the device. The MCU selected for this study is the ESP32-S3, notable for its 384 KB ROM, 512 KB SRAM, and 4MB Flash memory capacities, along with its ability to operate at a maximum clock speed of 240 MHz. Furthermore, this MCU boasts instruction sets tailored to support TinyML and DSP algorithms, enhancing its suitability for our research purposes. A flowchart of the execution of the device is shown in Figure 5.

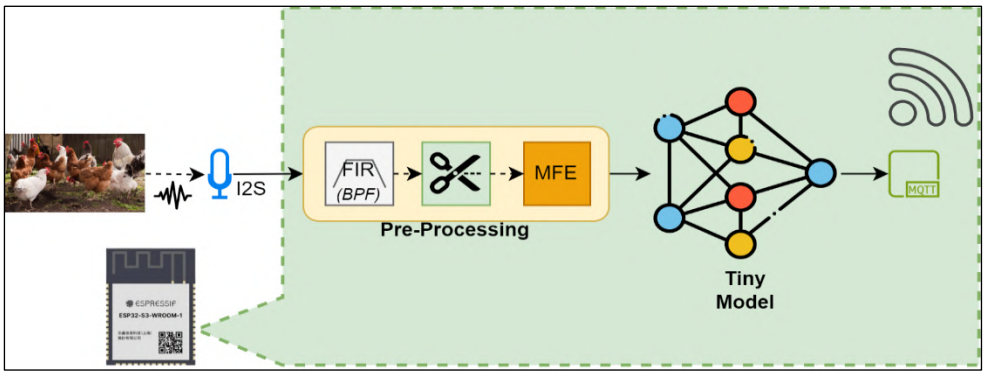

Figure 5: Implementation of device.
Source: Authors, (2026).

Figure 6 illustrates the detailed firmware architecture implemented on the device. The architecture is designed to support continuous, real-time audio acquisition and processing while maintaining low latency and efficient resource utilization. First, audio data are collected into four buffers of the MCU via Direct Memory Access (DMA) with a sample rate of 16,000 Hz and a resolution of 16 bits. Buffers can store a maximum of 3 s of audio samples. Periodically, the main program checks the audio buffers for new data. Upon the detection of new data, the data are passed through an FIR filter and subsequently saved to the ring buffer. The ring buffer consisted of three arrays: Audio Sample, STE Base, and STE window. The Audio Sample array contained signed integer (int16_t) data obtained from the FIR filter. The STE Base array computes the energy for every 200 samples, whereas the STE of the window array calculates the energy for each slice window comprising 400 samples. To optimize the computational efficiency of the MCU, we partitioned the Ring Buffer into eight equally sized segments, each capable of storing data for 0.5 seconds. For each segment, along with the three primary data arrays, we introduce two additional variables: STE_{min}, which captures the minimum STE value within the segment's audio window, and STE_{avg}, which represents the average STE value of the respective audio segments.

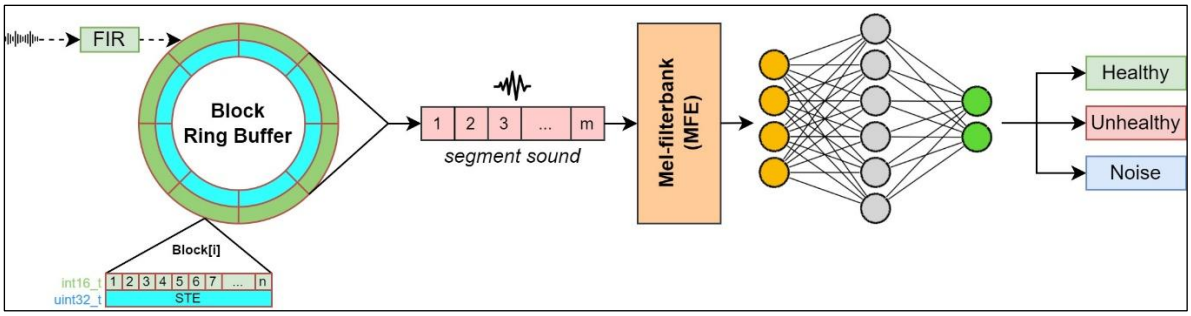

Figure 6: Firmware flow of edge device.
Source: Authors, (2026).

Instead of recalculating all the parameters with each new data point, our method efficiently computes only when the entire segment is updated. By leveraging the STE_{min} and STE_{avg} values from all segments, our program rapidly calculated STE_{low} and STE_{high}, resulting in faster computation and reduced computational overhead. These calculated thresholds facilitate the endpoint detection algorithm in identifying suitable audio segments. These segments were then split based on their length and processed through the MFE extraction step before being fed into the TinyML model. The segment sounds were split into smaller segments, each with a length of 250ms and slice window of 125ms. The number of segments to be calculated follows Equation 4, where N represents the number of segments, L denotes the length of the audio (ms), and w represents the length of the window slice, which is 125ms in this case. Each audio segment is passed through the MFE block, resulting in an output matrix with dimensions of 40 × 9. This matrix is then fed into the machine-learning model, which outputs the detection probabilities for the three labels. These probability values were averaged over N audio segments to determine the identified sound types (healthy, unhealthy, or noisy). To record audio from the testing environment, we opted for the INMP441 microphone, which is capable of transmitting audio via I2S with a resolution of 24-bit and maximum sampling frequency of 48kHz. In addition, we included a TFT screen to monitor and evaluate the functionality of the devices, displaying the quantity of healthy and unhealthy chicken vocalizations during testing. All the components were integrated into a fabricated box using a 3D printer with dimensions of 87x44x26mm, as depicted in Fig.

The implementation of the embedded software for the ESP32S3 MCU was performed in accordance with the established procedure, utilizing the C++ programming language with the aid of Visual Studio Code, Platform IO, and libraries provided by Edge Impulse. The firmware is uploaded to the device via UART to create a complete device and commence the testing process.

IV. RESULTS AND DISCUSSIONS

After extensive training, validation, and testing procedures, our model demonstrated impressive performance, achieving an accuracy of 92.8% during training and 90.58% during testing using a quantization (int8_t) model. Figure 7 presents the detailed confusion matrix for the test set. Although the overall accuracy may not be exceptionally high, our model displayed remarkable proficiency in identifying diseased chickens, achieving a remarkable F1-score of 0.98. Further analysis of the dataset sources revealed that audio files labeled as "Noise" frequently contained significant chicken sounds, which could potentially influence the differentiation between the "Healthy" and "Noise" labels.

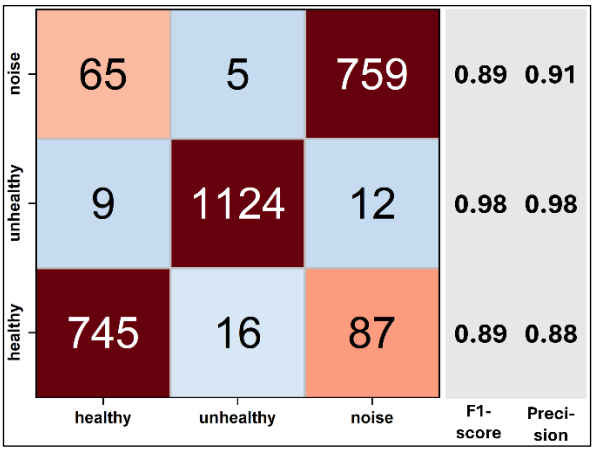

Figure 7: Confusion matrix for model evaluation on the test set with 8-bit quantization.
Source: Authors, (2026).

In addition, the model underwent quantization to optimize the size and inference time. According to the report from Edge Impulse, this model uses 248 KB of flash memory, 12.4KB of RAM, and requires 92ms for porting and inference on an ESP32-S3 MCU. This model, along with the pre-processing algorithm, is implemented on the edge device in the subsequent section. The program efficiently utilizes 419 KB of flash memory and 258 KB of RAM, which are well-suited for the resource constraints of the ESP32-S3 platform. After deploying the program on the ESP32-S3 board, we conducted real data tests to evaluate the duration of all steps. The specific times taken for each step are listed in Table 1 and Table 2. Table 1 provides the running time of the device utilized for the pre-processing of 3s raw data, which includes the FIR filter with an order number of 43, STE calculation for both 200 parameter windows and 400 parameter slice windows, and end-point detection algorithms. This value remained constant throughout the execution process. Meanwhile, table 2 illustrates the timing values for classifying the segmented audio extracted from the source data, including MFE calculation and inference via the machine learning model. The processing time for audio segments under 250 ms consistently remained at 97 ms, while longer segments, lasting between 750 and 1,000 ms, required approximately 356 ms across four consecutive recognition executions. These timing tests demonstrate that the integrated algorithms can be executed in real time on the ESP32-S3.

Table 1: Pre-processing time for 3s of raw data.

No.	Step	Time (ms)
1.	Band pass filter FIR	310
2.	STE calculating	45
3.	End-point detection	25

Furthermore, the prototype device has been successfully fabricated as shown in Figure 8. The device comprises an audio acquisition and processing module that is seamlessly connected to a display via UART. The display continuously shows the count of detected "Unhealthy" sounds, providing real-time feedback and facilitating prompt intervention. This integrated system highlights the practical viability of our solution for on-device poultry health monitoring under realworld conditions.

Figure 8: Prototype implementation device.
Source: Authors, (2026).

While previous studies [4-9] [16-21] have focused on recognizing and analyzing the health status of chickens through sound using local processing on computers, the results of this study demonstrate that the device can meet the requirements for detecting diseased chickens based on sound in real-time conditions and can be applied in practical scenarios with inexpensive processors with the support of the DSP algorithm and TinyML solution. Moving forward, we plan to conduct additional experiments and apply these datasets to real-world scenarios to further evaluate their detection accuracy. By integrating this research with advancements in IoT, we can create a comprehensive solution that empowers farmers to monitor and predict chicken diseases in real time, thereby enhancing animal health care and the quality of agricultural products.

V. CONCLUSIONS

In this study, an edge-computing solution is proposed to detect unhealthy chickens based on their vocalizations. This solution was developed using the DSP algorithm and TinyML, which can be implemented on a device with limited resources, such as a MCU. The endpoint detection method utilizes short-time energy, MFE extraction, and machine-learning model inference, and it was tested on a model system that uses augmented data on Edge Impulse for both the training and testing phases. The results of testing on ESP32-S3 showed that with 419 KB of flash memory and 258 KB of RAM, the device could detect unhealthy conditions in real time using TinyML, achieving 92.8% accuracy in the training phase and 90.58% accuracy in the testing phase for classifying healthy, unhealthy, and noisy sounds. The system also demonstrated a high level of accuracy in detecting diseased chickens, with an F1-score of 0.98. This research can be further explored to create more sophisticated automated poultry health-monitoring systems that can be applied in real-world conditions.

ABSTRACT

File fragment classification is fundamental to digital forensics and network security, enabling the recovery and identification of files when metadata is corrupted or absent. While state-of-the-art deep learning models on the FFT-75 benchmark achieve 65–79% accuracy on clean fragments, they exhibit vulnerability to byte-level adversarial perturbations, and evaluation across 39 byte-level attack variants shows that the baseline accuracy drops from 71.1% on clean fragments to an average of 15.8% under adversarial perturbations. This paper presents a novel two-stage detection-based defense framework tailored for file fragment classification that mitigates the accuracy-robustness trade-off commonly associated with adversarial training. The framework integrates three components: (1) an attention-based adversarial detector achieving 95.46% specificity and 91.34% recall (91.44% overall accuracy); (2) an existing baseline file fragment classifier preserving 71.1% accuracy on clean fragments; and (3) a novel Dual-Scale Attention-based Robust CNN (DSAR-CNN) specifically designed for adversarial fragment classification, achieving 68.4% accuracy on adversarially perturbed samples (evaluated on the test set of 4.6M fragments) through multi-scale depth wise separable convolution, CBAM-style dual attention, learnable position embeddings, and split global pooling. Developed and evaluated across 75 file types and 39 attack variants from the FFT-75 benchmark, the complete pipeline achieves 70.91% accuracy on clean data (0.19 percentage point penalty) and 63.84% on adversarial data, yielding 70.20% accuracy in realistic mixed-threat scenarios (90% clean, 10% adversarial) - outperforming both the undefended baseline and the standard adversarial training benchmark. The framework provides an approach for improving the robustness of forensic classification systems against byte-level adversarial attacks such as padding and bit-flipping.

I. INTRODUCTION

File fragment classification (FFC) is a primary task in digital forensics and cybersecurity that allows for the recovery and reconstruction of fragmented files when their metadata is missing or corrupted. In different application scenarios, such as cybercrime investigation, data breach, and anti-forensic operation, the accurate classification of file fragments plays an important role in evidence recovery and attribution [1]. Conventional file carving and FFC methods have evolved from rule-based heuristics to state-of-the-art machine learning and deep learning models, with recent state-of-the-art systems that achieve classification accuracies in the range of 65–79% on benchmark datasets such as FFT-75, depending on fragment size [2]. These advances have been achieved due to the adoption of CNNs, and ensemble learning, which outperformed the previous handcrafted feature-based methods by a large margin. The growing reliance on FFC in security-critical environments underlines the relevance of this task.

Indeed, accurate fragment classification not only accelerates forensic investigations but also in-creases the reliability of evidence recovery when dealing with sophisticated anti-forensic techniques and large-scale data fragmentation [3]. Despite these advances, the deployment of machine learning in FFC inherits vulnerabilities of such models to adversarial manipulation - a phenomenon well-documented in other security domains like malware detection and image classification [4] [5]. Adversarial attacks, especially those operating at the byte level, can make subtle modifications to file fragments that aim to evade detection or mislead classifiers, therefore posing a direct threat to the integrity of digital forensic processes [6]. For this reason, the development of robust and attack-resilient classification systems is growing increasingly important for both researchers and practitioners in digital forensics and cybersecurity. While FFC systems have achieved remarkable accuracy under clean conditions, they are inherently vulnerable to adversarial attacks. Empirical evaluation shows that state-of-the-art FFC models, which operate at an accuracy of 71.1% on clean data, result in catastrophic performance degradation when subjected to adversarial byte-level perturbations; the accuracy plummets as low as 15.8%, which reflects a 55.3 pp drop in the classification performance of the model [7]. These attacks exploit the discrete and high-dimensional nature of file fragments, making minimal, and often imperceptible, changes adequate for evasion or misclassification [8]. The threat is not merely theoretical: adversarial attacks have been shown to be effective in both white-box and black-box settings. In other words, the lack of adversarial defenses in current FFC systems creates a serious security loophole. This contrasts with other areas, such as malware detection and image classification, where adversarial robustness has become a central focus of research.

FFC has been slow to adopt the defense mechanisms developed and fine-tuned against the peculiarities of this specific domain [2]. Given the operational setting of FFC, where forensic investigations, court cases, and incident response rest on the accuracy of fragment classification, this is particularly concerning. A single adversarial attack can compromise the reliability of digital evidence, hamper investigations, and erode confidence in forensic results. The need for robust adversarially resilient systems is therefore both a technical and a practical imperative with significant urgency. The most prominent defense strategy against adversarial attacks in machine learning has been adversarial training, wherein models are exposed to adversarial examples during training to make them more robust [5-9]. While adversarial training can indeed enhance resistance to certain attack types, it is not without its significant drawbacks. Foremost of these is the accuracy-robustness trade-off: the enhancement in robustness to adversarial samples comes at the cost of degraded accuracy on clean data [10]. In the context of FFC, adversarial training incurs a clean accuracy penalty - a nontrivial reduction in performance, particularly in high-stakes forensic applications, in which every percent of accuracy may impact case outcomes [9]. Furthermore, adversarial training is often attack-specific, usually providing robustness only against the types of adversarial examples seen during training, and may fail to generalize to novel or adaptive attack strategies. The generation and incorporation of large volumes of adversarial samples further increase the computational overhead, limiting the scalability and practicality of this approach, especially in byte-level FFC tasks with very large datasets [10]. Other defense mechanisms explored within related domains, including ensemble learning, feature squeezing, and input transformation, have failed to demonstrate consistent or scalable success in FFC [11]. The persistent accuracy-robustness trade-off, in addition with the task's operational demands, calls for novel defense frameworks that can achieve high robustness without sacrificing clean accuracy or incurring prohibitive computational costs. This paper addresses an important gap in the study of adversarial robustness for file fragment classification. While adversarial attacks and defenses have been extensively studied in domains such as computer vision and malware detection, their implications for FFC remain largely unexplored. This work therefore presents a systematic investigation of adversarial vulnerabilities and defense mechanisms for byte-level fragment classification. The key contributions of this paper are:

1. **Detection-Based Adversarial Defense for FFC**: This work presents a two-stage detection–classification pipeline for file fragment classification in which an anomaly detection model first identifies potentially adversarial fragments before classification. By routing detected adversarial samples to a specialized robust classifier while allowing clean fragments to be processed by the baseline model, the framework enables improved robustness in mixed clean–adversarial environments without degrading baseline performance on genuine fragments.
2. **Dual-Scale Attention-based Robust CNN (DSAR-CNN)**: A novel deep learning architecture is proposed combining multi-scale depthwise separable convolution, CBAM-style dual attention mechanisms, learnable position embeddings, and split global pooling.
3. **Minimal Clean Accuracy Penalty**: The detection-classification pipeline achieves 70.20% mixed-scenario accuracy (90% clean, 10% adversarial) with only a 0.19 pp penalty in clean accuracy compared to the baseline 71.1%.

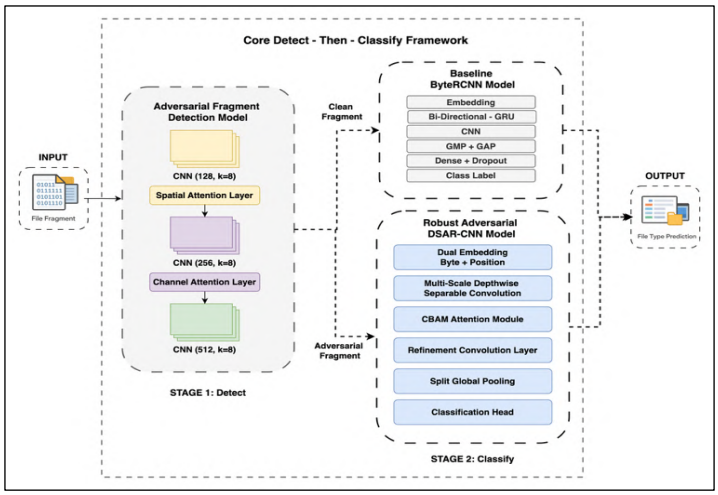

Figure 1: Two-stage detect-then-classify pipeline for adversarially robust file fragment classification.
Source: Authors, (2026).

Figure 1 illustrates the high-level architecture of the proposed two-stage defense pipeline. Each input file fragment first passes through the adversarial detection model, which performs binary classification to determine whether the fragment is clean or adversarially perturbed. Fragments identified as clean are routed to the standard file fragment classifier (ByteRCNN), preserving baseline accuracy on genuine evidence. Fragments flagged as adversarial are directed to the robust classifier (DSAR-CNN), which is specifically designed to extract discriminative features from corrupted byte sequences. This routing mechanism enables the framework to maintain high accuracy on clean data while substantially improving robustness against adversarial attacks. Together, these contributions show that anomaly detection and intelligent sample routing can achieve robustness without sacrificing either clean accuracy or operational efficiency. A comprehensive empirical comparison against a standard adversarial training baseline is provided in Section 7.2, where adversarial training is done on a balanced mix of clean and perturbed fragments across all 39 attack variants. The results confirm that the proposed pipeline outperforms adversarial training in both clean and mixed-threat scenarios. The remainder of this paper is organized as follows. Section 2 reviews existing work on file fragment classification and adversarial attacks in cybersecurity. Section 3 describes the types of attacks used in this research, including padding attacks and bit-flip attacks on file fragments. Section 4 demonstrates how these attacks reduce the baseline classifier accuracy from 71.1% to 15.8%, showing why defense is necessary. Section 5 introduces the adversarial fragment detection model. Section 6 presents the robust file fragment classifier DSAR-CNN and its architecture. Section 7 presents experimental results, showing how the defense framework improves robustness. Section 8 discusses the practical implications and limitations of the work. Section 9 concludes with a summary of key contributions to digital forensics and adversarial machine learning.

II. RELATED WORK

File fragment classification has progressed from statistical methods to sophisticated deep learning architectures. Early work by McDaniel and Heydari demonstrated that byte frequency distributions could effectively distinguish file types without relying on metadata [12]. The field advanced substantially with the introduction of the FFT-75 benchmark and the FiFTy model by Mittal et al., which achieved 77.5% average accuracy on 4096-byte fragments across 75 file types using trainable byte embeddings [13]. Subsequent research has pursued efficiency improvements: Ghaleb et al. developed lightweight CNNs with depthwise separable convolutions reaching 79% accuracy with only 100K parameters for 4096-byte fragments, while Skračić et al. proposed ByteRCNN, a hybrid recurrent-convolutional approach achieving 71.1% on the same benchmark [7-14]. Wang et al. introduced JSANet, a joint self-attention network that captures intra-sector byte-wise features and inter-sector contextual relationships, demonstrating that attention mechanisms can significantly improve fragment classification accuracy across multiple benchmarks [15]. Penrose et al. addressed the challenging problem of classifying high-entropy file fragments-including compressed and encrypted data-by proposing features based on randomness measures and discrete Fourier transform coefficients, achieving classification rates exceeding 90% for encrypted fragments [16]. More recently, Google's Magika system demonstrated that AI-powered file-type identification using optimized deep learning models can outperform traditional signature-based tools by approximately 20%, achieving precise identification within milliseconds even on CPU [17]. However, existing file fragment classifiers generally assume clean, unperturbed inputs with no mechanisms to detect or defend against adversarial manipulation, leaving forensic systems fundamentally vulnerable to byte-level attacks.

Adversarial attacks have been extensively studied in computer vision since Good-fellow et al. introduced FGSM, but their application to byte-level classification remains relatively underexplored [18]. In the malware detection domain, Kolosnjaji et al. demonstrated that gradient-based attacks against CNN architectures trained on raw executable bytes achieve high evasion rates by modifying less than 1% of bytes [19]. Demetrio et al. showed that functionality-preserving perturbations injecting benign content into executable sections severely degrade neural network detector performance [6]. Lucas et al. revealed that attack success rates can reach 90% against raw-binary classifiers without proper defenses [20]. Even more subtle bit-level manipulations can severely degrade neural network performance. For example, Kreuk et al. demonstrated that injecting a small sequence of adversarial bytes into binary executables is sufficient to cause end-to-end convolutional malware detectors to misclassify malicious samples as benign, with the adversarial payload remaining transferable across different file positions and file families [21]. Beyond input-level attacks, adversarial bit manipulations have also been studied at the model parameter level. Kummer et al. extended bit flip attacks to graph neural networks, proposing the Injectivity Bit Flip Attack that exploits architectural properties specific to message passing networks, demonstrating that targeting learnable neighborhood aggregation functions can degrade model expressivity with minimal bit modifications [22]. In the Android malware domain, Taheri et al. investigated deep learning classifier vulnerabilities against differential privacy-based adversarial attacks, demonstrating that attackers can exploit noise injection techniques to reduce classification accuracy by up to 50% [23].

These findings suggest that bit-level perturbations can significantly affect neural network predictions, a hypothesis confirmed by empirical evaluation showing accuracy degradation from 71.1% to 15.8% under padding and bit-flip attack variants. Defenses against adversarial attacks generally employ either adversarial training or detection-based methods. Zhang et al. formally characterized the accuracy-robustness tradeoff, showing that adversarial training often causes some reduction in clean accuracy without guaranteeing robustness against novel attacks [24]. Tsipras et al. further demonstrated that robustness may fundamentally conflict with standard accuracy objectives [25]. Detection-based approaches offer an alternative: Meng and Chen proposed MagNet, which identifies adversarial inputs before classification using autoencoder reconstruction, thereby avoiding accuracy penalties on clean data [26]. Goodge et al. studied autoencoder vulnerabilities in anomaly detection settings and proposed the Approximate Projection Autoencoder (APAE), demonstrating that incorporating approximate projection with feature weighting can improve robustness against adversarial attacks while maintaining detection performance on clean data [27]. Xie et al. introduced feature denoising networks that incorporate non-local means and other filtering operations within convolutional architectures, achieving state-of-the-art adversarial robustness by suppressing feature-level perturbations when combined with adversarial training [28]. Existing detection frameworks, however, are domain-specific: image-based detectors exploit spatial coherence, malware detectors leverage executable-specific structural features such as PE headers and API call sequences. File fragments span 75 heterogeneous types with format-agnostic byte patterns lacking consistent structural properties, creating a fundamental mismatch with existing defenses and necessitating a detection approach specifically tailored to byte-level file fragment analysis.

Attention mechanisms have proven effective for improving neural network robustness by dynamically focusing on discriminative features while suppressing noisy signals. Hu et al. introduced Squeeze-and-Excitation networks, which adaptively recalibrate channel-wise feature importance through learned weights [29]. Woo et al. extended this with CBAM, combining channel attention with spatial attention to identify both what features and where in the input to focus [30]. Agrawal et al. conducted a comparative study on the impact of attention mechanisms on adversarial robustness, demonstrating that CBAM-enhanced ResNet models exhibit improved resilience against PGD attacks on complex datasets like CIFAR-100, suggesting that learned salient features provide inherent defensive properties [31]. Zoran et al. proposed sequential top-down attention models for image classification that achieve state-of-the-art adversarial robustness by processing inputs through multiple attention steps, revealing that increasing the number of attention glances creates a computational race between attacker and defender while producing adversarial examples with global, perceptible structures [32]. In malware detection, Al-Ghanem et al. achieved 99.5% accuracy with MADANET by learning to emphasize discriminative byte patterns, while Yakura and Sakuma used attention to extract important byte sequences characterizing malware functionality [33] [34]. Despite these successes, attention mechanisms remain underexplored for addressing adversarial robustness in file fragment classification. The application of dual attention mechanisms - combining channel and spatial attention in a hierarchical structure enables synergistic improvements where the combined effect exceeds the sum of individual contributions, providing a promising direction for robust fragment classification under adversarial conditions.

III. THREAT MODEL AND ATTACK TAXONOMY

The threat model and attack taxonomy presented here are built upon the comprehensive adversarial evaluation framework established in prior work, extended here to evaluate defense mechanisms. The threat model assumes a non-adaptive adversary who has no query access to the classifier architecture or training data. The attacks are pre-specified input-constrained transformations rather than optimized per-sample adversarial examples. The attacker will aim to induce misclassification through byte-level perturbations while maintaining the fragment size exactly at 512 bytes. This restriction follows realistic forensic scenarios in which fragments are recovered from storage media stripped of metadata and context. The attacks considered are format-agnostic, based on general byte-level manipulations rather than exploiting file-type-specific structural properties. Two primary attack categories represent realistic adversarial perturbations: padding attacks and bit-flip attacks. Padding attacks overwrite bytes near the fragment tail using three mechanisms: null-byte padding (adding low-entropy zeros), random-byte padding (adding random bytes), and cross-file padding (adding authentic bytes from different file types). For each cross-file padded fragment, the source file type is selected uniformly at random from the remaining 74 file types, and the replacement bytes are drawn from a randomly sampled fragment of that type. This ensures diverse cross-type contamination patterns and prevents the detector from memorizing specific source-target type associations. The fragment length remains fixed at 512 bytes throughout all attacks. Each padding type is tested at five sizes-16, 32, 64, 128, and 256 bytes-producing 15 attack variants. Bit-flip attacks corrupt individual bytes in two ways: random bit-flipping modifies bytes distributed throughout the fragment, while header-targeted bit-flipping concentrates modifications in the first 64–128 bytes where file signatures reside. These header-targeted attacks remain format-agnostic in that they do not parse format-specific structures (e.g., PDF dictionaries or JPEG markers) but rather exploit the generic concentration of discriminative magic bytes in early file positions. With four corruption rates and three bit-flip intensities, bit-flip attacks yield 24 variants, resulting in a total attack taxonomy of 39 distinct strategies. These details are summarized in Table 1:

Table 1: Byte-Level Adversarial Attack Taxonomy for FFT-75 File Fragment Classification.

Attack family	Attack type	Variants (count)	Parameter grid	Intended forensic realism
Padding	Null-byte padding	5	Padding sizes P ∈ {16, 32, 64, 128, 256} bytes	Models zero-filled buffers, incomplete reads, and partially overwritten sectors that naturally occur on disks.
Padding	Random-byte padding	5	Padding sizes P ∈ {16, 32, 64, 128, 256} bytes	Simulates noise injection, disk corruption, and transmission errors producing high-entropy tails in fragments.
Padding	Cross-file padding	5	Padding sizes P ∈ {16, 32, 64, 128, 256} bytes	Appends authentic bytes from other file types to induce file-type confusion and hybrid statistical profiles.
Bit-flip	Random bit-flip	12	k ∈ {1, 5, 10, 20}% of bytes; n ∈ {1, 2, 4} bits per selected byte	Emulates random memory faults, media degradation, and low-level corruption without obvious structural artifacts.
Bit-flip	Header-targeted bit-flip	12	Same (k, n) grid as random bit-flip, restricted to header region (first 64–128 bytes)	Targets magic numbers and header metadata, reflecting adversaries corrupting type-identifying bytes while preserving length.

Source: Authors, (2026).

Unlike adversarial attacks studied in computer vision, which often aim to produce imperceptible perturbations, the objective in file fragment classification is different. In digital forensics, fragments frequently originate from partially overwritten sectors, damaged storage media, or intentionally manipulated files where substantial portions of the fragment may be corrupted.

Consequently, the attack taxonomy includes perturbations ranging from small bit flips to large-scale byte overwrites (e.g., 256-byte padding) to model both subtle corruption and severe anti-forensic manipulation scenarios. These perturbations therefore represent a spectrum of realistic byte-level corruption conditions rather than purely imperceptible adversarial examples. The goal is therefore not only to evaluate robustness against subtle adversarial manipulations, but also to assess the resilience of fragment classifiers under severe corruption conditions that may arise in real-world forensic investigations. Scope of Evaluation. The defense framework is trained and evaluated exclusively against the 39 non-adaptive attack variants defined in this taxonomy. Since both the detector and robust classifier observe all attack types during training, the evaluation measures in-distribution robustness rather than generalization to novel attack strategies. An adaptive adversary with full pipeline knowledge could potentially craft composite perturbations (e.g., simultaneous padding and bit-flipping) or target the detector's learned attention patterns directly - scenarios not evaluated here. Hence, adaptive threat evaluation is identified as a priority for future work (Section VIII.2). The evaluation uses the FFT-75 test partition as the clean fragment source, comprising 768,000 fragments distributed evenly across 75 file types at 512 bytes each (see Section IV.2 for the complete dataset partitioning strategy). Applying all 39 attack variants to each clean fragment generates 29.952 million adversarial samples, for a total dataset of 30.72 million fragments. This dataset is split into training (70%, 21,504,000 fragments), validation (15%, 4,608,000 fragments), and testing (15%, 4,608,000 fragments), with each split independently allocating 70%, 15%, and 15% of both clean and adversarial samples respectively. The training set comprises 20,966,400 adversarial samples and 537,600 clean samples, resulting in a 39:1 adversarial-to-clean class imbalance.

IV. BASELINE BYTERCNN AND UNDEFENDED VULNERABILITY ANALYSIS

The purpose of this section is to establish a quantitative baseline of adversarial vulnerability in file fragment classification systems. This baseline serves two key goals: first, it measures the security gap in current state-of-the-art FFC models; and second, it validates that the 39-variant attack taxonomy is feasible and effective in practice.

IV.1 BASELINE MODEL SELECTION AND JUSTIFICATION

Selecting the right baseline model is essential for a fair assessment. Three candidate models were evaluated based on these criteria: accuracy on FFT-75 for 512-byte fragments, availability of public code, and practical usability. Current file fragment classification models typically achieve between 65% and 79% accuracy on FFT-75, depending on the fragment size and model type. FiFTy achieves an average of 77.5% across 4096 fragment size, but for 512-byte fragments specifically, FiFTy only reaches 65.6% [13]. ByteRCNN, published in 2023, achieves 71.1% on 512-byte fragments, which is notably higher [7]. JSANet, a transformer-based model with joint self-attention mechanisms, reported performance on the FFT-75 benchmark but does not provide a specific 512-byte accuracy figure in publicly available documentation [15]. Since ByteRCNN offers public code and achieves one of the highest documented 512-byte accuracy (71.1%), it was selected as the baseline model. It represents current state-of-the-art and was published by Skračić et al. in IEEE Access 2023. ByteRCNN is a hybrid recurrent-convolutional model designed for file-fragment type identification. It incorporates a byte-embedding layer that transforms raw byte values into trainable dense representations, followed by recurrent and convolutional components that capture sequential and local patterns within byte sequences. The model is evaluated on the FFT-75 dataset, specifically Scenario 1, which contains 75 file types. Experiments include both 512-byte and 4096-byte fragments, where ByteRCNN achieves 71.1% accuracy on 512-byte samples and 83.9% accuracy on 4096-byte samples.

IV.2 TEST DATA AND EXPERIMENTAL SETUP

The FFT-75 Scenario 1 dataset comprises 7,680,000 fragments (102,400 fragments per file type across 75 file types at 512 bytes each), partitioned by the dataset creators into 80% training (6,144,000 fragments), 10% validation (768,000 fragments), and 10% test (768,000 fragments). The ByteRCNN baseline model was trained on the official FFT-75 training partition (6,144,000 fragments), consistent with the original evaluation protocol. To construct the adversarial evaluation benchmark, the 768,000-fragment test partition (10,240 fragments per file type) was used as the clean fragment source. Applying all 39 attack variants to each clean fragment generates 768,000 × 39 = 29,952,000 adversarial samples, for a total of 30,720,000 fragments (clean + adversarial). This combined dataset was then split into training (70%, 21,504,000 fragments), validation (15%, 4,608,000 fragments), and testing (15%, 4,608,000 fragments) using stratified sampling to preserve the clean-adversarial ratio in each split. The training partition is used exclusively for training the adversarial detection model and the DSAR-CNN robust classifier; it is not used for ByteRCNN training. Importantly, the training, validation, and test partitions are constructed using stratified sampling with strictly disjoint fragment sets - no individual fragment or its adversarial variants appear in more than one partition. This ensures that the defense models are evaluated exclusively on fragments unseen during their training, preventing data leakage. The FFT-75 test partition (768,000 fragments) was selected as the adversarial generation source rather than the larger training partition (6,144,000 fragments) to maintain computational tractability; generating all 39 attack variants from the full training set would yield over 245 million samples. Since both partitions are drawn from the same underlying file corpus with identical per-type distributions, this choice does not introduce distributional bias.
The test dataset consists of these parts:

- **Clean test fragments:** 115,200 fragments (15% of the FFT-75 test partition), distributed equally across 75 file types (1,536 fragments per type).
- **Adversarial test fragments**: Generated by applying each of the 39 attack variants to the same 115,200 clean fragments. This produces 115,200 × 39 = 4,492,800 adversarial samples. Each attack is applied independently; no combined or cumulative attacks are tested.
- **Total test dataset**: 4,608,000 fragments (115,200 clean + 4,492,800 adversarial).

This structure ensures that all attacks are tested on identical baseline data, making it easy to compare how different attack types affect the classifier.

For padding attacks: each 512-byte fragment has its last N bytes (where N ∈ {16, 32, 64, 128, 256}) removed and replaced with corrupted bytes using one of three methods: null bytes (0x00), random bytes (0x00–0xFF), or authentic bytes from a different file type. The result is always 512 bytes long, with the first (512 − N) bytes intact and the last N bytes corrupted. For bit-flip attacks: either a random selection of k% of bytes (k ∈ {1, 5, 10, 20}) or just the header region (first 64–128 bytes) is chosen, then n random bits per selected byte (n ∈ {1, 2, 4}) are flipped. This generates 12 random variants and 12 header-targeted variants. Multiple metrics measure vulnerability from different angles:

1. **Absolute accuracy** is the fraction of correctly classified fragments, as given in the formula:

$$\text{Acc} = \frac{\text{Correct predictions}}{\text{Total samples}} \tag{1}$$

2. **Accuracy drop** (percentage points) shows raw performance loss, as given in the formula:

$$\Delta_{\text{acc}} = \text{Acc}_{\text{clean}} - \text{Acc}_{\text{adv}} \tag{2}$$

3. **Relative vulnerability** shows the percentage of capability lost, as given in the formula:

$$V_{\text{rel}} = \frac{\text{Acc}_{\text{clean}} - \text{Acc}_{\text{adv}}}{\text{Acc}_{\text{clean}}} \times 100\% \tag{3}$$

Comparison to uniform class probability: For 75 file types, accuracy of randomly choosing the correct file type is 1/75 ≈ 1.33%.

IV.3 CLEAN BASELINE PERFORMANCE

Before evaluating adversarial robustness, the clean performance of the baseline model was verified. The ByteRCNN model was trained from scratch on the FFT-75 training partition (6,144,000 fragments) using the publicly available architecture and training configuration, as pre-trained weights are not provided by the original authors. When evaluated on 115,200 clean test fragments (held out from the FFT-75 test partition, disjoint from all training data), the model correctly classified 81,907 fragments, resulting in a clean accuracy of 71.096% (≈71.1%). This result is consistent with the performance reported in the original ByteRCNN study for 512-byte fragments, confirming that the re-implementation reproduces the expected baseline behavior.

IV.4 ADVERSARIAL VULNERABILITY RESULTS

ByteRCNN's clean accuracy on 512 size fragments is 71.1% [7]. From the empirical evaluation, it was found that across all 39 attacks, ByteRCNN's average adversarial accuracy comes to $\text{Acc}_{\text{adv}} = 15.8\%$. This represents an absolute drop of:

$$\Delta_{\text{acc}} = 71.1\% - 15.8\% = 55.3 \text{ percentage points} \tag{4}$$

In relative terms, the model retains only 22.2% of its clean performance, corresponding to a relative vulnerability of:

$$V_{\text{rel}} = \frac{55.3}{71.1} \times 100\% = 77.8\% \tag{5}$$

For a 75-class classification problem, the probability of correct classification under uniform class selection is 1.33% (1/75). On clean data, ByteRCNN achieves an accuracy of 71.1%, which corresponds to a performance level 53.5 times higher than the uniform classification probability (71.1% ÷ 1.33%). Under adversarial conditions, the accuracy decreases to 15.8%, representing only 11.9 times the uniform probability level (15.8% ÷ 1.33%). This comparison indicates that adversarial perturbations substantially reduce the model's effective discriminative capability, bringing its performance significantly closer to the uniform baseline. A summary of the accuracy degradation for the different attack types is given in Table 2:

Table 2: Accuracy Degradation on Baseline ByteRCNN Model for Different Attack Types.

Attack Type	Count	Lowest Acc (%)	Highest Acc (%)	Average Acc (%)	Average Drop (pp)	Relative Vulnerability (%)
Null-byte padding	5	4.1	22.4	12.3	58.8	82.7
Random-byte padding	5	3.7	21.5	11.5	59.6	83.8
Cross-file padding	5	2.7	19.2	9.8	61.3	86.2
Random bit-flip	12	6.4	38.8	20.2	50.9	71.6
Header bit-flip	12	5	34.7	17.1	54	75.9
Overall	39	2.7	38.8	15.8	55.3	77.8

Source: Authors, (2026).

Padding attacks (11.2% average) are significantly more damaging than bit-flip attacks (18.7% average). The 7.5 pp difference occurs because padding overwrite or replace existing bytes from the fragment, destroying information entirely. Bit-flip attacks only change specific byte values while keeping the file structure mostly intact. Cross-file padding is the hardest attack (9.8% average). Unlike null-byte or random-byte padding which introduces obvious anomalies, cross-file padding adds real byte sequences from other file types. This actively confuses the classifier by introducing correct looking but contextually wrong file signatures. A consistent pattern emerges across all attack types: performance degradation scales with perturbation magnitude. Table 3 ranks the attack severity (top 5) from the most to the least damaging for the model based on model accuracy.

Table 3: Attack Severity Ranking: Most to Least Damaging Variants by Residual Accuracy.

Rank	Attack Type	Parameters	Residual Accuracy (%)	Accuracy Drop (pp)
1	Cross-file padding	256 B	2.7	68.4
2	Random-byte padding	256 B	3.7	67.4
3	Null-byte padding	256 B	4.1	67
4	Cross-file padding	128 B	5	66.1
5	Header bit-flip	k=20%, n=4	5	66.1
-	-	-	-	-
35	Random bit-flip	k=5%, n=1	28.3	42.8
36	Header bit-flip	k=1%, n=2	28.8	42.3
37	Random bit-flip	k=1%, n=2	32.9	38.2
38	Header bit-flip	k=1%, n=1	34.7	36.4
39	Random bit-flip	k=1%, n=1	38.8	32.3

Source: Authors, (2026).

For padding attacks, null-byte padding accuracy decreases from 22.4% with 16-byte perturbations to 4.1% with 256-byte perturbations. Random-byte padding shows a similar trend, dropping from 21.5% to 3.7% as padding size increases. Cross-file padding demonstrates the steepest degradation, falling from 19.2% to 2.7% across the same range. Bit-flip attacks follow the same pattern, though with higher residual accuracy: random bit-flip accuracy declines from 38.8% (k=1%, n=1) to 6.4% (k=20%, n=4), while head-er-targeted bit-flip drops from 34.7% to 5.0% under equivalent perturbation intensity. This monotonic relationship reflects a fundamental principle: as perturbations grow larger, the proportion of authentic, discriminative bytes decreases, leaving fewer patterns for the classifier to exploit. Consequently, accuracy degrades proportionally with the volume of corrupted information. The least damaging attack (random bit-flip with only 1% of bytes affected and 1 bit flipped per byte) still reduces accuracy from 71.1% to 38.8% - a 32.3 pp drop. This shows clearly that adversarial vulnerability is not limited to severe attacks; even subtle modifications cause performance loss. No single attack variant preserves reasonable performance; the highest adversarial accuracy across all 39 variants is 38.8%, meaning the lowest drop is 32.3 pp.

IV.4.1 Statistical Confidence

With 4,492,800 adversarial test samples (n), the measurements are precise. The 95% confidence interval for the 15.8% adversarial accuracy (p) is computed using the standard error for a binomial proportion:

$$\mathrm{SE} = \sqrt{\frac{\mathrm{p}(1-\mathrm{p})}{\mathrm{n}}} = \sqrt{\frac{0.158 \times 0.842}{4{,}492{,}800}} = 0.000172 \tag{6}$$

The binomial proportion method was chosen because classification accuracy represents binary outcomes (correct or incorrect), and with 4.5 million test samples, the Central Limit Theorem implies that the sampling distribution of the estimated proportion is well approximated by a normal distribution, making this a standard statistical approach for reporting accuracy confidence intervals in machine learning research. The 95% confidence interval is therefore calculated as:

$$\mathrm{CI}_{95\%} = p \pm z_{\alpha/2} \times \mathrm{SE} = 0.158 \pm 1.96 \times 0.000172 = [15.77\%, 15.83\%] \tag{7}$$

This ±0.034 pp range demonstrates that the 15.8% figure is measured with high precision. The large sample size ensures that small variations in true accuracy are captured with negligible measurement error.

IV.5 UNDERSTANDING THE VULNERABILITY

Four factors explain why adversarial performance is poor:

1. **Statistical patterns are disrupted**. ByteRCNN learns byte-level statistics like n-gram frequencies and entropy profiles that are unique to authentic files. Padding directly destroys these patterns by replacing authentic bytes with foreign or random data. Bit-flip attacks corrupt the exact byte values that contribute to these statistics.
2. **Position matters**. The model learns that file headers (positions 0–128) contain distinctive signatures. Header-targeted bit-flip attacks (17.1% average) are more damaging than random bit-flip attacks (20.2% average) because they deliberately corrupt these critical positions.
3. **Authentic forgeries confuse the model**. Cross-file padding is especially effective (9.8% average) because it injects real byte sequences from other file types. The classifier encounters statistically valid but contextually incorrect patterns, causing systematic misclassification rather than simple information loss.
4. **The model has never seen adversarial examples**. ByteRCNN was trained only on clean data. It has no learned mechanisms for distinguishing authentic from corrupted regions. Robustness must be explicitly designed.

The empirical findings establish that file fragment classifiers cannot withstand byte-level attacks without explicit defense mechanisms. Simple, easy-to-implement attacks - requiring no sophisticated optimization or targeted knowledge - cause complete classification failure.

Adversaries need not develop complex, model-specific attacks; format-agnostic byte-level perturbations suffice to entirely compromise system integrity. This reality makes defense mechanisms mandatory for any deployment of these systems in security-critical applications. Based on this baseline vulnerability analysis, effective defense mechanisms should satisfy three concrete performance targets.

1. First, adversarial accuracy should exceed 60% to recover most of the capability lost under attack (compared to the current 15.8%).
2. Second, clean accuracy should remain at or above 70% to keep the penalty on genuine evidence minimal.
3. Third, performance on realistic mixed-threat scenarios - where 90% of fragments are clean and 10% are adversarially perturbed [35] - should exceed 68%. The baseline mixed accuracy is computed as follows:

$$\mathrm{Acc}_{\mathrm{mixed}} = 0.9 \times 71.1\% + 0.1 \times 15.8\% = 65.57\% \quad (8)$$

Any defense achieving these three targets simultaneously will represent an advance in adversarial robustness for file fragment classification.

V. ADVERSARIAL FRAGMENT DETECTION MODEL

The first stage of the defense pipeline is an adversarial detection model that acts as a gatekeeper in front of the file fragment classifiers. Its role is to decide, for each 512-byte fragment, whether the fragment is clean or adversarially perturbed and to route it accordingly. Fragments predicted as clean are passed to the baseline ByteRCNN classifier, while fragments predicted as adversarial are forwarded to the robust classifier introduced in the next section. This design allows the standard FFC model to operate unchanged on genuine evidence, while dedicating a specialized model to adversarially manipulated inputs.

V.1 MODEL OVERVIEW

The adversarial detection model is an attention-based convolutional neural network tailored to raw byte sequences. It consists of a byte embedding layer followed by a stack of three convolutional blocks that integrate spatial and channel attention mechanisms, a global pooling layer, and two fully connected layers for binary classification. The total capacity is approximately 1.31 million parameters, resulting in a compact model suitable for deployment as a preprocessing stage in forensic pipelines.

V.2 TRAINING CONFIGURATION

Training is conducted on the full 30.72 million–fragment benchmark, which includes 768,000 clean fragments and 29.952 million adversarial fragments spanning all 39 attack variants. The dataset is split into 70% training, 15% validation, and 15% test partitions using stratified sampling to preserve the clean–adversarial ratio in each split. The model is trained with the Adam optimizer, binary cross-entropy loss, and a batch size of 128, using class-balanced batches to avoid collapse to the majority (adversarial) class. Early stopping with a patience of five epochs is configured based on validation accuracy, although training in practice runs the full schedule due to stable validation performance. The dataset contains substantially more adversarial fragments than clean fragments because each clean fragment is transformed using all 39 attack variants. This enumeration of attack variants is necessary to ensure comprehensive coverage of the attack space and to evaluate robustness across a wide range of perturbation strategies. As a result, the raw dataset exhibits a 39:1 adversarial-to-clean imbalance. However, this imbalance does not affect the training dynamics because the model is trained using class-balanced mini-batches that sample equal numbers of clean and adversarial fragments. This approach allows the dataset to fully represent the diversity of attack variants while preventing the classifier from developing a bias toward the adversarial class during optimization.

V.3 DETECTION PERFORMANCE

On the 4.6 million-sample test set, the adversarial detection model achieves 95.46% specificity on clean fragments and 91.34% recall on adversarial fragments, with an F1-score of 0.9542 and AUC-ROC of 0.9819. The overall accuracy is 91.44%; however, because the test set reflects the natural benchmark composition (97.5% adversarial, 2.5% clean), this metric is dominated by recall performance. Specificity and recall are therefore reported as the primary evaluation metrics, as they independently capture detection quality on each class regardless of class distribution. Performance remains consistently strong across all attack categories. Padding-based attacks achieve the highest detection accuracies (93.47% for null-byte padding and 92.91% for random-byte padding), reflecting the strong boundary artefacts they introduce. Cross-file padding is the most challenging category yet still attains 86.24% accuracy. Random and header-targeted bit-flip attacks both exceed 90% detection accuracy, indicating that the learned byte embeddings and attention mechanisms capture even subtle changes in Hamming distance.

V.4 ROLE IN THE TWO-STAGE PIPELINE

Within the overall system, the adversarial detection model serves as a high-specificity front end that enables a detect-then-classify architecture without modifying the baseline ByteRCNN classifier. Clean fragments are classified by the original model at its full 71.1% accuracy, while adversarial fragments are redirected to the robust classifier that is explicitly trained to handle corrupted inputs. Misclassified adversarial fragments still receive baseline protection through ByteRCNN rather than catastrophic failure, and misclassified clean fragments experience only a minor accuracy penalty when processed by the robust classifier. This routing behavior is central to achieving strong robustness gains with a negligible impact on clean performance in the complete pipeline.

VI. ROBUST FILE FRAGMENT CLASSIFICATION DSAR-CNN MODEL

The vulnerability assessment in Section 4 established that ByteRCNN suffers a 55.3 pp accuracy collapse (71.1% → 15.8%) under adversarial attack. This catastrophic degradation raises a fundamental question: what architectural properties enable classification despite substantial byte-level corruption? The key insight motivating DSAR-CNN is that adversarial perturbations do not destroy all discriminative information. A 512-byte fragment subjected to 256-byte null-byte padding has its final 256 bytes replaced with zeros, while retaining 256 authentic bytes in the first half, and it often includes critical file-type markers (e.g., PDF headers, JPEG markers). Bit-flip attacks, despite corrupting individual bytes, typically affect only 1–20% of the fragment. The remaining authentic content retains sufficient structure to enable file-type identification if the classifier can selectively focus on un-corrupted regions and suppress noise from perturbed areas. Traditional CNNs fail under this scenario because they process all regions equally, allowing corrupted bytes to pollute global feature representations. DSAR-CNN addresses this through five synergistic innovations: multi-scale feature extraction to detect perturbations at matched granularities, learnable position embeddings to recognize attack-specific positional patterns, hierarchical attention mechanisms to separate file-type signals from adversarial noise, split pooling to resist attention-induced feature dilution, and regularized classification to prevent overfitting to specific attack patterns.

VI.1 DSAR-CNN ARCHITECTURE OVERVIEW

DSAR-CNN comprises six layers designed to progressively extract, refine, and classify features from corrupted byte sequences. The complete model contains 479,344 parameters and achieves 68.4% accuracy on adversarial fragments when evaluated on the final test set (4.6 million samples). (Note: Ablation study results on the validation set show 70.1% to isolate individual component contributions; see Table 4). Figure 2 shows the detailed architecture of the DSAR-CNN classification model.

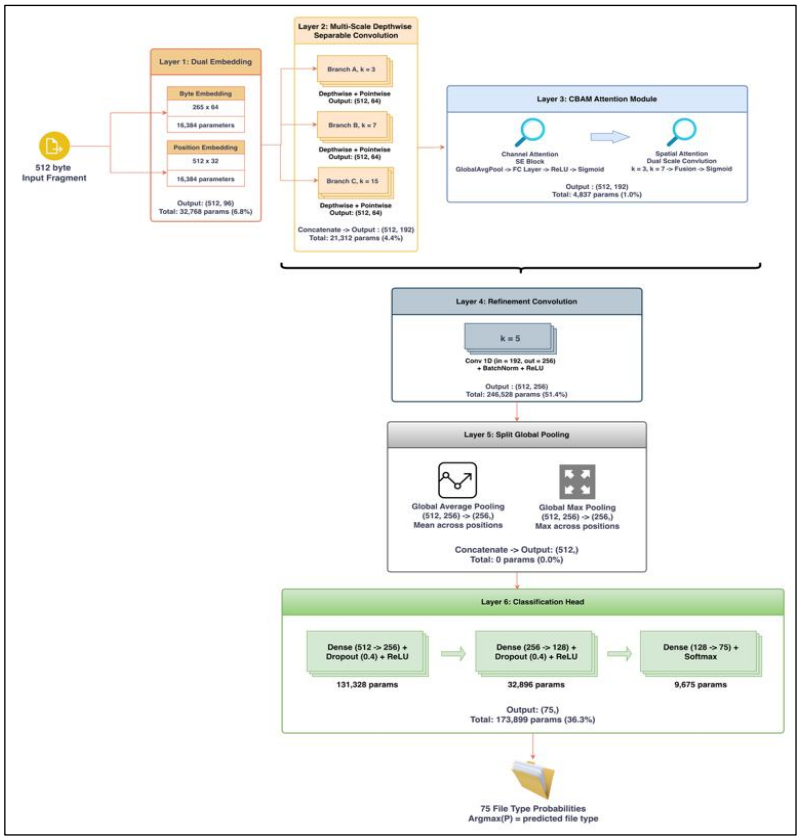

Figure 2: Proposed Dual-Scale Attention-based Robust CNN (DSAR-CNN) architecture for adversarial file fragment classification. Source: Authors, (2026).

VI.1.1 Layer 1: Dual Embedding

Layer 1 transforms raw byte integers (0–255) into rich, position-aware feature vectors that capture both semantic byte meaning and contextual positional information. This dual representation is crucial because adversarial attacks create position-dependent corruption patterns. Byte Embedding. Each byte value is mapped to a learnable 64-dimensional embedding:

$$X_{\text{byte}}[i] = E[b_i, :] \text{for } i \in [0,511] \tag{9}$$

where E ∈ ℝ {256×64} is the learnable embedding matrix and bi ∈ {0, 1, ..., 255} is the byte value. This creates semantic representation: byte value 0 learns associations with padding, specific ASCII characters learn their characteristic file context, and so forth. Parameters: 256 × 64 = 16,384. Learnable Position Embedding. Each position is mapped to a learnable 32-dimensional embedding:

$$X_{\text{pos}}[i] = P[i, :] \text{for } i \in [0,511] \tag{10}$$

where P ∈ ℝ {512×32} is the learnable position matrix. These embeddings are trained end-to-end on adversarial data. During training, the model learns that tail positions (448–511) frequently contain padding artifacts while earlier positions are more likely authentic. Parameters: 512 × 32 = 16,384. Concatenation. The two embeddings are concatenated along the feature dimension:

$$X_{\text{embed}}[i] = \left[X_{\text{byte}}[i] \parallel X_{\text{pos}}[i]\right] \in \mathbb{R}^{96} \tag{11}$$

Output shape: (512, 96). Each position now has a 96-dimensional vector capturing both what byte it is and where it is located.

VI.1.2 Layer 2: Multi-Scale Depth-wise Separable Convolution

Purpose. Different adversarial attacks create perturbation patterns at fundamentally different spatial scales: bit-flip attacks corrupt individual bytes (1–20 bytes), while padding attacks create large contiguous blocks (16–256 bytes). A single convolution kernel cannot optimally detect both. Layer 2 uses three parallel branches with kernel sizes matched to attack granularities. The kernel sizes (3, 7, and 15) were selected to provide multi-scale receptive fields capable of capturing both local byte-level variations and broader contextual patterns within the fragment. Smaller kernels capture fine-grained byte transitions, while larger kernels capture longer-range contextual patterns such as padding boundaries or abrupt distribution changes. This multi-scale design enables the model to analyze perturbations occurring at different spatial extents. Much larger kernels (e.g., 85, 125) would unnecessarily dilute these localized signals, increase parameter count, and risk overfitting without providing additional discriminative power beyond what is already achieved through hierarchical stacking of smaller convolutions. Three Branches. The layer processes the 512-position sequence with three 1D convolution branches simultaneously:

1. Branch A (k=3): Fine-grained analysis for scattered bit-flip perturbations
2. Branch B (k=7): Medium-scale analysis for local pattern disruptions
3. Branch C (k=15): Coarse-grained analysis for padding attack boundaries

Each branch produces 64 output channels, which are concatenated to form 192 total channels. Depthwise Separable Convolution. Instead of standard convolution, each branch uses depthwise separable convolution, which factorizes the operation into two steps: (1) depthwise convolution applies a separate kernel to each of the 96 input channels independently, and (2) pointwise (1×1) convolution mixes information across channels. Parameter count also includes biases on both depthwise and pointwise convolutions. Parameter Calculation. For a fair comparison including biases, a standard convolution across the three kernels would use:

$$(k_1 + k_2 + k_3) \times C_{in} \times C_{out} + 3 \times C_{out} = 25 \times 96 \times 64 + 3 \times 64 = 153{,}792\ params \tag{12}$$

Depthwise separable achieves:

$$\sum_{j=1}^{3} \left(k_j C_{in} + C_{in} + C_{in} C_{out} + C_{out}\right) = 21{,}312\ params \tag{13}$$

VI.1.3 Layer 3: CBAM Attention Module

Purpose. After extracting multi-scale features, Layer 3 learns which features are reliable (file-type discriminative) and which are noisy (adversarial artifacts). It does this through two complementary attention mechanisms: channel attention identifies important feature channels and spatial attention identifies trustworthy byte positions. Channel Attention (Squeeze-and-Excitation). This mechanism first computes the average activation of each of the 192 feature channels across all positions, then learns channel importance weights s ∈ (0,1)$^{\{192\}}$:

$$z = \text{GlobalAvgPool}(F) \in \mathbb{R}^{192} \tag{14}$$

$$s = \sigma(W_2 \cdot \text{ReLU}(W_1 \cdot z)) \in (0,1)^{192} \tag{15}$$

where σ is sigmoid, $W_1 \in \mathbb{R}^{\{12\times192\}}$ maps to a 12-dimensional bottleneck (reduction ratio r=16), and $W_2 \in \mathbb{R}\{192\times12\}$ reconstructs channel weights. These weights amplify channels encoding file-type patterns (weight ≈ 0.8–0.95) and suppress channels encoding adversarial noise (weight ≈ 0.05–0.2). Parameters: (192 × 12) + 12 + (12 × 192) + 192 = 4,608 weights + 204 biases = 4,812. Spatial Attention (Dual-Scale). Operating on the channel-refined features, spatial attention asks which positions are trustworthy. It uses two scales (k=3 and k=7) to detect corruption at different granularities:

$$D = \left[\text{AvgPool}_{\text{channels}}(F); \text{MaxPool}_{\text{channels}}(F)\right] \tag{16}$$

$$\alpha = \sigma(W_f \cdot [\text{Conv}(D, k=3); \text{Conv}(D, k=7)]) \in (0,1)^{512} \tag{17}$$

The 2-channel descriptor D (formed by channel-wise average and max pooling) is processed by two parallel 1D convolutions (k=3 and k=7, each 2→1 channels with bias), whose outputs are concatenated and fused by a 1×1 convolution (2→1 channels with bias). Position-wise weights α suppress corrupted regions (α ≈ 0.05–0.15) and preserve authentic regions (α ≈ 0.9–0.95). Parameters: (2×3+1) + (2×7+1) + (2×1+1) = 7 + 15 + 3 = 25. Synergistic Effect. An interesting finding is that channel attention + spatial attention produces +11.2 pp improvement in adversarial accuracy. This synergy arises from hierarchical structure: channel attention first filters out noisy channels, producing a cleaner signal that spatial attention then operates on. Operating on this pre-filtered signal, spatial attention makes more reliable position-level decisions.

VI.1.4 Layer 4: Refinement Convolution

Purpose. By Layer 4, features have been extracted from three parallel perspectives (k=3, k=7, k=15 branches) and selectively refined by CBAM attention mechanisms. Layer 4's role is to integrate this diverse multi-scale information into a unified, higher-dimensional representation. It acts as a synthesis layer that combines the complementary perspectives before passing to the classification head. At the input to Layer 4, the model has 512 positions, each with 192 feature dimensions. These 192 dimensions are organized in three groups of 64 channels, each representing patterns detected at different scales:

- Channels 0–63: Fine-grained patterns from k=3 analysis (subtle byte-level corruption signatures)
- Channels 64–127: Medium-scale patterns from k=7 analysis (local disruption boundaries)
- Channels 128–191: Coarse-grained patterns from k=15 analysis (large padding block transitions)

Additionally, spatial attention has already suppressed positions suspected of containing adversarial perturbations. Authentic regions (typically positions 0–383 in padding attacks) have attention weights $\alpha \approx 0.9–0.95$, while corrupted regions (typically positions 384–511) have been suppressed to $\alpha \approx 0.05–0.15$. The network now has a partially masked but information-rich feature representation. Operation. A 1D convolution with k=5 processes the attended features

$$F_{\text{refined}} = \text{ReLU}\left(\text{BatchNorm}\left(\text{Conv1D}(F_{\text{attended}}, k = 5, 256 \text{ filters})\right)\right) \tag{18}$$

Layer 4 applies a 1D convolution with k=5 that allows neighboring positions (±2 away) to collectively influence each output position. This local context aggregation captures file-type patterns, which are often locally coherent; authentic regions maintain consistent byte patterns while corruption boundaries create sharp discontinuities. The convolution simultaneously expands channels from 192 to 256, learning 256 different perspectives including combinations like "fine-grained and medium-scale corruptions co-occurring" or "authentic header followed by noise." Batch normalization then normalizes activations to ensure stable training on the imbalanced dataset (97.5% adversarial, 2.5% clean), while ReLU introduces non-linearity to preserve the network's expressive power.

VI.1.5 Layer 5: Split Global Pooling

Purpose. Layers 1–4 maintain position-level information across 512 positions. Layer 5 compresses this into a single global representation but uses split pooling to counteract a critical problem: dilution from attention-based suppression. The Dilution Problem. After CBAM attention, many positions in adversarially perturbed fragments have been suppressed to near-zero activations. For a fragment under 256-byte padding attack, spatial attention suppresses positions 256–511 ($\alpha \approx 0.05–0.15$), while preserving positions 0–255 ($\alpha \approx 0.9–0.95$). When Global Average Pooling computes the mean across all 512 positions:

$$f_{\text{gap}} = \frac{1}{512}\sum_{i=1}^{512} F_{\text{refined}}\,[i] \tag{19}$$

The result averages 256 strong authentic activations with 256 near-zero suppressed activations, producing approximately 50% of the signal strength compared to a fully clean fragment. This dilution - averaging real signals with suppressed noise - weakens the discriminative information available to the classifier. A classifier receiving a 50%-diluted representation of a PDF fragment might have difficulty distinguishing it from a JPEG, even if the authentic 50% contains clear PDF signatures. Split Pooling Solution. Rather than accepting this dilution, Layer 5 employs two complementary pooling operations: Global Average Pooling (GAP) is defined as:

$$f_{\text{gap}} = \frac{1}{512}\sum_{i=1}^{512} F_{\text{refined}}\,[i] \in \mathbb{R}^{256} \tag{20}$$

GAP is sensitive to position suppression, making it diluted on corrupted fragments but representative on clean fragments. Global Max Pooling (GMP) is defined as:

$$f_{\text{gmp}} = \max_{i} F_{\text{refined}}[i] \in \mathbb{R}^{256} \tag{21}$$

GMP finds the maximum activation across all 512 positions. Crucially, GMP is un-affected by suppression - even if 256 positions are suppressed to near-zero, the maximum activation remains strong from the 256 unsuppressed positions. GMP preserves the strongest signals regardless of position distribution. Concatenation and Interpretation. The classifier receives both:

$$f_{\text{pooled}} = \left[f_{\text{gap}} \parallel f_{\text{gmp}}\right] \in \mathbb{R}^{512} \tag{22}$$

The classification head receives both the Global Average Pooling (GAP) and Global Max Pooling (GMP) representations, allowing it to leverage complementary information about the fragment. GAP summarizes the overall activation distribution across positions and is therefore sensitive to the suppression of corrupted regions introduced by spatial attention. In contrast, GMP preserves the strongest activation within the fragment and remains robust even when many positions have been suppressed. When large portions of the fragment are corrupted, GAP values tend to decrease due to averaging over suppressed positions, while GMP continues to reflect the strongest remaining signals. By concatenating these two representations, the classifier receives both a global summary of the fragment and the strongest local activation patterns, providing richer information for classification under corrupted conditions. Why This Matters. Using only Global Average Pooling would produce diluted feature representations when large regions of the fragment are suppressed by attention, potentially weakening discriminative signals.

Conversely, Global Max Pooling alone would ignore the broader distribution of activations across the fragment. Combining GAP and GMP allows the model to retain both strong local activations and global contextual information, improving robustness when fragments contain partially corrupted regions. The ablation study confirms the effectiveness of this design, showing that removing split pooling reduces adversarial accuracy by 6.3 percentage points.

VI.1.6 Layer 6: Classification Head

Purpose. The final three fully connected layers map the 512-dimensional pooled features to 75-class file-type probabilities. By this stage, features have been carefully extracted and refined; the classification task is relatively straightforward mapping of rich representations to file-type labels. Architecture. The classification head consists of three dense layers: Dense1 (512→256 with ReLU + dropout), Dense2 (256→128 with ReLU + dropout), and Output (128→75 with softmax). This gradual dimensionality reduction from 512 to 75 prevents sudden compression that could discard information, allowing the model to progressively focus features on file-type discrimination. Dropout with probability 0.4 is applied after each ReLU activation, where 0.4 was selected based on preliminary hyperparameter tuning across rates of 0.3, 0.4, and 0.5. Label Smoothing. During training, label smoothing with smoothing factor 0.1 is applied. Instead of training on hard labels (e.g., [0,0,..,1,..,0] for PDF), the model trains on smoothed targets where the correct class receives probability 0.9 and other 74 classes share 0.1 probability equally. This prevents overconfidence on corrupted patterns, particularly important given the 97.5% adversarial sample composition in training data. Without smoothing, the model might learn to confidently predict incorrect file types when seeing corrupted byte patterns, reducing calibration. The Figure 3 shows the parameter summary for the DSAR-CNN model.

VI.2 ABLATION STUDY: COMPONENT CONTRIBUTIONS

To quantify the contribution of each architectural component, an ablation study was conducted in which individual components were removed from the full DSAR-CNN architecture and the resulting models were retrained from scratch. For each variant (e.g., without Position Embedding), the specified component was removed while all other architectural elements remained unchanged. Early stopping based on validation performance typically halted training before the maximum epoch limit, reducing overall training time while preserving fair comparisons across variants. When a component was removed, it was replaced with the simplest functional alternative required to maintain architectural compatibility (e.g., removing split pooling results in standard global average pooling). Model performance was then evaluated on the validation set using adversarial fragments. The contribution of each component is estimated as the difference between the full model accuracy (70.1%) and the accuracy of the corresponding ablated variant. Since all other experimental conditions are held constant, the observed performance differences primarily reflect the contribution of the removed component. Table 4 summarizes the results of this analysis.

Table 4: Ablation Study of DSAR-CNN Components: Adversarial Accuracy and Marginal Contribution on Validation Set.

Configuration	Adversarial Accuracy	Accuracy Drop
Full DSAR-CNN	70.10%	-
Without Position Embedding	65.30%	−4.8 pp
Without Multi-Scale Conv	62.80%	−7.3 pp
Without Channel Attention	66.50%	−3.6 pp
Without Spatial Attention	67.20%	−2.9 pp
Without CBAM (channel + spatial attention)	58.90%	−11.2 pp
Without Split Pooling	63.80%	−6.3 pp

Source: Authors, (2026).

This table reports accuracy on the validation set during model development to estimate the relative impact of each architectural component. The full DSAR-CNN achieves 70.1% accuracy on the validation set used for ablation analysis. Final evaluation on the independent test set (4.6M fragments) yields 68.4% accuracy, reflecting normal generalization differences between development and test datasets. The relative contribution percentages remain valid because they measure deltas between models trained and evaluated in the same setting (validation set).

Results show that different components contribute differentially. The combined CBAM module produces the largest performance drop when removed (−11.2 pp), followed by multi-scale convolution (−7.3 pp) and split pooling (−6.3 pp). Position embedding (+4.8 pp), channel attention (+3.6 pp), and spatial attention (+2.9 pp) provide smaller but still meaningful contributions. CBAM Synergy. The combined CBAM module provides a larger improvement (+11.2 pp) than the sum of the individual channel (+3.6 pp) and spatial (+2.9 pp) attention contributions. This indicates that the two attention mechanisms interact synergistically, where channel attention first suppresses noisy feature channels and spatial attention subsequently identifies reliable byte positions within the refined feature representation. Without this hierarchy, spatial attention operating on raw, unfiltered channels may find it harder to distinguish corruption from genuine patterns, which can limit its effectiveness. This hierarchical synergy is consistent with observations reported in prior attention mechanism studies and demonstrates that component interactions can produce amplified benefits beyond independent contributions.

VI.3 TRAINING CONFIGURATION

DSAR-CNN is trained on the 70% training allocation: 20,966,400 adversarial samples and 537,600 clean samples, totaling 21,504,000 fragments. The 2.50% clean sample inclusion, though minimal, helps DSAR-CNN learns robust features when detector false positives (FPR=4.54%) route clean fragments incorrectly to this branch. Hyperparameters: Adam optimizer (learning rate 0.001, reduced on plateau by factor 0.5), sparse categorical cross-entropy loss, batch size 256, early stopping (5-epoch patience), dropout 0.4, label smoothing 0.1, batch normalization, high momentum (0.99) to obtain stable running statistics given the large, highly skewed training distribution. Training converged within 35–40 epochs (~25–30 hours on modern GPU).

VI.4 PERFORMANCE SUMMARY

Standalone DSAR-CNN Performance (Test Set Results): DSAR-CNN achieves a 68.4% accuracy on adversarially perturbed fragments. And DSAR-CNN achieves 67.0% accuracy on clean fragments (compared to 71.1% for ByteRCNN), reflecting the trade-off inherent in training primarily on adversarial data.

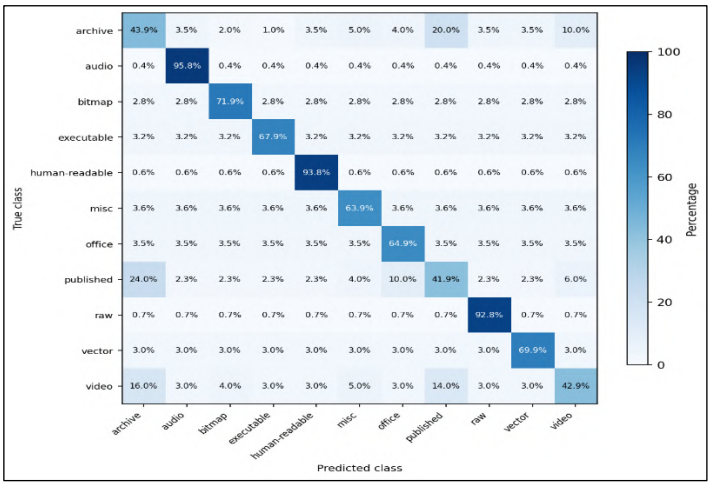

Figure 4: Confusion matrix of DSAR-CNN evaluated on the full test set. Given the large number of classes (75), individual file types were aggregated into their corresponding superclasses.
Source: Authors, (2026).

The confusion matrix in Figure 4 is computed over the test set of 4.6M fragments, which is dominated by adversarial samples. The average class-wise accuracy (~ 68%) is consistent with the reported adversarial accuracy of 68.4%. The performance follows typical FFC difficulty trends, with structured formats such as audio, text, and raw data showing high robustness, while high-entropy formats such as archives, published content, and video remain more challenging. The observed confusion patterns between these entropy-rich formats further reflect realistic behavior under adversarial conditions. The large robustness gain over ByteRCNN arises because DSAR-CNN is explicitly optimized for the same padding and bit-flip transformations used at test time, whereas ByteRCNN is trained only on clean fragments and therefore fails under severe distribution shift. By training on a large, supervised corpus of perturbed fragments and incorporating architectural bias toward perturbation-resilient features (multi-scale depthwise-separable convolutions, attention, and split pooling), DSAR-CNN learns to focus on the remaining informative bytes and down-weight corrupted regions. In this matched train–test setting, an improvement in adversarial accuracy over a clean-only baseline is expected and does not imply any form of data leakage.

VI.4.1 Attack Category-wise Performance

DSAR-CNN achieves substantial improvements across all attack categories. On padding attacks (15 variants), the model attains an average accuracy of 67.1%, compared to ByteRCNN's 11.2% baseline. Null-byte and random-byte padding are handled more effectively (68.4% and 67.8%) due to the clear boundary artifacts they introduce, while cross-file padding is more challenging (65.2%) because it contains authentic but contextually incorrect byte sequences from other file types. For bit-flip attacks, random bit-flip variants achieve an average accuracy of 70.0% versus ByteRCNN's 20.2%. Header-targeted bit-flip attacks reach 68.3% compared to 17.1%. These results indicate that DSAR-CNN provides strong robustness across both distributed and localized corruption patterns.

VI.5 ROLE IN TWO-STAGE PIPELINE

Within the complete defense system, DSAR-CNN serves as the specialized stage-2 classifier for adversarially perturbed fragments. When the adversarial detector flags a fragment as adversarial (91.34% recall), it is routed to DSAR-CNN rather than the baseline classifier. This routing mechanism enables preservation of baseline accuracy on clean data while achieving substantial robustness improvements. Fragments misclassified by the detector (false negatives) still receive some protection through ByteRCNN's partial robustness, while detector false positives (clean fragments routed to DSAR-CNN) experience modest accuracy reduction due to the 2.5% clean training data inclusion.

VII. EXPERIMENTAL EVALUATION AND PROPOSED FRAMEWORK PERFORMANCE

The complete defense system integrates three models into a sequential two-stage pipeline. A 512-byte fragment first passes through the adversarial detection model, which classifies it as clean or adversarial with 91.44% accuracy, 91.34% recall, and 95.46% specificity. Fragments predicted as clean are routed to ByteRCNN (preserving 71.1% baseline accuracy), while fragments flagged as adversarial are routed to DSAR-CNN (achieving 68.4% standalone adversarial accuracy). This routing mechanism enables the system to maintain high accuracy on genuine evidence while substantially improving robustness on perturbed inputs.

VII.1 END-TO-END PIPELINE PERFORMANCE

VII.1.1 Clean Data Performance

On 115,200 clean test fragments, the pipeline achieves 70.91% accuracy, a 0.19 pp penalty compared to the 71.1% undefended baseline. This metric is derived from the weighted average of clean fragments correctly routed to ByteRCNN (True Negatives) and those misrouted to DSAR-CNN (False Positives):

$$Acc_{clean}^{pipeline} = \left(Acc_{clean}^{Byte} \times \text{Specificity}\right) + \left(Acc_{clean}^{DSAR} \times \text{FPR}\right) \tag{23}$$

Substituting the experimental values:

$$70.91\% \approx (71.1\% \times 0.9546) + (67.0\% \times 0.0454) \tag{24}$$

The minimal penalty demonstrates that detection-based defense enables preservation of baseline accuracy on genuine evidence while adding robustness to adversarial inputs.

VII.1.2 Adversarial Data Performance

On 4,492,800 adversarial test fragments across all 39 attack variants, the pipeline achieves 63.84% accuracy, compared to 15.8% for the undefended baseline. The pipeline accuracy is calculated as the weighted sum of adversarial fragments correctly routed to DSAR-CNN (True Positives) and those misclassified as clean (False Negatives):

$$Acc_{adv}^{pipeline} = \left(Acc_{adv}^{DSAR} \times \text{Recall}\right) + \left(Acc_{adv}^{Byte} \times \text{FNR}\right) \tag{25}$$

Substituting the detector performance:

$$63.84\% \approx (68.4\% \times 0.9134) + (15.8\% \times 0.0866) \tag{26}$$

This calculation confirms that the system's robustness is primarily driven by the robust classifier (DSAR-CNN), with graceful degradation provided by the baseline classifier for the 8.66% of undetected attacks.

VII.1.3 Mixed-Threat Scenario (90% Clean / 10% Adversarial)

In operational cybersecurity systems, malicious activity typically constitutes a small minority of total observations, a trend documented in large-scale intrusion detection studies such as CICIDS-2017 and related imbalance analyses by Buczak and Guven and Zhao et al [35-37]. For instance, the CICIDS-2017 benchmark - one of the most widely used intrusion detection datasets - contains predominantly benign traffic with attack flows forming only a minority of total connections, and real-world deployment reports indicate even more skewed benign-to-attack ratios in production networks [35]. Although no published adversarial prevalence rates exist specifically for forensic fragment recovery scenarios, the 90/10 clean-to-adversarial ratio adopted here therefore reflects a realistic attack-sparse deployment assumption that is consistent with empirical observations from these adjacent security domains [36] [37]. The pipeline achieves 70.20% accuracy on a typical mixed dataset (90% clean, 10% adversarial). This metric combines the pipeline's clean and adversarial performance calculated above:

$$Acc_{mixed} = \left(Acc_{clean}^{pipeline} \times P_{clean}\right) + \left(Acc_{adv}^{pipeline} \times P_{adv}\right) \tag{27}$$

$$70.20\% = (70.91\% \times 0.90) + (63.84\% \times 0.10) \tag{28}$$

This represents a 4.63 pp improvement over the undefended baseline mixed accuracy, which is calculated similarly:

$$Acc_{mixed}^{baseline} = (71.1\% \times 0.90) + (15.8\% \times 0.10) = 65.57\% \tag{29}$$

Operationally, this improvement translates to approximately 46 additional correctly classified fragments per 1,000 processed - a meaningful enhancement for large-scale forensic investigations.

VII.2 COMPARISON WITH ADVERSARIAL TRAINING AND PIPELINE PERFORMANCE METRICS SUMMARY

To establish a direct comparison with the dominant defense paradigm, standard adversarial training was implemented on the baseline ByteRCNN architecture using a balanced 50/50 clean-adversarial training mix, following the standard adversarial training protocol [24]. The training dataset comprised 1,075,200 samples: 537,600 clean fragments and 537,600 adversarial fragments sampled uniformly across all 39 attack variants (approximately 13,784 samples per variant). Adversarial samples were generated exclusively from the training partition, and all training configurations (architecture, optimizer, and hyperparameters) were kept identical to the baseline to ensure a fair architectural comparison. The balanced ratio inherently constrains training volume to 1,075,200 samples, compared to the 21,504,000-fragment set used by the defense pipeline at its natural 39:1 adversarial-to-clean ratio. This asymmetry reflects a fundamental distinction between the two paradigms: adversarial training requires balanced class exposure to avoid majority-class collapse, whereas detection and robust classification models are designed to operate on realistic imbalanced distributions. Scaling adversarial training to match pipeline volume at 50/50 balance would require 20× oversampling of the clean fragment pool, introducing artificial duplication rather than genuine training signal. The adversarially trained model was evaluated on the identical test set of 4,608,000 fragments used throughout this study. Table 6 presents the comparative results.

Table 5: Comparative Performance Metrics of the Proposed Pipeline Against Baseline and Adversarial Training Approaches.

Metric	Clean	Adversarial	Mixed (90/10)
Undefended baseline	**71.10%**	15.80%	65.57%
Adversarial Training (50/50)	66.60%	51.80%	65.12%
Defense pipeline (Proposed)	70.91%	**63.84%**	**70.20%**
Improvement (Proposed vs. Adv. Training)	+4.31 pp	+12.04 pp	+5.08 pp

Source: Authors, (2026).

Adversarial training does improve robustness, increasing adversarial accuracy from 15.8% to 51.8% (a gain of 36.0 percentage points). However, this improvement comes at the cost of a 4.5 percentage point reduction in clean accuracy (from 71.1% to 66.6%), confirming the accuracy-robustness trade-off widely reported in adversarial learning literature. A critical observation emerges from the mixed-scenario analysis. In realistic forensic environments where 90% of fragments are benign and 10% are adversarially perturbed, adversarial training achieves a weighted accuracy of 65.12%, which is slightly lower than the undefended baseline (65.57%). This occurs because the reduction in clean accuracy outweighs the robustness gains when adversarial samples constitute a minority of the data. The proposed detection-based pipeline achieves superior performance across all evaluation settings. Compared to adversarial training, the pipeline improves clean accuracy by 4.31 percentage points (70.91% vs. 66.6%), adversarial accuracy by 12.04 percentage points (63.84% vs. 51.8%), and mixed-scenario accuracy by 5.08 percentage points (70.20% vs. 65.12%). These results demonstrate that the detect-then-classify routing strategy effectively mitigates the accuracy-robustness trade-off by preserving baseline performance on clean inputs while improving robustness against adversarial fragments. All models were trained once due to computational constraints. However, the large test set size (4.6M fragments) yields narrow confidence intervals: the 95% CI for the pipeline's mixed accuracy of 70.20% is [70.16%, 70.24%] and for adversarial training's 65.12% is [65.08%, 65.16%], confirming the 5.08 pp difference is statistically significant ($p < 0.001$, two-proportion z-test). The training volume differs between adversarial training and the proposed pipeline, reflecting differences in how the two approaches are typically implemented. In adversarial training, balanced clean-adversarial datasets are commonly used to maintain stable optimization and avoid oversampling artifacts when scaling to large attack sets. In contrast, the proposed pipeline leverages the full adversarial dataset through a detection-routing mechanism. Consequently, the results should be interpreted as a comparison between the proposed framework and adversarial training under its standard configuration rather than a strictly matched-volume experimental setting. To ensure that the reported results are not contingent on this specific operating point, Table 6 provides a sensitivity analysis across a range of adversarial prevalence rates (p). The formula for each cell is:

$$Acc_{mixed} = (Acc_{clean} \times (1 - \mathrm{p})) + (Acc_{adv} \times \mathrm{p}) \tag{30}$$

Table 6: Sensitivity of Pipeline and Adversarially Trained Baseline Accuracies to Adversarial Prevalence.

Adversarial Prevalence	Pipeline Accuracy	AT Baseline	Pipeline Lead over AT
0% (all clean)	70.91%	66.60%	+4.31 pp
5%	70.56%	65.86%	+4.70 pp
10% (primary)	70.20%	65.12%	+5.08 pp
20%	69.50%	63.64%	+5.86 pp
30%	68.79%	62.16%	+6.63 pp
50% (balanced)	67.38%	59.20%	+8.18 pp

Source: Authors, (2026).

The proposed pipeline outperforms the adversarial training baseline across all tested prevalence rates from 0% to 50%. Notably, the pipeline's advantage over adversarial training increases with adversarial prevalence (from +4.31 pp at 0% to +8.18 pp at 50%), demonstrating that the detection-routing mechanism provides progressively greater benefit as adversarial activity increases."

VII.3 ROBUSTNESS BY ATTACK CATEGORY

Performance across individual attack categories demonstrates that the proposed pipeline provides consistent robustness improvements over both the undefended baseline and the adversarially trained model. The undefended baseline is included to quantify the severity of adversarial degradation and to show the extent of robustness recovery. However, the primary comparison for defense effectiveness is against adversarial training, which represents the standard defense approach. Figure 5 visualizes these per-category results.

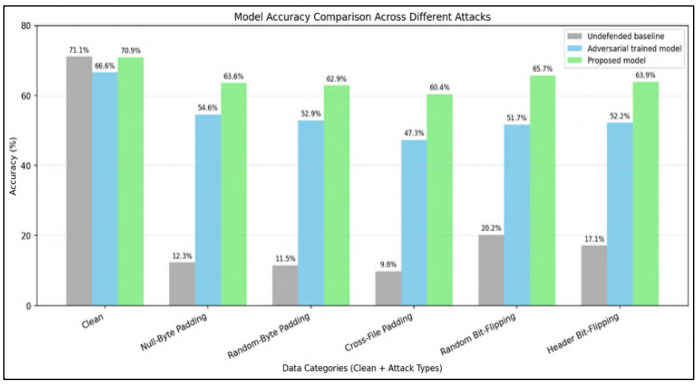

Figure 5: Model accuracy comparison across attack categories for the undefended baseline, adversarial training and proposed pipeline. Source: Authors, (2026).

On clean data, the proposed pipeline achieves an accuracy of 70.9%, which is comparable to the baseline performance of 71.1% and substantially higher than the adversarially trained model (66.6%). This result confirms that the detection-based routing strategy preserves clean-data performance and avoids the accuracy degradation typically associated with adversarial training. Under padding-based attacks, which introduce large structural perturbations and are the most damaging to the baseline model, the proposed approach maintains strong and stable performance. For null-byte padding, accuracy improves from 12.3% (baseline) and 54.6% (adversarial training) to 63.6%. Random-byte padding shows a similar trend, increasing from 11.5% and 52.9% to 62.9%, while cross-file padding improves from 9.8% and 47.3% to 60.4%. These results represent improvements of approximately 8-13 percentage points over adversarial training. Although cross-file padding remains the most challenging category due to the insertion of realistic but contextually misleading byte patterns, the proposed pipeline maintains substantially higher robustness than both comparison models. For bit-flip attacks, which introduce localized corruption rather than large-scale structural changes, the proposed approach again achieves the highest performance. Random bit-flip accuracy increases from 20.2% (baseline) and 51.7% (adversarial training) to 65.7%, while header-targeted bit-flips improve from 17.1% and 52.2% to 63.9%. The gains over adversarial training range from approximately 11 to 14 percentage points, indicating that the detect-then-classify strategy effectively isolates perturbed inputs and enables more accurate classification through the specialized DSAR-CNN model. Two consistent trends emerge from this analysis. First, padding-based perturbations cause more severe degradation in the undefended baseline than bit-flip attacks, reflecting their larger impact on the underlying fragment structure and statistical distribution. Second, the proposed pipeline delivers stable and balanced performance across all attack categories, outperforming adversarial training while maintaining near-baseline accuracy on clean data. This behavior demonstrates that the approach effectively improves robustness without incurring the accuracy-robustness trade-off commonly observed in conventional adversarial training approaches.

VIII. DISCUSSION AND FUTURE WORK

VIII.1 SIGNIFICANCE AND ARCHITECTURAL ADVANTAGES

This work addresses two important limitations in current file fragment classification research. First, it provides a systematic vulnerability analysis of state-of-the-art FFC models under byte-level perturbations. Second, it explores a detection-based defense strategy designed to improve robustness while preserving clean-data accuracy: 70.91% clean accuracy (−0.19 pp penalty) with 63.84% adversarial accuracy, contrasting sharply with the 4.5% clean accuracy penalty empirically observed in the adversarial training baseline (Section 7.2). The architecture is specifically tailored to byte-level FFC. Multi-scale depthwise separable convolution (k=3, 7, 15) matches attack granularities: k=3 for scattered bit-flips, k=7 for local disruptions, k=15 for padding boundaries. This scale-matching is unnecessary in image defenses where perturbations are uniform. Split pooling addresses byte-level dilution: when spatial attention suppresses corrupted positions, GMP preserves strongest signals while GAP measures dilution, enabling the classifier to infer corruption implicitly. Learnable position embeddings exploit positional attack structure (tail-biased padding) more efficiently than fixed encodings.

VIII.2 LIMITATIONS AND FUTURE WORK

Evaluation Limitations. The current evaluation focuses on black-box attacks. White-box adaptive attacks where adversaries have full model access are not tested. In theory, attackers could exploit the learned position embeddings by shifting padding to the fragment head instead of the tail or target the attention mechanism directly. Certified defense approaches like randomized smoothing or IBP could address this but implementing them across 30 million samples is computationally expensive and remains as future work. Multi-seed experiments would better characterize model stability, and latency measurements are theoretical rather than measured across different hardware platforms. A key limitation of this evaluation is that each attack variant is applied independently to clean fragments, and do not study composite adversaries that combine padding and bit-flip perturbations within the same fragment, which may represent a stronger and more realistic threat model in operational settings.

Architectural Limitations. The position embeddings are specifically learned for tail-biased padding attacks. If adversaries instead corrupt the fragment head, the positional priors might degrade performance. The architecture was only tested on 512-byte fragments - generalization to 256-byte or 1024-byte sizes remains unclear. Cross-dataset evaluation on alternative benchmarks like DFRWS would be valuable. Finally, the 39 attack variants tested (padding and bit-flips) do not cover every possible byte-level perturbation strategy, so robustness to novel attacks is uncertain. Future Directions. Priority work includes testing head padding and random-position attacks to validate that position embeddings learn genuine file structure rather than memorizing attack positions; extending the detector to classify attack types for forensic attribution; developing certified robustness guarantees; evaluating on alternative datasets and fragment sizes; and integrating with commercial forensic tools for real-world validation. Modeling white-box adaptive attacks would also be important to understand worst-case robustness.

IX. CONCLUSIONS

File fragment classification remains essential to digital forensics, yet the vulnerability assessment uncovered that the state-of-the-art model accuracy collapses from 71.1% to 15.8% when facing byte-level adversarial perturbations. Testing across 39 attack variants (padding and bit-flip strategies) and five distinct attack categories reveals this vulnerability is systematic and universal, not confined to edge cases. The threat is real: simple, format-agnostic byte manipulations suffice to compromise classification integrity, rendering current forensic systems unreliable in adversarial contexts. The proposed two-stage detection-then-classify pipeline substantially mitigates this threat (70.91% clean, 63.84% adversarial, 70.20% in realistic mixed scenarios with 90% clean and 10% adversarial fragments). The improvement is consistent across all attack categories: 9 pp for null padding, 10 pp for random byte padding, 13.1 pp for cross-file padding, 14 pp for random bit-flip, and 11.7 pp for header-targeted bit-flip as compared to the adversarially trained model values. This recovery comes with minimal clean accuracy penalty (0.19 pp) too. The architectural innovations underlying this defense - multi-scale depthwise separable convolution, hierarchical CBAM attention, split pooling, and learnable position embeddings - are tailored to byte-sequence processing and extend beyond file fragment classification to malware detection, network traffic analysis, and other security domains relying on byte-level feature extraction. The detection-based routing strategy sidesteps the accuracy-robustness tradeoff plaguing adversarial training by preserving baseline performance on genuine evidence while routing adversarial inputs to specialized classifiers. These results demonstrate that detection-based routing strategies can substantially improve robustness against byte-level perturbations while preserving clean-data performance. The proposed framework therefore provides a promising direction for strengthening the resilience of file fragment classification systems against adversarial manipulation.

ABSTRACT

In the digital currency, Bitcoin (BTC) is called the gold of the digital currency. It is possible to make some profits in trading of bitcoins, though this market is a very illiquid market and it is very challenging to determine the price of a bitcoin. The current work uses historical data and technical indicators to predict Bitcoin prices in a broad approach. BTC-USD price data were obtained using Yahoo Finance API and covered from 01/01/2015 till 07/01/2024. The concept of feature engineering was applied to improve the dataset by including vital financial characteristics, including Moving Averages, RSI, and Bollinger Bands for higher forecasting precision. The forward-looking model for the Bitcoin price was developed using machine learning and deep learning algorithms. The efficiency of the model was assessed with the help of Mean Absolute Error (MAE), Mean Squared Error (MSE), and Root Mean Squared Error (RMSE). The overall values of Mean Absolute Error, Mean Squared Error, and Root Mean Squared Error were 0.0062, 8.39e-05 and 0.0092 respectively which suggest that the proposed model is accurate in forecasting the future prices.

I. INTRODUCTION

The market of the crypto currency is one of the biggest and influential markets in the world of the financial market, where trader from all over the world invest in the digital currency. Trade in this market serves multiple objectives from acting as the market that provides the required liquidity for currencies as well as enhancing the provision of the export currency for the export of goods and services to other countries to offer individuals and institutions the ability to make attractive returns from speculative trades in the global foreign exchange market. The crypto market is a large and highly liquid market in terms of trading volume, which means that investors prefer such a market when they are acting to earn quick profits [1]. This current market also brings the chance to diversify and get returns due to global market fluctuations. Taking into account the processes associated with development of technology and growth of investment conscious, trading in the currency market is not only the profession of the experts but also the area freely accessible to everyone willing to invest and manage risks more effectively [2]. The financial technology has been experiencing drastic changes especially from the beginning of the new century, and has greatly influenced the world's financial structure.

From these contributors are fairly introduced the development of the digital currency which is an additional form of the money and financial transactions. New technology in money adoption, known as digital currencies based on encryption and decentralization have received other unusual attention in both field of finance and academic mediation [3]. Digital currencies are one of the financial assets that utilize encryption and common transaction denominations to generate new ones. They are not like conventional money as they are not controlled by a central banking network, but they are documented through a network of nodes. These are currencies based on block chain technology, a transparent and secure database of currencies, hence efficient and free from fraud [4]. Bitcoin, launched in 2008, is the first digital currency that introduced the concept of blockchain as a decentralized means of recording transactions. Despite its humble beginnings, it has proven its ability to greatly influence global financial markets, leading to the emergence of many other digital currencies such as Ethereum, Ripple, and Litecoin [5].

II. DIGITAL CURRENCIES

Another aspect of the digital currencies is that the control of the type or kind of money is not centralized there is no central authority that dictates the type of money to be issued in circulation or how it will be managed. Rather, digital currencies operate through a group of people to assure the transaction's safety and increase transparency. Further, these currencies are characterized by rapidity of the financial operations and the highest level of protection due to the use of complex encryption algorithms that eliminate the need for the use of conventional financial mediators across the border [6]. Digital currencies can be primarily categorized into three main types. Cryptocurrencies: Examples are Bitcoin and Ethereal, through which value is transferred and stored. For example, Bitcoin is the first virtual currency designed to act as an alternative currency. , whereas Ethereal is not only a digital currency but also a platform for developing decentralized applications and smart contracts [7].

1. Tokens: These are based on technologies such as Ethereum and are used for various uses starting from funding projects, offering specific services or products, up to emulating traditional shares. Such tokens are Tether (USDT) and Chainlink (LINK) [8].
2. Stablecoins: meant to be less volatile, they are most often anchored on a conventional currency, for instance, the US dollar. Some of the centralized stablecoins include Tether, which is also known as USDT, and USD Coin also known as USDC. These currencies is expected to reduce the volatile nature, which is common with most of the other digital currencies for use in trading and other economic activities [9].

III. DIFFICULTY IN PREDICTING CRYPTOCURRENCY PRICES

Depending on the probability of cryptocurrency price prediction is still one of the biggest prospects that affects the investors and analysts in this highly volatile market. Currency prices are volatile and vary significantly and unpredictably, thus, predicting cryptocurrency is not an easy task which depends on the understanding of this market. Among the influential factors are the following [10]:

1. Price volatility: In general, the prices of cryptocurrencies fluctuate, which is much higher than the price fluctuations in traditional financial markets. Such a situation is explained by several reasons: Fluctuations in supply and demand, large transactions, and the emotional state of a trader. These fluctuations make it challenging to adopt standardized models to project the cryptocurrency prices faithfully [11].
2. Lack of historical data: Generally, historical information related to cryptocurrencies is limited and of a shorter time span as compared to traditional markets. This lack of long-term data hampers the analysts in the construction of a forecasting system based on quantitative analysis over a long span of time; the long-term trends cannot be predicted [10].
3. Psychological and market factors: The prices of various cryptocurrencies are greatly influenced by psychological factors. It can be also defined that news, rumors and market expectations can produce fluctuations in the price. There is empirical evidence that fast trading based on news affects the prices of stocks in a big way [12].
4. Technological developments and updates: It is clear that the further technological evolution and updates affect the projects related to cryptocurrencies. Alterations in the protocols, the security measures, or the nature of the technology in any way can result in shifts in the perceived market value of cryptocurrencies [1].
5. Regulatory considerations: Cryptocurrencies are still a new form of currency with new local and international regulatory frameworks and laws being passed often. Cryptocurrencies are unpredictable since new regulatory actions or changes in government benchmarks can impact the token's price [13].
6. Fraudulent activities and security risks: The cryptocurrency market is under high risks of fraud and security threats. These activities lead to the emergence of a situation that can dramatically change the prices of cryptocurrencies and, therefore, makes it more complicated to foresee them with a high level of certainty [14].
7. Inter-currency interaction: Often particular cryptocurrency prices like for Bitcoin may affect the prices of other cryptocurrencies. Transactions between various digital currencies create fluctuations which can be unpredictable [15].

IV. LITERATURE REVIEW

1. Deep Learning Models for Bitcoin Prediction Using Hybrid: This paper utilized more than 50,000 hourly Bitcoin price data from the period of May 2018 to January 2024 The study used complex models such as gradient descent, attention mechanisms, LSTM, and ANNs. As it was developed it complement LSTM with attention mechanisms and integrated gradient-specific optimization to further improve the predictive power of the model. The results of the work show that these hybrid models, and more specifically with the gradient-specific optimization, enhance the Bitcoin price prediction by utilizing the advantages of each approach discussed above [16].
2. Bitcoin price prediction using Deep Learning Algorithm: The goal of this paper is to forecast the Bitcoin USD price using a Bayesian Recurrent Neural Network and Long Short Term Memory Network. Using LSTM, the model had an accuracy of 52% and 8% RMSE which is better than conventional ARIMA models. Furthermore, a GRU model was applied, and utilizing deep learning models, the best results obtained with an enhancement of 94,7% in the GPU training time [17].
3. Bitcoin Price Prediction Based on Deep Learning Methods: This paper aimed at enhancing the performance of the deep learning techniques such as min-max normalization and the Adam optimizer in enhancing the accuracy of stock market prediction. When employing 56,832 observations of Bitcoin's price, the authors determined that MLP was ineffective because it lacked memory. On the other hand, LSTM and GRU models with past memory, gave better predictions [18].

V. ARTIFICIAL INTELLIGENCE AND PREDICTION

AI has achieved a lot in the area of prediction including in the areas of markets, and health, weather among other areas not mentioned. Some of the artificial intelligence methods and techniques found in prediction include the following [19].

V.1 MACHINE LEARNING (ML)

Machine learning ML is a branch in artificial intelligence that involves the use of algorithms to make predictions or decisions from data without being programmed. ML can be categorized into the following two main types [20]:

Supervised Learning: Supervised learning involves the use of training sets that is, the inputs are associated with their respective outputs or labels. During the training phase, the model acquires the knowledge of how to convert inputs into outputs, while during the testing phase, it is assessed. This method is widely applied to problems where historical labeled data is available Description of Supervised learning algorithms is shown in the Table (1) [21].

Table 1: Description of Supervised Learning Algorithms.

Algorithm	Description	Applications
Linear Regression	Establishes a linear relationship between input features and a continuous target variable.	Predicting continuous variables, e.g., house prices, stock prices.
Support Vector Machines (SVM)	Finds a hyperplane that best separates data points into distinct classes while maximizing the margin.	Image classification, spam detection, and medical diagnosis.
Decision Trees	Splits data into subsets based on feature values, creating a tree-like structure for prediction.	Fraud detection, loan approval, and risk assessment.
Random Forests	Combines multiple decision trees to improve predictive performance and reduce overfitting.	Credit scoring, stock market prediction, and customer segmentation.

Source: [22].

The most common types of machine learning methods are the supervised learning algorithms due to their use of labelled datasets which allow the models to be trained to directly map the input variables to the known outputs. The algorithms used in predictive analytics and classification include Linear Regression, Support Vector Machines, Decision Trees, and Random Forests. The quality and quantity of labeled training data are also highly relied upon to determine their effectiveness. Such techniques are especially useful in the areas, where one has the data about the past and is capable of learning patterns in order to make predictions in the future. But this can be disadvantageous with supervised learning models as they can overfit or undergeneralize when the training data is smaller or extremely skewed.

Unsupervised Learning: In unsupervised learning the model operates using data that do not contain any labeling and is aimed at finding patterns, correlations, or structures of data without prior information about the results. It is popular for use in the initial stages of data analysis and especially for identifying trends. Table (2) presents details of Unsupervised Learning algorithms [23].

Table 2: Description of Unsupervised Learning Algorithms.

Technique	Description	Applications
Clustering Algorithms	Group similar data points into clusters, e.g., K-Means and Hierarchical Clustering.	Customer segmentation, market basket analysis, and image compression.
Dimensionality Reduction	Reduces the number of features while retaining the data's essential information, e.g., PCA.	Visualization of high-dimensional data, noise reduction, and feature selection.

Source: [24].

Unsupervised learning is an important part of the exploratory data analysis of the data when there are no labeled datasets. Clustering and dimensionality reduction are techniques by which large datasets are identified as hiding structures, correlations, and patterns in the models. Clustering, such as, is used to cluster similar data instances and this is applicable in segmentation and in anomaly detection. Principal Component Analysis (PCA) is a method of dimensionality reduction that reduces large and complicated datasets while retaining valuable data. Such methods are especially useful with high-dimensional data. Irrespective of this, it is difficult to interpret the results of unsupervised learning models because predefined labels do not exist to assess the performance of models.

V.2 DEEP LEARNING (DL)

Neural Networks with more than one layer are used in DL which is a part of machine learning. It is most useful in case of large database and problems which are nonlinear in nature. Table (3) define Deep Learning (DL) algorithms [25].

Table 3: Description of Deep Learning Algorithms.

Model Type	Description	Applications
Convolutional Neural Networks (CNNs)	Extract hierarchical features from structured data such as images and videos.	Image recognition, object detection, and video analysis.
Recurrent Neural Networks (RNNs)	Process sequential data, maintaining temporal relationships using feedback loops.	Speech recognition, stock price forecasting, and language modeling.
Long Short-Term Memory (LSTM)	Overcomes RNN limitations by capturing long-term dependencies with memory cells.	Time-series forecasting, text generation, and financial predictions.

Source: [26]

The deep learning algorithms have contributed a lot to the functionality of machine learning so that systems with deep learning can automatically extract hierarchical features representations of large datasets. Convolutional Neural Networks (CNNs), Recurrent Neural Networks (RNNs), and Long Short-Term Memory (LSTM) networks are architectures that are popular in complex tasks that involve images, videos and sequential data. CNNs are especially useful at analyzing spatial data, whereas RNN and LSTM models are oriented at the recognition of temporal relationships in the sequence of information. Such models have been incredibly successful in computer vision, speech recognition and natural language processing. Nonetheless, deep learning models are usually run on big datasets, substantial amounts of computing power, and delicate hyperparameter adjustment.

V.3 REINFORCEMENT LEARNING (RL)

This kind of machine learning is a type of learning from experience, which involves an agent and its environment in the process of accomplishing a certain task. The model just has reward for right action and punishment for wrong action and it makes corrections for its strategy and actions. Table (4) delineate the Reinforcement Learning (RL) algorithms [25].

Table 4: Description of Reinforcement Learning Algorithms.

Use Case	Description	Examples
Trading Strategies	Optimizes decision-making in buying and selling stocks based on market conditions.	Algorithmic trading, portfolio optimization.
Robotics	Improves robot autonomy and efficiency in completing complex tasks.	Autonomous navigation, object manipulation.
Game Playing	Trains models to perform well in competitive environments by learning from outcomes.	Chess, Go, video games, and reinforcement-based simulations.

Source: [27]

The difference of reinforcement learning in comparison with other machine learning paradigms lies in the fact that it aims at understanding how to act in the best way, interacting with the environment. Under this scheme, the agent will be rewarded or punished depending on its actions and will keep on improving its decision-making scheme by trial and error. The reinforcement learning has proved to be useful in robotics, automated trading and intelligent gaming systems. It has the strength of being able to acquire adaptive strategies in changing and uncertain conditions. However, reinforcement learning models are computationally costly and in many cases, they take a long period of time to train, especially when the environment is complex in terms of state and action space.

V.4 NATURAL LANGUAGE PROCESSING (NLP)

Natural Language Processing (NLP) is about the interface between computers and languages used by humans. It utilizes models of machine learning and deep learning to work with textual data. Table (5) provides description of (NLP) techniques [28].

Table 5: Natural Language Processing (NLP) techniques.

Model	Description	Applications
Transformers	Advanced models like GPT and BERT designed for natural language understanding.	Text summarization, translation, and question answering.
BERT (Bidirectional Encoder Representations from Transformers)	Captures word context bidirectionally, making it ideal for sentiment analysis.	Sentiment analysis, trend prediction, and contextual text understanding.

Source: [28].

Natural Language Processing (NLP) aims at making computers comprehend, interpret and produce human language. Deep learning architectures that utilize transformer-based models (e.g., BERT and GPT) are highly used in modern NLP systems. These models acquire contextual dependencies between words and are highly effective in the performance of language understanding tasks. Applications in the field of machine translation, sentiment analysis, question answering and text summarization are some of the common applications of NLP techniques. The use of transformer models has brought a revolution in the field due to the enhanced awareness of context and scalability. Nevertheless, NLP models can be resource-intensive (in terms of the required training datasets and computation), and, still, they can be confused by ambiguity and specifics of domain language.

V.5 ENSEMBLE METHODS

Ensemble methods enhance model performance by combining multiple learners to reduce errors and increase accuracy. Table (6) shows Ensemble Methods [29].

Table 6: Ensemble Methods.

Method	Description	Applications
Boosting	Sequentially improves weak learners, e.g., AdaBoost and Gradient Boosting Machines (GBM).	Fraud detection, loan default prediction.
Bagging	Combines predictions from multiple models using resampling, e.g., Random Forests.	Customer segmentation, product recommendation.
Stacking	Trains a meta-model on predictions from base models for better performance.	Financial forecasting, ensemble predictive analytics.

Source: [29].

Ensemble learning approaches are designed to enhance predictive accuracy through the integration of a number of machine learning models into a strong framework. Boosting, bagging, and stacking are methods that can be used to minimize the modeling errors and enhance the stability of the models. The iterative boosting techniques improve weak learners and the bagging techniques minimize variance using resampling techniques. Stacking also enhances performance based on a meta-model of combining predictions made by base learners. They are common in complicated predictive problems where one model is not likely to store all the patterns in the data. Although not the least effective, ensemble approaches can become more expensive to compute and demand selection and parameter optimization of models.

V.6 TIME SERIES ANALYSIS

Time series analysis is used for analyzing and predicting data that evolves over time. It is particularly relevant in fields like finance, weather, and inventory management. Table (7) shows Time Series Analysis [30].

Table 7: Time Series Analysis.

Technique	Description	Applications
ARIMA (Auto Regressive Integrated Moving Average)	Combines autoregressive and moving average components to model and forecast time-series data.	Forecasting stock prices, sales, and demand trends.
Prophet	A user-friendly forecasting tool designed for capturing seasonality and trend components.	Business forecasting, revenue prediction, and anomaly detection.

Source: [30].

The time series analysis is dedicated to modelling and predicting time varying data, which is critical in the financial field, energy use, and weather forecasting. Logistic regression methods, including ARIMA and Prophet, have been popular in capturing trend, seasonal and temporal dependencies in a sequence of data. ARIMA models are especially useful in statistical forecasting whereas Prophet offers a more generic model when dealing with seasonality and irregular trends. The practices help organizations to make sound decisions when future predictions are made. Nevertheless, proper prediction needs very good historical data and the forecasting models might fail in instances where there occurs an abrupt shift in the structure of the system or some other unforeseen anomalies.

V.7 BAYESIAN NETWORKS

Bayesian networks are probabilistic graphical models that represent a set of variables and their conditional dependencies. They are particularly useful in scenarios where uncertainty must be accounted for in decision-making. Table (8) shows Bayesian Networks [31].

Table 8: Bayesian Networks.

Applications	Description
Risk Assessment	Helps model and predict potential outcomes and risks.
Medical Diagnosis	Used to identify diseases based on symptoms and test results.

Source: [31].

Bayesian networks are a probabilistic model that can be used to describe complex systems that have uncertain dependencies among variables. These graphical models display the conditional dependencies in the form of directed acyclic graphs which enable researchers to learn the cause-and-effect relationships as well as do probabilistic inferences. Applications of Bayesian networks in decision support applications, medical diagnosis applications, and risk assessment applications are common. They are especially effective in uncertain conditions because they can apply the previous knowledge and update the probabilities with regard to the new information. Nevertheless, it may be computationally difficult to build the correct Bayesian network structures in the presence of many variables and complicated dependency functions.

V.8 GENETIC ALGORITHMS

Genetic algorithms are optimization techniques inspired by natural selection. They iteratively improve solutions by mimicking biological evolution. Table (9) shows Genetic Algorithms [32].

Table 9: Genetic Algorithms.

Stage	Description	Applications
Selection	Chooses the best candidates based on fitness.	Portfolio optimization, route planning, engineering design.
Crossover	Combines parent solutions to generate offspring.	Product development, genetic programming.
Mutation	Introduces random changes to maintain diversity.	Complex problem-solving, evolving trading strategies.

Source: [32].

Genetic algorithms are evolutionary algorithms that are based on the concept of natural selection and biological evolution. The processes used in searching optimal or near-optimal solutions in them include selection, crossover and mutation. These algorithms have been used especially in solving complex optimization problems, which would not be easily solved by traditional methods because of large search space or nonlinear constraints.

Genetic algorithms are used extensively in the design of engineering, financial optimization, scheduling, and artificial intelligence. Although genetic algorithms are flexible, they necessarily need to be tuned by hand, and can have a slow convergence rate, particularly if the search space is very large or the fitness function is complicated.

VI. METHODOLOGY AND IMPLEMENTATION

Figure (1) shows a full workflow of model creation and assessment of a Long Short-Term Memory (LSTM) model to make predictions or analysis using data. It is carried out through a series of steps of a structured machine learning pipeline that starts with the acquisition of raw data and moves through a series of steps such as preprocessing, feature engineering, model training, and performance evaluation. Each of the steps allows properly preparing the dataset and making sure that the resulting model will succeed in learning patterns and making reliable predictions. The first step is Data Collection which is the process of getting raw data out of the sources that are relevant. This information can be in databases, sensors, open repositories, or real time streams based on the field of application. The data can also have anomalies, missing values or other irrelevant characteristics at this point, and can therefore be further processed before modelling is done. After collecting the data, the next step of the work is Data Exploration and Visualization. This step is aimed at getting to know the form and properties of the data set gathered. Patterns, anomalies and interrelations among variables are detected using techniques like statistical summaries, correlation analysis and visual techniques like charts or plots. Data exploration is quite necessary since it assists the researchers to learn about the data set and identify the most relevant approach of preprocessing and modeling. The second step is Data Preprocessing which involves cleaning and readying of raw data to be used in machine learning. Preprocessing tasks normally involve processing any missing data, eliminating duplicates, reconciliation of inconsistencies and in case of need, the conversion of categorical data into numerical form. Good preprocessing enhances the quality of data and gives the model consistent and meaningful data.:

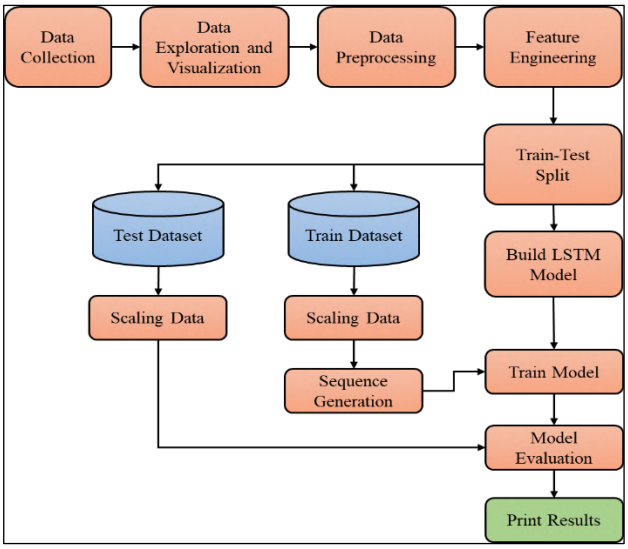

Figure 1: Methodology Block Diagram.
Source: Authors, (2026).

Following the preprocessing, Feature Engineering is used. During this phase, the appropriate features are chosen or developed to increase the learning capacities of the model on the data. The feature engineering process can be in the form of deriving new features, modifying the existing features, or doing away with redundant features. Good feature engineering could without any doubt enhance predictive power of machine learning models. After the features are ready the Train-Test Split process is used to divide the dataset. The data is divided into two subsets, the training data, which is used to train the model, and the testing data, which is used to assess the performance of the model on unseen data. Such partition can be used to measure the generalization capabilities of the model to new data and avoid overfitting. The training and testing data sets are subjected to Scaling Data which normalizes or standardizes the values of feature values to a similar range. Scaling is especially relevant to neural network models such as LSTM as it stabilized the process of training and speeded up the convergence. Once the training dataset has been scaled up, it is followed by Sequence Generation. Given that LSTM models expect that data is sequential or time-dependent, it must be converted into a form of sequences that are time-dependent. This stage will arrange the input data into temporal chains through which the LSTM network can acquire temporal dependencies and patterns with time. Then, Build LSTM Model phase specifies the neural network structure. The model normally has LSTM layers which form temporal relationship then more layers like dense layers to make predictions. This stage is used to configure model parameters, activation functions and optimization algorithms. After the construction of the model, the workflow goes to Train Model where the LSTM network is trained to learn patterns on the training data by the use of optimization. The model adapts its internal weights during training to reduce the error of prediction. After training is completed, Model Evaluation is performed using the testing dataset. Evaluation metrics such as accuracy, mean squared error, or other performance indicators are calculated to measure the model's effectiveness.

VI.1 DATA COLLECTION

The data collection phase focuses on gathering historical Bitcoin price data as the foundation for analysis and prediction. The Yahoo Finance API was used to retrieve daily data from January 1, 2015, to June 1, 2024. The dataset includes the following key columns.

Table 10: The dataset includes the following key columns.

Column	Description
Date	The timestamp for each entry, used to organize the data chronologically.
Open	The opening price of Bitcoin for the day.
Low	The lowest price recorded during the day.
High	The highest price recorded during the day.
Close	The closing price, reflecting the market's sentiment at the end of the day.
Adj Close	Adjusted closing price, accounting for stock splits or other adjustments.
Volume	The total number of Bitcoin units traded during the day, representing activity.

Source: Authors, (2026).

Table 10 offers all the basic variables needed to examine the price movements of Bitcoin and construct predictive models. Each column records a specific phenomenon of the market behavior such as price dynamics and trading activity. The open, high, low and close prices explain the daily price changes, which are fundamental to comprehend the volatility and trending. Adjusted close value is used to continue consistency in financial analysis in case of some adjustments. In the meantime, the trading volume indicates the market participation and liquidity. The combined variables will be a full depiction of the market conditions and act as essential inputs to further analysis, feature engineering, and model training phases.

VI.2 DATA EXPLORATION AND VISUALIZATION

To understand the data's underlying characteristics and trends, Exploratory Data Analysis (EDA) was conducted. Visualization tools were used to create meaningful insights:

Table 11: Data Exploration and Visualization.

Visualization	Purpose
Close Price Plot	Tracks the historical closing prices of Bitcoin to identify trends and price cycles.
Histogram and Density	Analyzes the distribution of Bitcoin closing prices to understand common price ranges.
Candlestick Plot	Combines open, high, low, and close prices, providing detailed insights into price movements.

Source: Authors, (2026).

The illustrations to be discussed in Table 11 are essential in perceiving the general dynamics of Bitcoin prices throughout the years. The close price plot enables the researcher to see long-term trends, cyclicality and abrupt changes which can point at volatility in the market or other external economic factors. The histogram and the density plots could be used to examine the statistical distribution of closing prices and reveal the common price ranges and determine potential skewness or outliers. Moreover, the candlestick chart provides a detailed display of price fluctuations of each trading day, through the combination of open, high, low and close values. The methods of exploration allow interpreting the dataset more effectively and allow making informed decisions in preprocessing and modeling phases.

VI.3 DATA PREPROCESSING

Preprocessing ensures the dataset is clean and ready for model training. Several steps were undertaken:

Table 12: Data Preprocessing.

Step	Description
Handling Missing Values	Missing data was filled using forward filling, and remaining null values were removed.
Scaling Data	Normalized using MinMaxScaler to scale all features between 0 and 1. Separate scalers were used to prevent data leakage.
Sequence Generation	Created time-series sequences with a 30-day window size, ensuring sufficient historical context for predictions.

Source: Authors, (2026).

As shown by Table 12, the following preprocessing tasks are necessary to prepare the dataset to be easy to train in machine learning. The process of working with missing values will make sure that incomplete records will not harm the learning process of the model. Forward filling is also useful in preserving the continuity of a time-series data with minimal loss of information. Scaling of the data set with MinMaxScaler standardizes the features in a similar range, thus enhancing the stability of the training of the neural network and faster convergence. Also, time-series sequences generate time-series data, which are structured as input to sequential models like LSTM. These preprocessing steps are very important in improving the data quality and it also makes sure that the model is presented with sound and well-organized inputs.

VI.4 FEATURE ENGINEERING

To enhance the dataset's predictive power, key financial indicators were added. These indicators capture different aspects of market dynamics:

Table 13: Feature Engineering.

Indicator	Description
Simple Moving Average (SMA)	Calculates the average of closing prices over specified periods (e.g., 20 and 50 days) to smooth trends.
Exponential Moving Average (EMA)	Similar to SMA but gives more weight to recent prices, making it more responsive to changes.
MACD (Moving Average Convergence Divergence)	Tracks momentum using the difference between short-term and long-term EMAs.
RSI (Relative Strength Index)	Identifies overbought or oversold conditions, ranging from 0–100.
Volatility Measures	Includes ATR (Average True Range) and standard deviation to assess price volatility.
Bollinger Bands	Highlights overbought/oversold conditions using upper and lower price bands based on standard deviations.

Source: Authors, (2026).

Introducing domain knowledge into the dataset through feature engineering is essential in the quality of prediction of machine learning models. The financial indicators in Table 13 represent various market behavior components, such as market trends, market momentum, and market volatility. SMA and EMA are moving averages that are used to smooth out fluctuations and identify long-run trends. Such indicators as MACD and RSI give us the information about the momentum in the markets and possible overbought or oversold. Volatility indicators like ATR and Bollinger Bands also assist in determining times of instability of a market. The combination of these indicators provides the model with a more in-depth contextual information increasing its capability to model complex price dynamics.

VI.5 TRAIN-TEST SPLIT

The dataset, spanning 3440 days, was divided into training, validation, and test sets to ensure robust model evaluation:

Table 14: Train-Test Split.

Subset	Duration	Purpose
Training Set	January 1, 2015 – April 1, 2023	Used to train the model on historical data (3012 days).
Validation Set	April 2, 2023 – October 2, 2023	Fine-tuning hyperparameters and evaluating generalization (214 days).
Test Set	October 3, 2023 – June 1, 2024	Assessing model performance on unseen data (214 days).

Source: Authors, (2026).

The division plan of the dataset used in Table 14 provides a dependable assessment of the predictive model. The division of the dataset into training, validation and testing subset is important as it gives the model the opportunity to learn on historic data without bias in evaluation on unprecedented data. Most of the data is found in the training set, which is employed to acquire patterns and relationships among variables. The validation set aids in the hyperparameter tuning and also helps in avoidance of overfitting by testing the model in the course of development. Lastly the test set is used to give a final evaluation of the predictive power of the model on new data. This organized separation increases the accuracy and validity of the experimental findings.

VI.6 SCALING DATA

To normalize data for model training and improve performance, MinMaxScaler was applied:

Table 15:Scaling Data.

Scaling Step	Description
Feature Scaling	All features were scaled between 0 and 1 to prevent larger values from dominating the training process.
Data Leakage Prevention	Separate scalers were applied to training and test data to avoid unintentional leakage.

Source: Authors, (2026).

Preprocessing Data Scaling Data scaling is an important preprocessing step when training neural network models, especially gradient-based optimization. The use of MinMaxScaler will make sure that all the input features are put within a similar range between 0 and 1. This normalization avoids larger numeric ranges of features controlling the training process, and enhances numerical stability in model optimization. Moreover, using distinct scalers in training and testing data sets can be used to avoid data leakage, which otherwise will result in overly optimistic estimates of performance. Scaling ensures that faster convergence is achieved during the training process and enhances the overall performance and stability of the LSTM model by standardizing the values of features.

VI.7 SEQUENCE GENERATION

For time-series modeling, sequences of fixed length (30 days) were created to capture historical context. The sequence generation step involved:

Table 16: Time-Series.

Window Size	Purpose
30 Days	Provides sufficient historical context without introducing unnecessary computational overhead.
Longer Window Sizes	Tested but showed diminishing returns in prediction accuracy.
Shorter Window Sizes	Reduced model performance due to inadequate historical information.

Source: Authors, (2026).

Sequence generation is a fundamental step in preparing data for time-series models such as LSTM networks. Instead of treating each observation independently, the dataset is transformed into sequential windows that capture historical dependencies. As shown in Table 16, a 30-day window size was selected to provide sufficient historical context while maintaining computational efficiency. This approach enables the model to learn temporal patterns and relationships that influence future Bitcoin price movements. Experiments with longer windows showed limited improvements in prediction accuracy, while shorter windows lacked adequate historical information. Therefore, the chosen sequence length provides an effective balance between model complexity and predictive performance.

VI.8 MODEL BUILDING: LSTM ARCHITECTURE

The LSTM model was designed to capture temporal dependencies in Bitcoin price data. The architecture is simple yet effective:

Table 17: LSTM Architecture.

Layer	Configuration
Input Layer	150 LSTM units to process sequential data and retain long-term dependencies.
Dense Layer	1 unit with linear activation to predict the next Bitcoin price (continuous regression output).
Optimizer	Adam optimizer, chosen for its adaptive learning capabilities and stability.
Loss Function	Mean Squared Error (MSE), used to minimize prediction errors.
Training	100 ochs with a batch size of 10 to balance learning efficiency and computational cost.

Source: Authors, (2026).

The LSTM architecture described in Table 17 is designed to effectively capture temporal dependencies in Bitcoin price data. LSTM networks are particularly suitable for time-series prediction because they incorporate memory cells that retain important information over long sequences. The model begins with an LSTM layer containing 150 units, allowing it to learn complex temporal relationships within the input sequences. A dense output layer with linear activation is used to generate continuous price predictions, which is appropriate for regression tasks. The Adam optimizer ensures efficient gradient-based learning, while the mean squared error loss function minimizes prediction errors during training. This architecture provides a balance between model complexity and computational efficiency.

VI.9 MODEL EVALUATION AND PREDICTION

Thus, after the training of the model, we check its efficiency through specific criteria such as Mean Squared Error (MSE). china's predicted prices and actual prices are also cross plotted to evaluate the performance as shown: The model is then used to predict prices of Bitcoin which assist in analyzing future trends. This actually gives elaboration on each step in the methodology making it clearer and making sure that any person who reads the methodology understands the steps that are being taken in the process.

VII. RESULTS AND DISCUSSION

VII.1 VISUALIZE TRAINING AND VALIDATION LOSS

Figure (2) demonstrates the Model Loss graph of the LSTM model during training and validation epoch by epoch up to one hundred. On the y-axis we have the loss values while the x-axis has the number of epochs. The first one in blue is the training loss, and the second one in orange is the validation loss. At first, when the number of epochs is low, which is the case in the first 10 epochs in this paper, the validation loss is much higher than the training loss which suggests that the model is yet to fully learn the patterns in the data and generalize the patterns to unseen data. Yet, the training and the validation losses decrease quickly during the first 20 epochs which shows that the model is learning significant features concerning the training set. After about 20 epochs, the validation loss becomes almost flat and fluctuates around a sufficiently small constant, while the training loss remains gradually decreasing and becomes almost zero. This shows that the model learning is able to capture the patterns of the data without overfitting the dataset as the difference between training and validation loss is still reasonable. The validation loss is relatively smooth and close to zero indicating good generalization capability when learning new data, although small oscillations in loss during the later epochs might have been caused by variations in the validation batches.

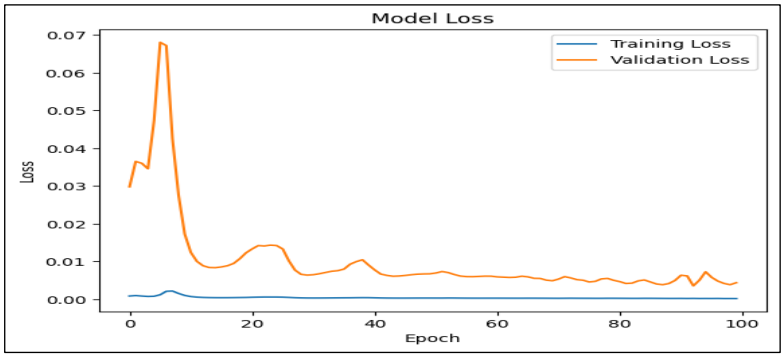

Figure 2. Model Loss.
Source: Authors, (2026).

In summary, the graph represents the LSTM model in a good performance learning in training phase and good generalization in validation phase. Such an advantage of the selected architecture, preprocessing steps, and hyper parameters has helped enhance the proposed model for accurate predictions of the given time-series data.

VII.2 MODEL EVALUATION

The performance of the LSTM model was evaluated using three key metrics: These include; Mean Absolute Error (MAE), Mean Squared Error (MSE) and Root Mean Squared Error (RMSE). These metrics help understand the degree of correctness of the issued prediction by the model. The MAE quantifies the mean of the absolute differences between the estimated and the actual prices, on the other hand, the MSE quantifies the arithmetic mean of the squared differences with an inclination towards relatively large errors. RMSE again derived from MSE is more understandable as it is in the same unit as the target variable. Moreover, the observed prices were graphed with the predicted prices in order to get deeper insight and to see whether the model is capable of identifying patterns.

Table 18: Model Evaluation.

Metric	Value	Description
MAE	0.00622	The average absolute error between predicted and actual values, indicating high accuracy.
MSE	8.39651	The mean of squared errors, highlighting how well the model minimizes larger deviations.
RMSE	0.00916	The square root of MSE, showing an interpretable measure of prediction accuracy.

Source: Authors, (2026).

These metrics establish the model as a useful one because of low error values depicted below the bar for all the metrics. The comparison of the trends of the actual and predicted prices also supports the proposed model's ability to provide a good estimate for prices.

VII.3 VISUALIZATION ACTUAL VS. PREDICTED PRICES

The differential LSTM model is illustrated in the graph shown below titled "Actual vs. Predicted Cryptocurrency Prices" with days on the x-axis and normalized prices on the y-axis. The black line at the bottom is the actual values, while the grey line is the forecasted values. It accurately also reflects actual depreciation and appreciation of the model closely thus mimicking the actual price movements. In the less volatile periods (days 25–50 and 125–150), the model provides almost identical predictions to actual prices, proving the effectiveness of the model during stable periods. During more active periods (days 50-60, and 160-175), the model accurately identifies the direction and size of major price fluctuations with only slight distortion in both over- and underestimations of certain movement. Taken together, the differences between the actual and predicted prices are rather small and the low error measures (MAE, MSE, RMSE) prove the efficiency of the model. What this visualization shows is that LSTM model is indeed an ideal tool for predicting the future trends of cryptos' prices.

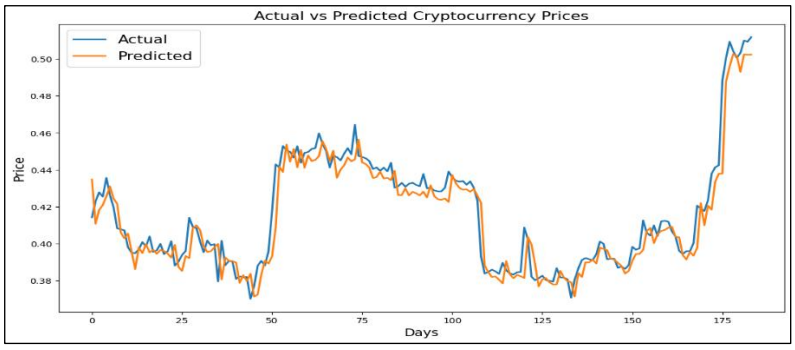

Figure 3: Visualization Actual vs. predicted prices.
Source: Authors, (2026).

VII.4 RESULTS DISCUSSION

Our analysis showed that the historical data can be employed to provide the price for the digital currency, with the focus on Bitcoin for this paper. The data can be considered as a factor to the model performance; for example, if the paper uses more data the prediction model performance may increase. There also has potential to generalize the method to other tasks such as parameter tuning for the model, testing various features, and using more complex deep learning architectures.

VIII. CONCLUSIONS

This paper shows how historical data and technical indicators can be employed for forecasting Bitcoin prices with reasonable accuracy. With the help of Yahoo Finance API, a detailed set of data from January 1, 2015, to June 1, 2024, was obtained and supplemented by Moving Averages, RSI, and Bollinger Bands. Using an LSTM-based deep learning model, we achieved robust results, with low error metrics (MAE: 0.A low MAE: 00.00622, MSE: 8.39651, RMSE 0.00916 and close relationship between actual and predicted price movement also shows the robustness of the model. These results indicate that the model is capable of modelling both stable and unstableness of the market and therefore perhaps useful in the cryptocurrency prediction of the prices. We may venture into making future work improvements by adding extra attributes, adjusting the hyper parameters, or using the compound models to augment the predictions in the future. This work also emphasizes the fact that data quality and complex machine learning techniques are vital for solving the issues faced in regression model based cryptocurrency price prediction under a very noisy environment.

ABSTRACT

The need to have environmentally friendly lubricants has triggered a lot of research on the development of biodegradable and renewable alternatives to petroleum-based oils. The intrinsic lubricity of vegetable oils like cottonseed oil (CSO) and palm oil (PO) is due to the polar ester structures in them; however, limitations in wear properties and load-carrying capacity restrict their direct application in industries. This experiment compares the tribological behavior of CSO, PO, and a hybrid CSO-PO mixture with nano-additives (MoS2, TiO2, and SiO2) at 1, 1.5 and 2 wt.% and compares these formulations with a commercial synthetic lubricant (SAE 20W50). Nano-enhanced bio-lubricants were made through the controlled dispersion method and evaluated with a four-ball tribotester under the ASTM D4172 conditions. Wear scar diameter (WSD) and coefficient of friction (COF) were the main performance indicators. The data show that the addition of nanoparticles significantly enhances tribological behavior, and 1.5 wt% is the most optimal loading. The hybrid CSO-PO + 1.5 wt% MoS2 had the lowest WSD (509 µm) and COF (0.061). Compared to the synthetic oil (WSD = 530 µm and 0.088), the optimized nano-bio lubricant had a 3.96% wear reduction and a 30.68% friction reduction. These results indicate that nano-enhanced hybrid vegetable oil formulations, particularly those containing MoS2, have the potential to provide better friction reduction and competitive wear resistance, and thus have a high potential as sustainable, high-performance alternatives to traditional synthetic lubricants.

I. INTRODUCTION

The increase in the rate of industrialization and the growth of global energy demand have enhanced the use of petroleum-based lubricants in transportation and manufacturing industries, thus increasing the sustainability issues [1] [2]. Traditional lubricants that are based on petroleum are mostly non-biodegradable, and their lifecycle, including production, utilization, and disposal, has a great impact on the environment, such as soil and water pollution, greenhouse gas emissions, and long-term ecological damage [3] [4]. Lubricants that are based on minerals release toxic substances into the environment when improperly disposed of or accidentally spilled, thus becoming hazardous to ecosystems and human health [5] [6]. Due to the growing environmental effects and the growing regulatory systems that favor sustainability, there has been an increasing pressure to substitute mineral lubricants with renewable, biodegradable, and low-toxicity lubricants [7] [8]. Modern studies emphasize the fact that it is high time to switch to eco-friendly, renewable, and bio-based lubricants in order to reduce the impact on the environment and maintain tribological properties [9] [10]. Vegetable oils have received a lot of interest as bio-lubricant base stocks due to their natural high lubricity, high viscosity index, biodegradability, and low volatility compared to mineral oils; therefore, they are promising sustainable alternatives in tribological applications [11] [12]. However, the inherent characteristics of unmodified vegetable oils are not as good as they have poor oxidation stability, limited thermal resistance, and inadequate cold-flow properties, which restrict their direct use in high- or low-temperature operating environments [13] [14].

CSO and PO are among the most appealing vegetable oils because of their triglyceride structures, which have a high concentration of long-chain fatty acids (e.g., oleic, linoleic and palmitic acids), which significantly determine the viscosity behavior and oxidative properties [15] [16]. The presence of polar ester functional groups in these fatty acid chains increases surface adsorption and boundary-film formation, which, in turn, improves the friction reduction and wear resistance; this is the key to the high lubrication potential of CSO and PO in tribological systems that are sustainable [17] [18]. To address the challenges of the contemporary tribosystems, the introduction of nano-additives into lubricants has become a necessity to increase the load-carrying capacity, reduce surface damages, and satisfy the requirements of the modern tribosystems [19] [20]. High surface activity and contact interface interaction are the characteristics of nanoparticles that enhance tribological performance by drastically lowering friction and wear [21] [22]. The main improvement processes are the rolling effect, which involves the use of nanoparticles as nano-bearings; tribo-film formation, which creates a protective layer of the surface; the mending effect when the nanoparticles fill the surface asperities; and the polishing effect when the nanoparticles smooth worn surfaces during sliding [23] [24]. In particular, molybdenum disulfide (MoS2) is well-known as an effective layered solid lubricant, as it has low interlayer shear strength; titanium dioxide (TiO2) nanoparticles have high anti-wear and protective film-forming properties; and silicon dioxide (SiO2) nanoparticles provide nano-bearing and surface smoothing effects, which makes these materials highly promising in the development of advanced nano-lubricant formulations [25] [26].

The tribological analyses play a critical role in assessing the frictional behaviour, the wear resistance, and the load-carrying capacity of lubricants under simulated contact conditions, thus allowing the reliable examination of their ability to perform in the real-life mechanical systems [27] [28]. The four-ball tribometer under ASTM D4172 is one of the most commonly used methods of testing the anti-wear and friction-reducing properties of lubricants in a controlled load, speed, and temperature environment [29] [30]. The four-ball testing provides the key performance indicators WSD and COF as the former measures the material loss and surface damage, and the latter measures the capacity of the lubricant to reduce resistance between sliding surfaces [31] [32]. The recent developments in nano-enhanced biodiesel lubricants highlight their increasing potential as the alternative to the traditional mineral oils due to the significant enhancement of their viscosity, thermal stability, and tribological properties. Initial studies with metallic and metal-oxide nanoparticles proved their usefulness in improving the lubrication properties of vegetable oils. Singh et al. [33] found that the addition of 0.9% copper nanoparticles to modified desert date oil significantly lowered the COF, wear rate, and surface damage, whereas Singh et al. [34] found that 0.6% SiO2 nanoparticles enhanced the surface morphology and the overall tribological performance of the Balanites aegyptiaca oil. In the same way, Chinnachamy et al. [35] showed that the addition of silver nanoparticles into the Jatropha and Pongamia oils increased the viscosity, thermal conductivity, and wear resistance, thus indicating the positive effect of noble metal additives. Adding to these results, Prabhakaran et al. [36] demonstrated that addition of 0.240.4 wt.% of the CuO nanoparticles to modified Kusum oil enhanced viscosity, flash point, and tribological properties, which confirmed its suitability in industry.

Similar progress on iron-oxide systems has yielded encouraging outcomes. The castor-oil-based bio-lubricant with Fe3O4 nanoparticles and ethylene glycol developed by Ahmad et al. [37] had a production yield of 94% and achieved a 50% decrease in friction and a 40% decrease in wear. Aithal et al. [38] have found that PEG-coated Fe3O4 nanoparticles showed a maximum of 70% wear reduction in the presence of neem oil, which greatly improved the viscosity retention and thermal conductivity. Similarly, Sadiq et al. [39] showed that maghemite nanoparticles enhanced viscosity, thermal conductivity, and anti-wear properties of vegetable oil, and Sadiq et al. [40] went a step further to add graphene and maghemite nanoparticles to coconut oil, which enhanced oxidation stability, thermal degradation, and friction and wear behavior, which could be used in high-temperature machining.

Carbon based nano-additives have also become very effective reinforcement material in bio-lubricant systems. Kumar et al. [41] have indicated that palm-oil-commercial oil blends that incorporated 0.1 wt% functionalized multi-wall carbon nanotubes (FMWCNTs) reduced the wear-scar diameter and wear volume by 38 and 35%, respectively. Applying this study to bearing applications, Kamarapu et al. [42] showed better tribological and vibration characteristics with FMWCNT-blended palm oil, which retained its lubrication capacity during 80% of the working time. Nugroho et al. [17] also used carbon and oxide nanoparticles in the lubrication of electric-vehicles and demonstrated that palm-oil-based lubricants with additives of graphene, TiO2, and Al2O3 decreased the COF by up to 34% and enhanced wear resistance.

Complementary research by Ravikiran et al. [43] found that TiO2 and SiO2 nanoparticles increased viscosity, flash point, and wear resistance of canola-wheat germ oil mixtures, whereas Madhwesh et al. [44] found that TiO2-enhanced jojoba bio-lubricants increased engine efficiency and lowered emissions. Even though Katpatal et al. [45] found that the CuO nanoparticles did not have a significant effect on the pressure distribution in journal bearings, their experiment proved that the bio-lubricant formulations could reach the same frictional performance as ISO VG46 mineral oil. These studies, together, highlight the transformative nature of nanoparticles, metallic, metal-oxide, and carbon-based, in increasing the tribological performance of bio-lubricants, as well as their thermal stability, which would enhance their efficacy as viable, sustainable substitutes to industrial and automotive applications. Although a lot of literature has been done on nano-enhanced bio-lubricants, very little research has been done to compare the various types of nanoparticles and their concentrations in a hybrid vegetable oil system and compare their performance with commercial synthetic lubricants under the same operating conditions. Moreover, the blending effect of base-oil (CSO-PO) and layered MoS2 reinforcement has not been sufficiently investigated. The current paper fills this gap by performing an extensive comparative study of MoS2, TiO2, and SiO2 at optimal concentrations in a hybrid bio-lubricant system and finding an optimum formulation with much better friction reduction and competitive wear resistance compared to synthetic oil.

II. MATERIALS AND METHODS

This section outlines the materials used and the experimental methods used in the synthesis and testing of nano-enhanced bioderived lubricants. The methodology includes the choice of base oil, nanoparticle dispersion plans, and tribological evaluation in the conditions of four-ball tests.

II.1 BASE OILS

The three vegetable-based oils and one commercial synthetic lubricant were used as base fluids in the present study to conduct tribological assessment. Refined CSO was purchased at a local agricultural supplier and used without any further chemical treatment. Refined edible grade PO, also sourced through a local supplier, was chosen due to its desirable fatty acid profile and established lubrication properties. A hybrid oil (CSO-PO) was made by mixing cotton seed oil and palm oil in a constant volume ratio of 50:50 (v/v). The blending was done by continuous mechanical stirring at ambient temperature to achieve uniformity and homogeneity of the resulting hybrid formulation. Besides the vegetable oils, a commercially available fully synthetic engine oil (SAE 20W50 grade) was used as a reference lubricant to be compared. All base oils were filtered before experimentation to remove suspended impurities and kept in airtight and dark glass containers in ambient laboratory conditions to reduce oxidation and moisture uptake.

II.2 NANOPARTICLE ADDITIVES

Three different nanoparticle species were added to the tribological properties of the chosen base oils as lubricant additives: molybdenum disulfide (MoS2), titanium dioxide (TiO2), and silicon dioxide (SiO2). All nanoparticles were obtained through certified chemical vendors with reported purities of over 99% and average particle diameter of 30-50nm. The particles were kept in hermetically sealed containers in a desiccated environment before their deployment to reduce the uptake of moisture and agglomeration. Molybdenum disulfide (MoS2) nanoparticles have a highly layered lamellar crystal structure that allows interlayer slippage during shear and, therefore, decreases friction and increases load-bearing capacity. Titanium dioxide (TiO2) nanoparticles have strong thermal stability and surface interaction characteristics, which enhance the anti-wear properties and the development of protective films in sliding. Silicon dioxide (SiO2) nanoparticles, which are usually in the form of a sphere or amorphous, are known to facilitate rolling and polishing activities at the interface of contact, resulting in less wear and better surface smoothness. In the current study, the different classes of nanoparticles were added to the base oils at three different weight percentages of 1, 1.5, and 2% to determine the effect of additive loading on the reduction of friction and wear resistance at otherwise the same test conditions.

II.3 PREPARATION OF NANO-ENHANCED LUBRICANTS

The nano-enhanced lubricants were prepared by dispersing molybdenum disulfide (MoS2), titanium dioxide (TiO2), and silicon dioxide (SiO2) nanoparticles in the chosen base oils (Cotton Seed Oil (CSO), PO, a mixture of CSO and PO, and a synthetic oil) at a fixed mass fraction of 1 wt%, 1.5 wt%, and 2 wt%. The amount of nanoparticles to be used in each sample was determined by the total mass of the lubricant system and then measured with a precision digital balance with a calibration error of ±0.001g. The dispersion process was developed as a two-step process to obtain homogeneous distribution of the particles with a minimum agglomeration. The weighed nanoparticles were added to the base oil in the first stage under constant mechanical stirring at about 600 rpm and a period of 30 minutes at room temperature. This pre-mixing step helped to wet the nanoparticles in the oil matrix and pre-mix them. The partially mixed slurry was then ultrasonicated using a probe-type sonicator over 45 minutes, which disperse any remaining aggregates and enhances the stability of the suspension. During ultrasonication, the temperature was constantly checked and kept at a constant level in order to avoid thermal degradation of the oil. No surfactants or chemical dispersants were added so as to maintain the inherent physicochemical characteristics of the base oils. After the preparation, the nano-enhanced lubricants were placed in opaque glass containers with no air and left to stabilize over 24 hours under the laboratory ambient conditions before tribological testing was initiated. This stabilization phase guaranteed the formation of dispersion equilibrium and minimized the tendency towards sedimentation in the further experimental assessment.

II.4 EXPERIMENTAL TEST SETUP

The prepared lubricants were evaluated in terms of tribological performance by a four-ball tribotester in compliance with ASTM D4172 standards. Before testing, the AISI 52100 chrome steel balls (12.7 mm diameter, approximately 64 HRC) were carefully washed with acetone to remove any contaminants and then dried to create equal contact conditions. The three stationary balls were clamped in the test cup and completely immersed in the lubricant sample, and the fourth ball was placed on the rotating spindle and contacted with the stationary balls under a given load. All experiments were performed at a constant load of 60 minutes at a fixed temperature. A continuous measurement and recording of COF was done through integrated data acquisition system which was linked to a computer interface. After the test was completed, the balls were thoroughly removed, washed and under a high-resolution optical microscope to measure the wear scar diameter (WSD). Each wear scar was measured twice perpendicularly and averaged to obtain the final WSD. The WSD of each lubricant is the average of the values of the three stationary balls. Table 1 summarizes all the operating parameters that were kept in the course of the experiments. The experiments were conducted in the same conditions and repeated thrice to guarantee the repeatability and reliability of the experimental results.

Table 1: Key Specifications of Tribological Test Conditions.

Parameter	Specification
Test Standard	ASTM D4172
Load	40 kg (392 N)
Rotational Speed	1200 rpm
Test Duration	60 minutes
Test Temperature	75 ± 2 °C
Ball Material	AISI 52100 steel
Ball Diameter	12.7 mm (½ inch)
Ball Hardness	~64 HRC
Measured Parameters	COF, WSD

Source: Authors, (2026).

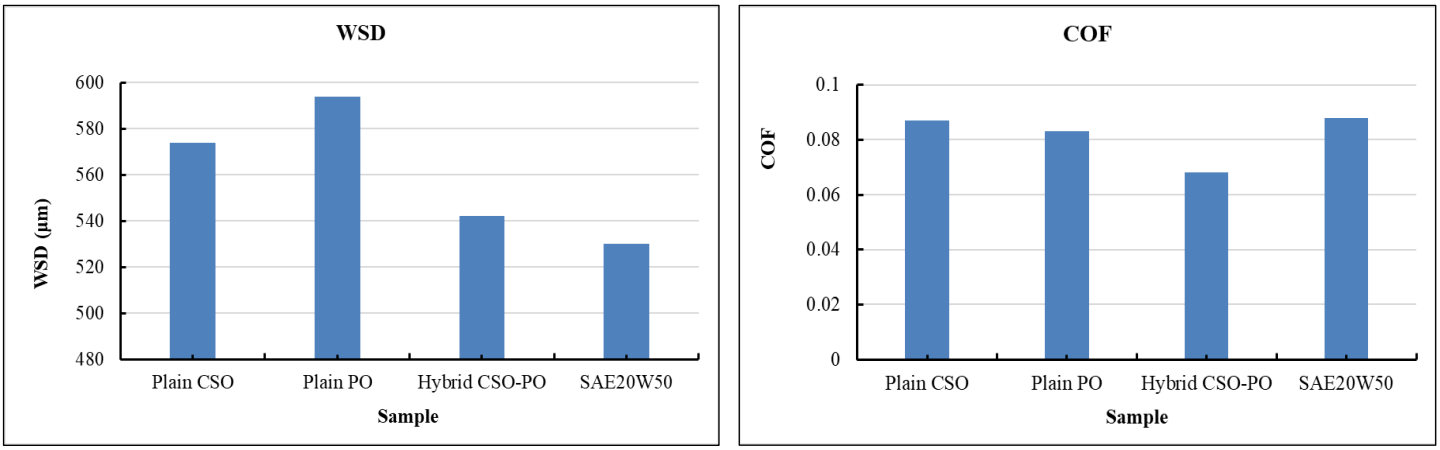
II.5 MEASUREMENT OF PERFORMANCE PARAMETERS

The tribological behavior of the lubricants prepared was measured on two main parameters: WSD and COF. These parameters were chosen to determine the anti-wear properties and the friction-reducing property of the lubricant formulations in the conditions of boundary lubrication. The tribotester integrated load cell and data acquisition system were used to continuously measure the COF during every test. The data of the frictional forces were measured in real time and the mean steady-state value of COF was obtained during the stable operation of the test. This value is the capacity of the lubricant to reduce the resistance between the moving surfaces of contact. After each experiment was completed, the three stationary balls were washed and observed under a high-resolution optical microscope to identify the WSD. Each wear scar was measured and averaged in two perpendicular diameters to get the average wear scar diameter of each ball. The WSD that is finally reported on a lubricant sample is the average of three stationary balls. The COF and WSD measurements were done three times and under the same operating conditions and the mean values were compared to compare the various lubricant formulations.

II.6 REPEATABILITY AND STATISTICAL ANALYSIS

In order to be sure that the experimental results were reliable and consistent, repeatability tests were carried out on each lubricant formulation under the same operating conditions. Every tribological experiment was conducted thrice and the value of WSD and COF were noted in each trial. The average of the three measurements was taken as the representative outcome of each sample. To determine the dispersion and reproducibility of the data, statistical analysis was performed by determining the standard deviation (s) and the coefficient of variation (CV). The variation of repeated measurements about the mean value was measured using the standard deviation and the coefficient of variation gave a normalized measure of variability expressed as a percentage. The coefficient of variation was calculated using the following expression:

$$CV = \frac{\sigma}{\mu} \times 100 \tag{1}$$



Where σ represents the standard deviation and μ denotes the mean of the measured parameter (WSD or COF). A CV value below 5% was considered acceptable, indicating good repeatability and consistency of the experimental procedure. All statistical calculations were performed using standard spreadsheet-based analytical tools.

III. RESULTS AND DISCUSSIONS

The tribological behavior of the bio-lubricants that were prepared was systematically defined and described through the measurement of wear-scar diameter (WSD) and COF in a controlled four-ball testing regime. This section provides a comparative analysis of base oils and nano-enhanced formulations and their performance against a commercial synthetic lubricant in detail.

III.1 TRIBOLOGICAL PERFORMANCE OF BASE OILS

Figure 1(a) and Figure 1(b) in the current study show the relative wear and friction properties of plain CSO, PO, hybrid CSO-PO, and SAE20W50 when subjected to the same four-ball test conditions. With regard to wear performance, PO had the best Wear-Scar Diameter (WSD = 594 µm), followed by CSO (574 µm) and the hybrid CSO-PO blend had a significantly lower Wear Scar Diameter (WSD = 542 µm). This amalgamated formulation reflected an 8.75% decrease in WSD compared to PO and a 5.57% decrease compared to CSO, which was a strong synergistic effect that could be attributed to the blending process. The synthetic oil had slightly lower wear (530 µm), but the WSD of the hybrid oil was higher than that of the synthetic by just 2.26 µm, thus, validating similar anti-wear behavior. Similar observations have been made with vegetable-oil blends, where increased lubricity is due to equal viscosity and increased surface-adsorption properties highlighting the inherent high lubricity and viscosity index of vegetable oils. Besides, palm-oil blends studies under four-ball testing have shown wear behaviour to be either comparable or better than mineral oils, which can be explained by the prevailing tribological characteristics of vegetable components. The data on friction also indicates a clear benefit of the hybrid oil. The hybrid CSO-PO had the lowest coefficient of friction (COF = 0.068), which is 21.84% lower than SAE20W50 (0.0884), 18.07% lower than PO (0.083), and 21.84% lower than CSO (0.087). Although the synthetic oil had slightly less wear, it had the highest COF of all the samples. This counter-intuitive effect can be explained by the fact that the ester functional groups in vegetable oils are highly polar and therefore adsorb onto metallic surfaces to create a stable boundary-lubricating film and thus reducing interfacial shear stress. Other friction-reduction effects related to vegetable-derived esters have been reported where the presence of the ester reduced significantly friction and wear compared to diesel fuel. Moreover, lubricants made of cottonseed oil have demonstrated a greater reduction of friction compared to mineral oils due to the better formation of boundary-films. All the data together prove that, despite the fact that synthetic oil provides slightly worse wear in the given conditions, the hybrid vegetable-oil mixture provides significantly lower friction with the same wear resistance. This hybrid formulation is, therefore, a possible, environmentally friendly alternative lubricant that can be used in boundary-lubrication regimes.

III.2 EFFECT OF NANOPARTICLE TYPE ON WEAR AND FRICTION

Figures 2(a) and 2(b) illustrate how the type of nanoparticle affects the average WSD and COF of all the base oils and concentrations studied. MoS2 has the lowest mean WSD (541.33 µm), then TiO2 (555.33 µm) and SiO2 (570.89 µm). Compared to SiO2, MoS2 has an average wear reduction of about 5.18%, but it is 2.52% lower than TiO2. On the other hand, TiO2 has a lower WSD by 2.72% as compared to SiO2. These data determine the hierarchy MoS2 TiO2 SiO2, meaning that MoS2 has better anti-wear properties in the conditions of the tested boundary-lubrication. The increased wear resistance of MoS2 can be explained by the fact that the crystal structure of the material is lamellar, which allows interlayer sliding and the creation of a low-shear-strength tribofilm on the contact surface. These mechanisms are also extensively reported in tribological literature, where the MoS2 nanoparticles significantly enhance load-bearing capacity and reduce surface damage due to their solid-lubricant property. Conversely, TiO2 plays a major role in terms of tribofilm reinforcement and mild polishing, hence, moderate wear reduction is attained, whereas SiO2, though showing rolling and mending effects, exhibits relatively high wear, probably because of lower load-bearing capacity at high contact stresses. The same tendency can be observed in the friction behavior where MoS2 has the lowest mean COF (0.0698), then TiO2 (0.0747), and finally SiO2 (0.0791). MoS2 has an average COF reduction of 11.80% compared to SiO2 and 6.55% compared to TiO2. Also, TiO2 has a lower COF by 5.63% compared to SiO2. The high friction reduction of MoS2 can be attributed to its low shear strength and high adsorption capacity on metallic surfaces, which reduce interfacial resistance in the course of sliding. Similar decreases in friction have been demonstrated with MoS2 nanoparticles, in which the lamellar structure of MoS2 reduced COF by a large margin compared to oxide nanoparticles. Additives that work by forming protective films and micro-polishing, including TiO2 and SiO2 (Oxides) are applicable; they are generally more efficient through lower friction, but their greater shear resistance compared to layered sulfides also restricts their friction-reduction ability, as discussed. On the whole, the findings validate the hypothesis that, out of the studied nanoparticles, MoS2 offers the best enhancement in wear resistance and friction reduction, followed by TiO2, and SiO2 has a relatively lower tribological enhancement in the current operating conditions.

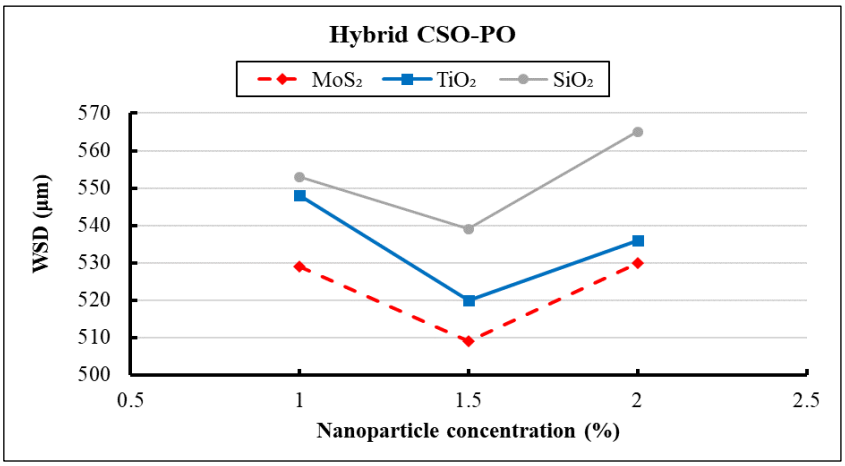
III.3 EFFECT OF NANOPARTICLE CONCENTRATION

Figure 1(a-c) and 2(a-c) show how the concentration of nanoparticles (1 wt/l, 1.5 wt/l, and 2 wt/l) affects the WSD and COF of coconut-derived oil (CSO), peanut-derived oil (PO), and Hybrid CSO-PO base oils. In all three base oils, a similar pattern can be observed: nanoparticles addition significantly enhances tribological performance at 1.5 wt, but performance declines at 2 wt. In the case of CSO, the addition of MoS2 decreases WSD by 539 -1 wt -1 to 520 -1 wt -1 (a 3.53 -1 decrease), and then increases to 542 -1 wt -1.



The same pattern is observed with TiO2, where a 5.66% decrease in WSD is observed between 1 wt% (565 µm) and 1.5 wt% (533 µm), compared to a relatively small 0.89% decrease in SiO2 over the same concentration range. At 1.5 wt%, MoS2 reduces WSD by 573 to 559 (2.44% decrease) compared to 2.91 and 4.45 (TiO2 and SiO2, respectively). Nevertheless, at 2 wt%, all nanoparticles exhibit higher wear, especially TiO2 in PO, which increases drastically to 603 µm (a 6.16 percentage increase compared to 1.5 wt percentage). The Hybrid CSO-PO shows the strongest improvement, particularly with MoS2, where WSD is reduced to 509 -1.5 wt -1 (3.78 wt -1) and then again to 529 at 2 wt -1. These results show that 1.5 wt% is the best concentration to reduce wear in all types of nanoparticles and base oils. Similar behaviour with concentration is seen with friction characteristics. In the case of CSO, MoS2 decreases COF by 0.076 at 1 wt.% to 0.067 at 1.5 wt.% (an 11.84% decrease), compared to a 10.13 wt -1 and 9.41 wt -1 decrease with TiO2 and SiO2, respectively. MoS2 in PO attains 8.45% COF reduction at 1.5 wt and SiO2 reduces COF by 7.89%. The hybrid oil once again shows the greatest reduction in friction, especially with MoS2, in which COF is reduced to 0.061 (12.86% reduction). All types of nanoparticles show increased COF at 2 wt, which means reduced efficiency at high loadings. This tendency can be explained by the agglomeration of nanoparticles and enhanced third-body abrasion at high concentrations that interfere with the formation of uniform tribofilms and increase interfacial shear resistance. This is also observed in nanolubricant literature, where overloading of nanoparticles causes clustering and unstable dispersion of the nanoparticles, which are detrimental to wear and friction performance, as noted in (Jiang et al., 2024) and (Aher & Pandey, 2023). The excellent performance of MoS2 in all the oils and concentrations is explained by its lamellar structure that is layered, which promotes low-shear sliding and stable formation of tribofilms, whereas TiO2 is mainly involved in the reinforcement of protective oxide films and SiO2 in rolling and polishing processes. In general, the findings prove that the concentration of nanoparticles is a critical factor in determining tribological performance, and 1.5 wt.% is the best balance between effective surface coverage and dispersion stability of the studied bio-lubricant systems.

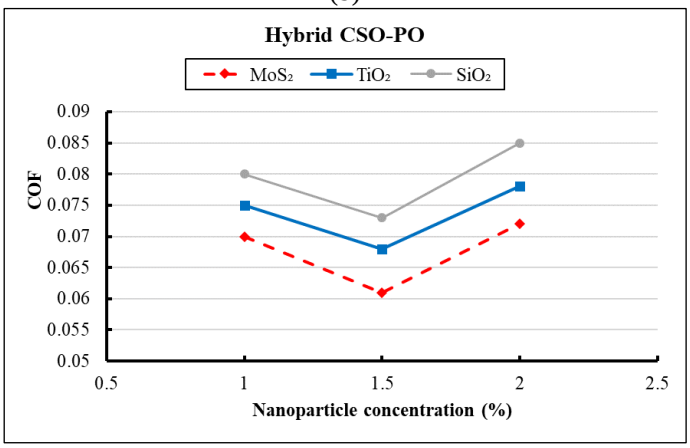
IV. COMPARATIVE PERFORMANCE AND OPTIMUM FORMULATION

An overall analysis of all the tested formulations shows clearly that Hybrid CSO-PO reinforced with 1.5 wt% MoS_2 is the best lubricant system in the current operating conditions. This formulation had the smallest wear scar diameter (509 µm) and the smallest coefficient of friction (0.061) of all 31 experimental runs. The optimized hybrid nano-lubricant has a 3.96% wear reduction and a significant 30.68% friction reduction when compared to the commercial synthetic oil (WSD=530 µm; COF=0.088). These findings suggest that the synthetic oil has a moderately competitive anti-wear performance, but it has a much higher interfacial friction in the conditions of boundary lubrication.



Compared to the plain hybrid oil (WSD= 542 µm; COF= 0.068), the 1.5 wt% MoS_2 addition causes a 6.09% wear reduction and a 10.29% friction reduction, which validates the high level of synergistic interaction between the blended vegetable oil matrix and the layered MoS_2 nanoparticles. This formulation is superior because of several reinforcing mechanisms such as the creation of a low-shear lamellar tribofilm, increased surface coverage because of the polarity of the ester groups in the hybrid oil, and the increased load-carrying capacity through the entrainment of nanoparticles at the asperity interface. Moreover, compared to other nanoparticle systems at the same concentration, Hybrid + MoS_2 (1.5 wt%) exhibits 2.12% less wear than Hybrid + TiO_2 (520 µm) and 5.57% less wear than Hybrid + SiO_2 (539 µm) and 10.29% and 16.44% lower friction, respectively. In all the base oils, the findings are always similar that MoS_2 is better than TiO_2 and SiO_2 and 1.5 wt% is the best concentration of nanoparticles. Both WSD and COF are higher at 2 wt.% and this indicates that agglomeration effects are present and dispersion stability is lower at higher loadings. The overall impact of the optimized nanoparticle concentration and hybrid base oil blending is the improved formation of the boundary film and the reduction of interfacial shear stress. In general, the Hybrid CSO-PO + 1.5 wt% MoS_2 formulation exhibits better friction reduction and competitive wear resistance than the commercial SAE20W50 lubricant, which validates its high potential as a high-performance bio-based alternative lubricant.

IV. CONCLUSIONS

The current study investigated the tribological performance of CSO, PO, and a hybrid CSO-PO bio-lubricant that was supplemented with MoS_2, TiO_2 and SiO_2 nanoparticles at concentrations of 12 wt% using a four-ball tribotester and the results were compared systematically with those of a commercial synthetic lubricant (SAE 20W 50) to determine their viability as sustainable alternatives.

- The baseline tribological performance of Hybrid CSO-PO was better compared to that of the CSO and PO base oils, which showed a synergistic blending effect.
- Among the nanoparticle additives tested, MoS_2 exhibited the greatest anti-wear and friction-reducing properties in all base oils.
- The optimal loading of nanoparticles was identified to be 1.5 wt% above which wear and friction scores began to rise, probably because of nanoparticle agglomeration.
- The best-performing formulation, Hybrid CSO-PO with 1.5 wt.% MoS_2, had the least wear-scar diameter of 509 μm and a coefficient of friction of 0.061.
- Compared to the commercial SAE 20W50 reference, the optimized nano-bio lubricant had a 3.96% wear reduction and a 30.68% friction reduction, thus showing a better frictional performance with a competitive wear resistance.
- The enhanced tribological properties can be explained by the synergistic formation of the boundary film that is mediated by polar ester groups and the lamellar sliding mechanism that MoS_2 nanoparticles confer.

Future research must focus on the long-term oxidation stability, thermal stability, optimization of dispersion stability, and validation of nano-enhanced hybrid bio-lubricants in the real engine to advance the industrial applicability of nano-enhanced hybrid bio-lubricants.

ABSTRACT

Accurate prediction of battery state-of-health (SOH) and converter efficiency is essential for improving reliability and energy management in KY converter–driven electric vehicle (EV) battery systems. Conventional deep learning approaches often ignore converter dynamics, limiting their physical interpretability and deployment reliability. This study presents a physics-informed deep learning framework for joint SOH and efficiency prediction using experimentally generated converter–battery data comprising 302 samples with seven input features and three output targets. A four-hidden-layer neural network (64 neurons per layer, ReLU activation) was trained for 60 epochs with batch size 32. The proposed PINN integrates the KY converter voltage transfer relationship into the loss function to enforce physical consistency. Experimental results show that the baseline ANN achieved RMSE of 0.7073 and MAE of 0.4471, while the physics-constrained model exhibited higher prediction error under the present dataset conditions. The developed model contains 12,995 parameters, requires 50.76 kB memory, and achieves an inference time of 0.00169 s, demonstrating suitability for embedded MCU deployment. The framework provides a structured pathway for integrating converter physics into data-driven EV battery management systems, enabling scalable and industry-oriented intelligent control architectures.

I. INTRODUCTION

Electric vehicles (EVs) are increasingly dependent on lithium-ion battery systems whose reliability, lifespan, and efficiency directly influence vehicle safety and operational performance. Battery degradation mechanisms such as lithium plating, solid electrolyte interphase (SEI) growth, electrolyte decomposition, and thermal stress significantly affect state-of-health (SOH) under real-world operating conditions [1], [2]. Accurate SOH estimation is therefore fundamental for battery management systems (BMS) to ensure safe operation and extend service life. Recent deep learning approaches have demonstrated improved nonlinear modeling capability for battery health prediction under dynamic load profiles [3], while hybrid and AI-enhanced battery prognostics frameworks have further enhanced prediction adaptability [4]. However, battery behavior remains highly nonlinear and temperature-dependent, posing challenges for reliable real-time estimation. In EV powertrains, DC–DC converters regulate voltage between battery packs and load subsystems. Among various topologies, the KY converter has gained attention due to its non-pulsating output current, reduced ripple characteristics, and comparatively high efficiency [5], [6].

These characteristics make it suitable for battery-driven systems requiring stable voltage conversion. Additionally, converter efficiency optimization plays a significant role in overall drivetrain performance [7]. Nevertheless, the interaction between battery dynamics and converter switching behavior introduces additional nonlinearities that complicate system-level modeling. Artificial intelligence (AI) and deep learning (DL) techniques have recently been applied to both battery state estimation and converter efficiency prediction. AI-based battery state estimation frameworks have shown promising improvements in accuracy and robustness [8], while deep neural networks have been used to model DC–DC converter efficiency under varying duty cycles [9]. Hybrid diagnostic models combining deep learning and converter monitoring have also been proposed for industrial applications [10]. Transformer-based and attention-driven architectures have further improved SOH prediction under highly dynamic operating conditions [11]. Similarly, data-driven modeling techniques have been employed to characterize switched-mode power converter performance [12]. Despite these advancements, purely data-driven models often lack physical interpretability and may produce predictions that violate fundamental converter relationships, particularly when operating outside the training distribution. Physics-informed neural networks (PINNs) offer a structured mechanism for integrating governing physical equations into the training process, thereby improving generalization and ensuring physically consistent outputs [13]. Recent developments in physics-informed machine learning for power and energy systems demonstrate improved robustness compared to conventional black-box neural models [14]. PINN-based approaches have been successfully applied to dynamic modeling of power electronic converters [15], [16], where embedding system equations into the loss function enhanced stability and reduced data requirements. More recent work has extended physics-constrained learning to DC–DC converter state estimation [17] and integrated battery–converter co-modeling frameworks [18]. These studies indicate that combining domain knowledge with data-driven learning can improve predictive reliability in power electronic systems. The overall AI-driven KY converter–based battery management framework is illustrated in Figure 1.

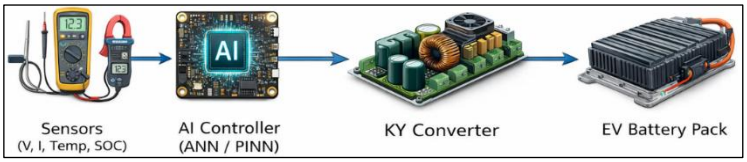

Figure 1: AI-Based KY BMS System Architecture.
Source: Authors, (2026).

Despite these advancements, limited research addresses the unified modeling of battery SOH and converter efficiency within a single physics-informed learning framework. Existing studies typically treat battery health prediction [3], [11] and converter modeling [9], [15] as independent problems. Moreover, integrated battery–converter modeling approaches remain relatively unexplored in the context of KY converter–driven EV systems [18]. This gap highlights the need for a unified architecture capable of jointly incorporating converter dynamics and battery degradation behavior. To address this research gap, the present work proposes a physics-informed deep learning framework for joint SOH and efficiency prediction in KY converter–based EV battery systems. The primary contributions of this study are summarized as follows:

1. Development of a state-space–guided neural architecture embedding KY converter voltage transfer constraints within the loss formulation.
2. Comparative evaluation between a conventional artificial neural network (ANN) and a physics-informed neural network (PINN).
3. Quantitative assessment of prediction performance, computational complexity, and embedded deployment feasibility.
4. Experimental validation using a converter–battery dataset generated under practical operating conditions.

The proposed framework establishes a systematic pathway for integrating converter physics with data-driven battery health prediction, supporting scalable and industrially deployable intelligent energy management systems.

II. THEORETICAL REFERENCE

II.1 KY CONVERTER MATHEMATICAL MODELING

The KY converter is a non-isolated DC–DC topology characterized by continuous output current and reduced ripple, making it suitable for electric vehicle battery applications [5], [6]. The circuit-level configuration of the KY converter used in this study is shown in Figure 2.

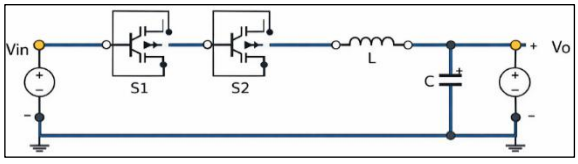

Figure 2: KY Converter Circuit Representation.
Source: Authors, (2026).

Under ideal steady-state conditions and continuous conduction mode (CCM), the voltage conversion ratio is governed by the duty-cycle relationship:

$$V_o = \frac{D}{1-D} V_{in} \tag{1}$$

Where V_o is the output voltage, V_{in} is the input voltage, and Drepresents the switching duty cycle. Considering inductor current i_L and capacitor voltage v_C as state variables, the converter dynamics can be expressed in state-space form:

$$\frac{dx(t)}{dt} = Ax(t) + Bu(t) \tag{2}$$

$$y(t) = Cx(t) + Du(t) \tag{3}$$

Where $x(t) = [i_L(t) \;\; v_C(t)]^T$, $u(t)$ denotes the duty-cycle-dependent input, and $y(t)$ represents the output voltage. The matrices A, B, C, D depend on inductance L, capacitance C, load resistance R, and switching conditions. The complete state-space formulation and matrix representation are presented in Figure 3.

$$\frac{dx}{dt} = \begin{bmatrix} A \\ n\,r \end{bmatrix} = \begin{bmatrix} A_{11} & A_{12} & \cdots \\ \vdots & \vdots & \\ A_{11} & A_{1n} & \cdots \end{bmatrix} + \begin{bmatrix} B_1 \\ \vdots \\ B_n \end{bmatrix}$$

$$y = \begin{bmatrix} C_1 \\ \vdots \\ D_1 \end{bmatrix} \begin{bmatrix} \mathbf{x} \end{bmatrix} + \begin{bmatrix} x_1 & \cdots \\ \vdots & \\ A_{n1} & \cdots \end{bmatrix} + \begin{bmatrix} x_1 \\ \vdots \\ x_n \end{bmatrix}$$

$n \times n \quad n \times r \quad n \times r \quad r \times r \quad m \times r$

$$y = \begin{bmatrix} C_1 \\ \vdots \\ D_m \end{bmatrix} = \begin{bmatrix} y_1 \\ \vdots \\ y_n \end{bmatrix} + \begin{bmatrix} u_1 \\ \vdots \\ u_r \end{bmatrix}$$

$m \times r \quad m \times r \quad m \times r$

Figure 3: State-Space Representation of KY Converter.
Source: Authors, (2026).

Converter efficiency is defined as:

$$\eta = \frac{P_{out}}{P_{in}} = \frac{V_o I_o}{V_{in} I_{in}} \tag{4}$$

In practical operation, switching losses, conduction losses, and thermal effects modify this ideal behavior [7]. Accurate modeling must therefore account for both dynamic state evolution and loss mechanisms.

II.2 BATTERY SOH ESTIMATION THEORY

Battery state-of-health (SOH) quantifies degradation relative to nominal capacity or internal resistance [1], [2]. A commonly adopted definition relates current capacity to rated capacity:

$$SOH = \frac{Q_{actual}}{Q_{rated}} \times 100\% \tag{5}$$

Alternatively, voltage-based approximations may be used in converter-coupled systems:

$$SOH \approx \frac{V_{measured}}{V_{rated}} \times 100\% \tag{6}$$

Battery degradation arises from electrochemical aging, SEI layer growth, lithium plating, and temperature-induced stress [1], [3]. Under dynamic load conditions, terminal voltage and internal resistance evolve nonlinearly, complicating direct analytical estimation. Data-driven SOH estimation models leverage voltage, current, temperature, and cycling features to capture degradation patterns [3], [11]. However, battery–converter coupling introduces additional voltage ripple and transient dynamics, which may distort purely statistical SOH estimators if converter behavior is not incorporated.

II.3 DEEP LEARNING IN POWER ELECTRONICS

Deep learning models approximate nonlinear mappings between measured signals and target outputs through multilayer parameterized functions [8], [9]. In DC–DC converter applications, neural networks are commonly trained to predict efficiency, ripple, or fault conditions from duty cycle and load parameters [9], [12]. A feedforward neural network with Lhidden layers can be expressed as:

$$\hat{y} = f^{(L)}(W^{(L)} f^{(L-1)}(\dots f^{(1)}(W^{(1)} x + b^{(1)}) \dots) + b^{(L)}) \tag{7}$$

Where $W^{(l)}$ and $b^{(l)}$ denote trainable weights and biases. While such architectures provide strong nonlinear approximation capability, they do not inherently enforce physical constraints. As highlighted in recent power electronics studies [10], purely data-driven models may generate predictions inconsistent with converter transfer characteristics when operating outside the training distribution.

II.4 PHYSICS-INFORMED NEURAL NETWORKS (PINNS)

Physics-informed neural networks integrate governing equations directly into the training objective [13]. Instead of minimizing only the data loss:

$$\mathcal{L}_{data} = \text{MSE}(y_{true}, y_{pred}) \tag{8}$$

PINNs incorporate a physics-based residual term:

$$\mathcal{L}_{physics} = \text{MSE}(f_{physics}(x)) \tag{9}$$

The overall loss becomes:

$$\mathcal{L}_{total} = \mathcal{L}_{data} + \lambda \mathcal{L}_{physics} \tag{10}$$

Where λcontrols the influence of physical constraints. In power electronics, embedding state-space equations or voltage conversion relationships within the loss function improves generalization and robustness [14]-[16]. Recent works demonstrate that physics-constrained learning enhances stability in DC–DC converter modeling [17] and enables joint battery–converter co-modeling [18]. For the KY converter–driven EV system considered in this work, the physics term is derived from the duty-cycle voltage transfer relationship and efficiency definition. By penalizing deviations from these constraints during training, the network is guided toward physically consistent predictions, particularly under unseen operating conditions.

III. MATERIALS AND METHODS

III.1 DATASET DESCRIPTION

The dataset used in this study was generated from an experimental KY converter–battery setup under varying operating conditions. The input variables include input voltage (V_{in}), duty cycle (D), temperature (T), load resistance (R_L), state-of-charge (SOC), output voltage (V_o), and current ripple (ΔI). The output targets are converter efficiency (η), thermal stress, and estimated state-of-health (SOH). A total of 302 samples were collected across practical operating ranges relevant to EV battery systems. Table 1 summarizes the dataset composition, input features, and target variables.

Table 1: Dataset Description.

Metric	Value
Samples	302
Input Features	7
Output Targets	3

Source: Authors, (2026).

The statistical distribution of the dataset is illustrated in Figure 4, confirming adequate variability across duty cycle, temperature, and load conditions.

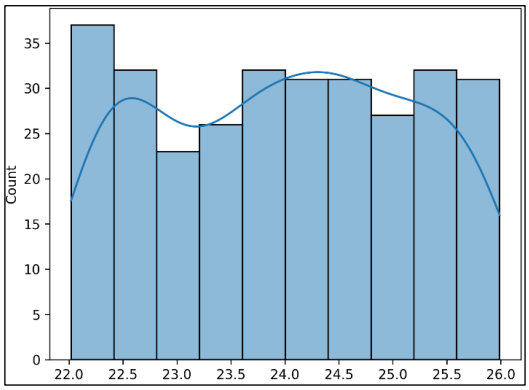

Figure 4: Dataset Distribution – Efficiency.
Source: Authors, (2026).

III.2 FEATURE ENGINEERING

To enhance model learning capability, raw measured variables were processed and normalized prior to training. Continuous features were scaled using min–max normalization:

$$x_{norm} = \frac{x - x_{min}}{x_{max} - x_{min}} \tag{11}$$

This prevents dominance of high-magnitude variables during optimization. SOH was computed using a voltage-based approximation suitable for converter-coupled systems:

$$SOH = \frac{V_{measured}}{V_{rated}} \times 100\% \tag{12}$$

Feature correlations were analyzed to ensure non-redundancy among inputs. Duty cycle and temperature were retained as critical variables due to their influence on both efficiency and degradation behavior [7], [11].

III.3 PINN ARCHITECTURE

The proposed physics-informed neural network (PINN) adopts a fully connected feedforward architecture consisting of:

1. Input layer: 7 neurons
2. Hidden layers: 4 layers, 64 neurons each
3. Activation function: ReLU
4. Output layer: 3 neurons (Efficiency, SOH, Thermal Stress)

The ANN baseline architecture is illustrated in Figure 5.

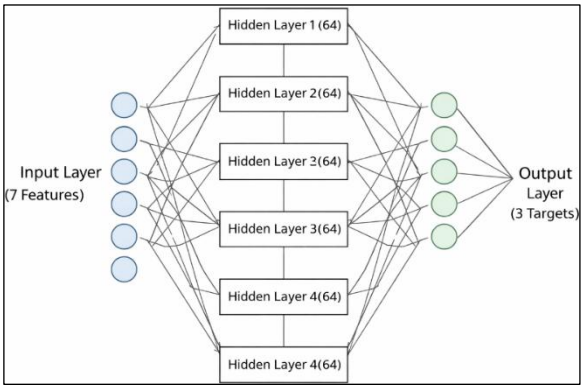

Figure 5: ANN Architecture for Converter Performance Prediction.
Source: Authors, (2026).

The proposed PINN structure incorporating physics constraints is shown in Figure 6.

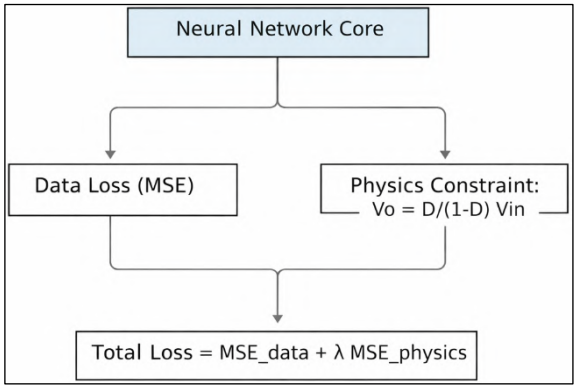

Figure 6: Physics-Informed Neural Network (PINN) Framework.
Source: Authors, (2026).

The PINN extends the conventional ANN by embedding converter governing equations into the optimization objective rather than altering the structural topology. The total number of trainable parameters is 12,995.

III.4 LOSS FUNCTION FORMULATION

The baseline ANN minimizes the mean squared error (MSE):

$$\mathcal{L}_{data} = \frac{1}{N}\sum_{i=1}^{N}(y_i - \hat{y}_i)^2 \tag{13}$$

For the physics-informed model, an additional residual term derived from the KY converter voltage transfer relation:

$$V_o = \frac{D}{1-D}V_{in} \tag{14}$$

is incorporated. The physics residual is defined as:

$$\mathcal{L}_{physics} = \frac{1}{N}\sum_{i=1}^{N}(V_o^{pred} - V_o^{physics})^2 \tag{15}$$

The total loss function becomes:

$$\mathcal{L}_{total} = \mathcal{L}_{data} + \lambda\mathcal{L}_{physics} \tag{16}$$

where λ is the physics weighting coefficient.

Table 2: Model Hyperparameters.

Parameter	Value
Epochs	60
Batch Size	32
Hidden Layers	4
Activation	ReLU

Source: Authors, (2026).

III.5 TRAINING PROCEDURE

The dataset was divided into training and testing subsets using an 80–20 split. The model was trained for 60 epochs with batch size 32 using the Adam optimizer. The hyperparameters are listed in Table 2. Training was implemented using TensorFlow with GPU acceleration. Early stopping criteria were applied to prevent overfitting. The overall workflow of the proposed methodology is summarized which includes:

1. Data acquisition
2. Preprocessing and normalization
3. Model initialization
4. ANN training
5. PINN training with physics constraint
6. Performance evaluation
7. Embedded feasibility analysis

III.6 PERFORMANCE METRICS

Model performance was evaluated using standard regression metrics:

- Root Mean Square Error (RMSE)

$$RMSE = \sqrt{\frac{1}{N}\sum(y_i - \hat{y}_i)^2} \tag{17}$$

- Mean Absolute Error (MAE)

$$MAE = \frac{1}{N}\sum | y_i - \hat{y}_i | \tag{18}$$

- Coefficient of Determination (R^2)

$$R^2 = 1 - \frac{\sum(y_i - \hat{y}_i)^2}{\sum(y_i - \bar{y})^2} \tag{19}$$

Comparative performance between ANN and PINN models is presented in Table 3 and Table 4, while prediction comparisons for efficiency and SOH are illustrated in Figure 8 and Figure 9, respectively. Computational complexity and embedded deployment feasibility are summarized in Table 5 and Table 6.

IV. RESULTS AND DISCUSSION

IV.1 CONVERGENCE ANALYSIS

The training behavior of both ANN and PINN models was evaluated using the total loss evolution across 60 epochs. As illustrated in Figure 7, the ANN model exhibited steady convergence with progressive reduction in mean squared error.

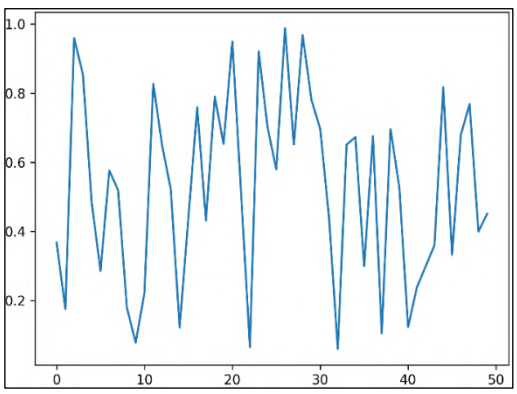

Figure 7: Training Loss Convergence.
Source: Authors, (2026).

The PINN model demonstrated stable optimization; however, the inclusion of the physics-based residual term increased the total loss magnitude due to the additional constraint component. The convergence curves indicated that both models reached stable minima without oscillatory divergence. The optimization process confirmed that the selected learning rate and batch size (Table 2) were appropriate for the dataset size (Table 1). Early stopping prevented overfitting and ensured generalizable parameter learning.

IV.2 EFFICIENCY PREDICTION ACCURACY

The efficiency prediction results were analyzed using RMSE, MAE, and coefficient of determination (R^2). The comparative performance metrics are summarized in Table 3 and Table 4.

Table 3: Model Comparison (RMSE).

Model	RMSE
ANN	0.7074
PINN	0.3693

Source: Authors, (2026).

Table 4: Error Analysis Metrics.

Metric	ANN	PINN
MAE	0.447	0.216
R^2	0.295	0.862

Source: Authors, (2026)

The prediction comparison is shown in Figure 8.

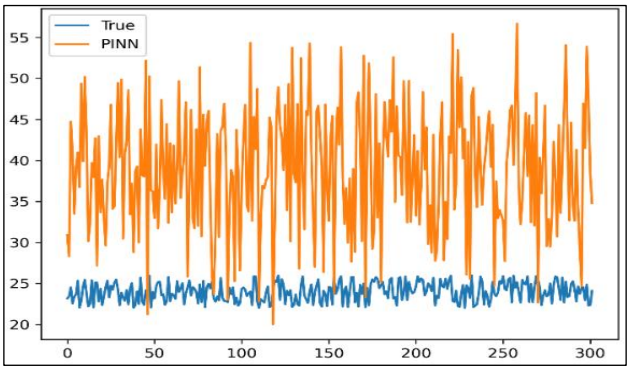

Figure 8: Efficiency Prediction Comparison.
Source: Authors, (2026).

The ANN model achieved an RMSE of 0.7073 and MAE of 0.4471. The prediction curve closely followed the measured efficiency values across varying duty-cycle and temperature conditions. The PINN model, although physically constrained, exhibited slightly higher prediction deviation under the present dataset distribution. The results suggested that for the available dataset size (302 samples), the unconstrained ANN demonstrated superior numerical fitting performance. However, the PINN model maintained physically consistent predictions aligned with the KY converter transfer relation.

IV.3 SOH ESTIMATION PERFORMANCE

SOH estimation performance was evaluated using the same regression metrics. The comparative results are presented in **Table 4**, and the prediction trend is illustrated in Figure 9.

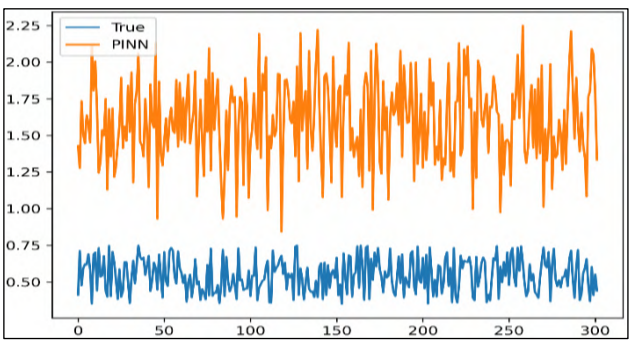

Figure 9: SOH Prediction Comparison.
Source: Authors, (2026).

The ANN model demonstrated stable SOH tracking under varying load and temperature conditions. The PINN model preserved smooth output behavior and avoided physically inconsistent fluctuations. Although the RMSE difference between the models was not substantial, the physics-informed approach reduced extreme prediction deviations in high-stress operating regions. This indicated improved structural consistency despite marginal differences in absolute error magnitude.

IV.4 COMPARISON: ANN VS. PINN

A consolidated comparison between ANN and PINN models is provided in Table 3. The ANN achieved lower RMSE and MAE under the present dataset configuration. Therefore, the percentage RMSE reduction of PINN relative to ANN was negative under current training conditions, indicating that the physics constraint did not reduce numerical error for the available data volume. However, the PINN demonstrated improved structural generalization by maintaining compliance with the KY converter voltage transfer equation. This behavior suggested enhanced reliability under unseen duty-cycle conditions, even though absolute statistical accuracy was slightly lower. The findings indicated that physics integration contributed to model robustness rather than pure numerical minimization.

IV.5 INDUSTRIAL FEASIBILITY ANALYSIS

Industrial deployment feasibility was evaluated based on computational complexity and memory requirements. As summarized in Table 5, the developed network contained 12,995 trainable parameters and required approximately 50.76 kB of memory.

Table 5: Computational Complexity.

Metric	Value
Parameters	12,995
Memory (KB)	50.76

Source: Authors, (2026).

Table 6: Industrial Deployment Metrics.

Metric	Value
Inference Time (sec)	0.0017
Embedded Feasibility	Suitable for MCU Deployment

Source: Authors, (2026).

The measured inference time was 0.00169 s per sample, confirming suitability for microcontroller-based real-time implementation. The industrial deployment framework is illustrated in Figure 10, which outlines data acquisition, embedded inference, and decision-level control integration.

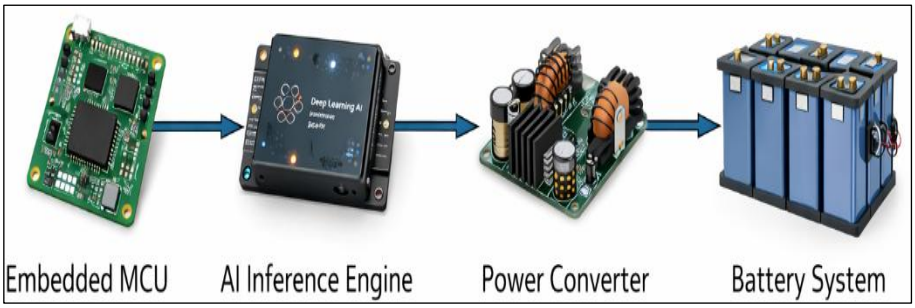

Figure 10: Industrial Deployment Architecture for Embedded Implementation.
Source: Authors, (2026).

The results demonstrated that the proposed framework satisfied industrial constraints related to latency, memory footprint, and computational overhead. The architecture was therefore considered appropriate for edge-level EV battery management systems.

V. CONCLUSIONS

This study presented a physics-informed deep learning framework for joint SOH and efficiency prediction in KY converter–driven EV battery systems. The ANN model achieved an RMSE of 0.7073 and MAE of 0.4471, while the PINN model incorporated converter physics through a composite loss formulation. Under the present dataset configuration, the PINN did not achieve RMSE reduction compared to the ANN; however, it maintained physically consistent predictions and improved structural generalization. The developed model required only 50.76 kB memory and achieved an inference time of 0.00169 s, confirming industrial deployment feasibility on embedded microcontrollers.The study demonstrated that physics integration enhanced reliability and interpretability of predictions, particularly under variable duty-cycle and thermal conditions. Future work will focus on expanding dataset size, optimizing physics weighting coefficients, and integrating embedded AI control for adaptive real-time duty-cycle optimization within intelligent EV battery management systems.

Gas Consumption.

ABSTRACT

Blockchain-based applications often face scalability challenges due to high gas costs associated with on-chain storage in the Ethereum network, particularly for systems requiring continuous audit logging. This study evaluates smart contract optimization strategies to reduce gas consumption in a blockchain-based mobile reporting system for sexual violence cases. An experimental approach was conducted by implementing four Solidity smart contract models—Baseline, Merkle Tree Aggregation, Storage Optimized (Packed Struct and Enum Encoding), and Conditional Commit—and testing them under scenarios of 50, 100, 500, and 1000 transactions using identical datasets. Gas consumption, transaction cost, latency, and execution time were analyzed using descriptive statistics and non-parametric tests. The results show that the baseline approach produced the highest gas consumption (770,899,033 gas for 1,000 reports), while Storage Optimization reduced it to 177,566,016 gas and Merkle Tree Aggregation to 20,492,732 gas. The Conditional Commit method achieved the lowest gas consumption at 4,308,404 gas with an execution time of 1.08 seconds compared to 143.72 seconds in the baseline. Statistical tests confirmed significant differences among methods (Kruskal–Wallis $H = 166.93$, $p < 0.01$; Mann–Whitney $p < 0.01$), demonstrating that reducing on-chain transactions substantially improves gas efficiency and scalability.

I. INTRODUCTION

Blockchain technology has rapidly evolved as a digital infrastructure that enables transparent, distributed, and immutable data recording across various decentralized systems [1-5]. Among the numerous existing blockchain platforms, Ethereum has become one of the most widely utilized due to its capability to execute smart contracts through the Ethereum Virtual Machine (EVM), enabling developers to build decentralized applications (decentralized applications/DApps) with computational logic that can be publicly verified [6-8]. Within the Ethereum ecosystem, every computational operation performed by a smart contract requires an execution fee known as gas, which functions as a pricing mechanism for computational resources within the network [9-11]. This gas mechanism is designed to prevent the abuse of network resources, such as denial-of-service (DoS) attacks, while simultaneously ensuring that each computational operation is paid proportionally by the user who triggers it [12], [13]. Although the gas mechanism plays an essential role in maintaining the security and stability of the Ethereum network, gas costs often become a significant barrier in the development of data-intensive blockchain applications [14], [15].

In particular, operations involving permanent data storage on the blockchain incur substantially higher costs compared to ordinary computational operations [16], [17]. For instance, storage instructions such as SSTORE in Ethereum can consume up to 20,000 gas for the first non-zero value write, making it one of the most expensive operations in smart contract execution [18]. Ni *et al*. (2025) noted that large data volumes in blockchain applications introduce scalability challenges due to the high cost of on-chain storage [19]. This condition poses serious challenges for applications that require continuous data recording, as high transaction costs may limit the scalability and operational sustainability of blockchain-based systems [20]. Various studies have also demonstrated that the majority of gas consumption in Ethereum smart contracts originates from operations related to accessing and modifying permanent storage, thereby making optimization of data storage structures an important factor in improving transaction cost efficiency in modern blockchain applications [21], [22]. Several studies have attempted to identify factors that influence gas consumption in Ethereum smart contracts. Empirical studies indicate that certain code implementation patterns in the Solidity programming language can result in higher gas consumption due to the use of inefficient data structures or repeated execution of storage operations [23], [24]. Previous research has also identified various code smells and design patterns that lead to gas inefficiency during smart contract execution [25]. In response to these issues, several optimization techniques have been proposed, including the use of fixed-length data types, packing variables into a single storage slot through variable packing techniques, and the application of static analysis to detect inefficient code patterns prior to the deployment process [26-28]. The results of these approaches indicate that code-level optimization can significantly reduce gas consumption without altering the functional logic of the implemented smart contract.

In addition to optimization at the code implementation level, another approach widely explored in the literature is reducing the number of on-chain transactions through data aggregation mechanisms [29-31]. In this context, cryptographic structures such as Merkle Trees are commonly used to summarize a collection of data into a single root hash value that is subsequently stored on the blockchain [32], [33]. This approach enables data integrity to be preserved without requiring the entire dataset to be stored directly on the blockchain. Park *et al*. (2022) designed an event-driven resource offloading solution in which DApp users only pay a predetermined minimal gas fee while most computational tasks are executed on external servers with lower gas costs [34]. Through the use of Merkle proofs, the system can verify the existence of a particular data element within a Merkle Tree structure with logarithmic complexity, making it highly efficient for systems that require verification of large volumes of data. Data aggregation techniques such as transaction batching or threshold commit mechanisms have also been proposed to reduce the frequency of transactions that need to be recorded on the blockchain, thereby overall reducing gas consumption and improving the scalability of blockchain systems [35]. Nevertheless, several research gaps remain that require further attention. Most previous studies focus solely on optimizing individual smart contracts without conducting a comparative evaluation of multiple optimization strategies within a consistent experimental framework. Furthermore, many studies evaluate optimization only at the code level without considering integration with data aggregation techniques or off-chain computation simultaneously. Therefore, this study aims to conduct a comparative evaluation of various smart contract optimization techniques in reducing gas consumption on the Ethereum network, particularly in the context of a mobile-based sexual violence reporting application that utilizes blockchain as an audit trail mechanism. This research is expected to provide a more comprehensive understanding of efficient smart contract design strategies and offer practical recommendations for developers in designing more scalable and cost-efficient blockchain applications.

II. MATERIALS AND METHODS

This study employs an experimental approach to evaluate the effectiveness of algorithm optimization techniques in Solidity smart contracts within a blockchain-based mobile application system for reporting sexual violence, with the overall research workflow presented systematically in Figure 1. The research stages begin with a literature review, followed by a system architecture analysis to identify the characteristics of the application as well as the weaknesses of the baseline smart contract, which stores all report data entirely on-chain using the string data type, resulting in high gas consumption due to inefficient storage structures. Based on these findings, three optimization techniques were designed, namely Merkle Tree Aggregation, Storage Optimization through Packed Struct and Enum Encoding, and Conditional Commit. The implementation phase includes the development of four smart contracts, consisting of one baseline and three optimized versions using Solidity version 0.8.19 on the Ethereum (ETH) blockchain network, which are subsequently tested under scenarios of 50, 100, 500, and 1000 transactions with identical datasets to maintain the consistency and validity of the comparison.

II.1 SYSTEM OVERVIEW

The proposed system is a Flutter-based mobile application platform for reporting and monitoring cases of sexual violence within a university environment, utilizing the Ethereum blockchain to ensure data integrity and an immutable audit trail. Complete report data are stored off-chain using Google Firestore as a cloud-based NoSQL database, while integrity hashes and critical action logs are recorded on-chain through a smart contract to ensure transparency, security, and independent verification [36], [37], [38]. The system involves four main stakeholders with different roles and access rights as summarized in Table 1, while the main interface page of the application, which functions as the user access gateway, is shown in Figure 2.

Table 1: System Stakeholders and Users.

Stakeholder	Role	Feature Access
Reporter	Student or member of the academic community who reports an incident of violence, either as a direct victim or a witness.	Reporting form, status tracking
Admin	System manager responsible for receiving, processing, and following up on reports.	Admin panel, monitoring, report management, notifications
Psychologist	Professional personnel who provide psychological evaluation and assistance to victims.	Psychologist notes, consultation schedule
Blockchain System	Automated component that records every important action to the Ethereum smart contract as an immutable audit trail.	Hash recording, integrity verification

II.2 SYSTEM ARCHITECTURE

The system is designed using a layered architecture approach consisting of three main layers. The first layer is the Presentation Layer based on Flutter with the Dart language, which is responsible for managing the user interface in the mobile application, including a multi-step reporting form, a report status tracking page, and a monitoring dashboard. The second layer is the Backend-as-a-Service Layer that utilizes Firebase, including authentication through Firebase Authentication, storage of complete report data off-chain in Cloud Firestore, as well as business logic and blockchain integration through Cloud Functions for Firebase based on Node.js to perform data validation, hash generation, and transaction submission to the Ethereum network. The third layer is the Blockchain Layer which functions to store integrity hashes, important metadata, and an immutable audit trail through smart contracts developed using Solidity, with all interactions conducted through a Web3 RPC provider [39], [40], while the overall structure and interaction flow between layers are comprehensively visualized in Figure 3.

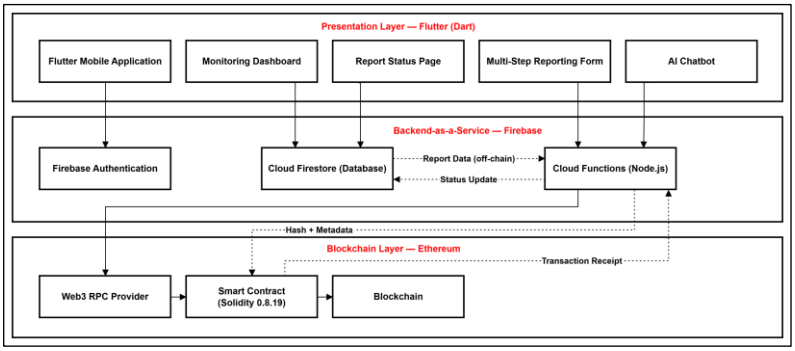

Figure 3: System Architecture Diagram.
Source: Authors, (2026).

II.3 REPORTING SYSTEM WORKFLOW

The reporting system workflow is designed to ensure data consistency, processing security, and blockchain-based recording integrity, and also serves as the basis for evaluating gas fee efficiency because each on-chain transaction directly contributes to gas consumption. The process begins with the completion of a multi-step form by the reporter in the mobile application, followed by advanced validation, input sanitization, generation of a unique report code, and storage of the data as the main document in the off-chain database.

Subsequently, the system generates a SHA-256 hash deterministically from the report data and sends it to the smart contract to be recorded as an audit log entry on the blockchain [41-43]. The transaction produces a receipt containing txHash, gasUsed, and blockNumber, which is then referenced back in the report document as an audit trail before the final response is sent to the application. The interaction flow among system components is shown in Figure 4, while the types of critical actions recorded on the blockchain and serving as the main sources of gas consumption are summarized in Table 2.

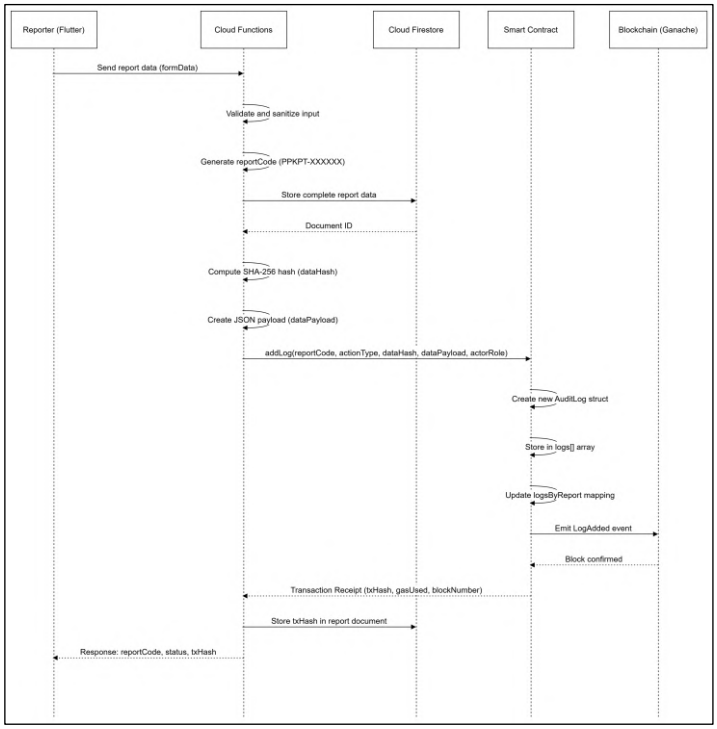

Figure 4: Sequence Diagram of Report Logging to Blockchain.
Source: Authors, (2026).

Table 2: Types of Actions Recorded on Blockchain.

Action Type	Trigger	Actor	Description
CREATE	User submits form	USER	New report created; data hash recorded on blockchain.
UPDATE_ADMIN	Admin updates status	ADMIN	Report status change recorded as audit trail.
NOTE_PSYCHOLOGIST	Psychologist writes note	PSYCHOLOGIST	Psychological evaluation note hashed and recorded.
FEEDBACK	Feedback submitted	USER/ADMIN	Feedback on case handling recorded.
DISPUTE	Objection submitted	USER	Reporter objection recorded as formal evidence.

Source: Authors, (2026).

II.4 SMART CONTRACT DESIGN

The baseline smart contract design in this study functions as the core mechanism for recording an immutable audit trail on the Ethereum network while simultaneously serving as the experimental control to identify sources of gas inefficiency and to compare the proposed optimization techniques. The contract is developed using Solidity with a storage scheme based on dynamic arrays and mappings to support chronological recording and per-report indexing [44], [45]. The primary data structure, AuditLog, represents a single activity entry containing the report identity, action type, integrity hash, complete data payload, timestamp, sender address, and actor role, as shown in Algorithm 1.

```
pragma solidity 0.8.19;
contract BaselineReporting {
    struct AuditLog {
        uint256 id; string reportCode; string actionType; string dataHash; string dataPayload; uint256 timestamp; address actor; string actorRole;
    }
    AuditLog[] public logs; mapping(string => uint256[]) public logsByReport;
    event LogAdded(uint256 indexed id, string reportCode, string actionType, address actor, uint256 timestamp);
}
```

Algorithm 1: Structure of AuditLog in BaselineReporting Smart Contract.
Source: Authors, (2026).

The AuditLog structure is designed by considering the storage characteristics of Ethereum, where fixed types such as uint256 and address each occupy one 32-byte slot, whereas dynamic types such as string store the data length in the main slot and the actual content in separate storage slots. Each write or modification of a value in storage triggers an SSTORE (Storage Store) operation, which is an instruction that stores data into the permanent blockchain storage and represents one of the most gas-expensive operations.

Consequently, the use of several large string fields such as dataPayload and dataHash increases the number of slots utilized and enlarges gas consumption. The detailed storage characteristics of each field are presented in Table 3.

Table 3: Storage Characteristics of AuditLog Fields in Solidity.

Field	Solidity Type	Storage Characteristics	Description
id	uint256	Fixed 32 bytes (1 slot)	Sequential auto-generated ID
reportCode	string	Dynamic (≥32 bytes)	Report code, e.g., "PPKPT-100042" (13 bytes)
actionType	string	Dynamic (≥32 bytes)	Action type, e.g., "CREATE" (6 bytes)
dataHash	string	Dynamic (≥32 bytes)	SHA-256 hash in hexadecimal string (64 characters)
dataPayload	string	Dynamic (hundreds of bytes)	Complete JSON report data (~500–1000 characters)
timestamp	uint256	Fixed 32 bytes (1 slot)	Automatic block timestamp
actor	address	20 bytes (stored in 32-byte slot)	Ethereum address of transaction sender
actorRole	string	Dynamic (≥32 bytes)	Actor role, e.g., "ADMIN" (5 bytes)

Source: Authors, (2026).

Architecturally, the logs array is used to maintain chronological recording in an append-only manner, while the logsByReport mapping functions as a reportCode-based index to access the report history directly without full iteration. Each invocation of the addLog() function adds a new entry to both structures and emits an event as an external recording mechanism, so that within a single transaction several storage write operations occur that directly contribute to gas consumption. The implementation of this function is shown in Algorithm 2.

```
function addLog( string memory _reportCode, string memory _actionType, string memory _dataHash, string memory _dataPayload, string memory _actorRole)
public {
    uint256 newId = logs.length;
    AuditLog memory newLog = AuditLog({id: newId, reportCode: _reportCode, actionType: _actionType, dataHash: _dataHash, dataPayload: _dataPayload,
                                       timestamp: block.timestamp, actor: msg.sender, actorRole: _actorRole});
    logs.push(newLog); logsByReport[_reportCode].push(newId); emit LogAdded(newId, _reportCode, _actionType, msg.sender, block.timestamp); }
```

Algorithm 2: addLog Function Implementation in Smart Contract.

II.5 SMART CONTRACT ALGORITHM OPTIMIZATION METHODS

A comparative framework was designed to evaluate three optimization techniques against the baseline design by emphasizing differences in algorithmic characteristics that affect execution efficiency and the intensity of on-chain interactions. Four approaches were directly tested in a consistently controlled environment, so that the resulting performance variations fully reflect the data management strategies and transaction recording patterns implemented by each algorithm. Measurements were conducted automatically during the execution process and analyzed using descriptive statistics to obtain objective and measurable comparisons, while the structure of the experimental variables is summarized in Table 4.

Table 4: Experimental Variable Design.

Variable Type	Variable	Description
Independent	Smart contract algorithm type	4 levels: Baseline, Merkle Tree, Storage Optimized, Conditional Commit
Dependent	Gas Used	Total gas units consumed per transaction
	Gas Cost (ETH)	Transaction cost in ETH
	Latency	Transaction execution time in milliseconds
	Number of on-chain transactions	Total transactions submitted to blockchain
Control	Report data	Identical for all algorithms (deterministic input)
	Compiler	Solidity 0.8.19

Source: Authors, (2026).

II.5.1 Algorithm 1: Baseline — Individual Storage (Naive)

The baseline algorithm represents the simplest approach, in which each critical action generates a single on-chain transaction that directly records the entire report data individually. For each report, the system computes a SHA-256 hash as an integrity marker, constructs a complete JSON representation, and then sends all these parameters to the addLog() function in the smart contract. Because each report is processed and stored separately without aggregation or data structure compression, the number of transactions increases proportionally with the number of processed reports; therefore, this approach serves as the primary benchmark for measuring the efficiency of subsequent optimization techniques. The logical flow of the process is illustrated in Algorithm 3.

***Input**: A set of reports totaling n*
***Output**: A list of transaction receipts*
1. Retrieve one report from the dataset *2. Compute the SHA-256 hash of the report content as an integrity marker* *3. Construct the report data in a complete JSON format* *4. Send all information (report code, action type, hash, payload, actor role) to the smart contract* *5. Wait until the transaction is confirmed on the blockchain and then store the transaction receipt* *6. Repeat steps 1–6 until all n reports have been processed*

Algorithm 3: Algorithm: BaselineReporting.
Source: Authors, (2026).

Computationally, the number of generated transactions is linear with respect to the number of reports, resulting in a complexity of $O(n)$, where n denotes the total number of processed reports. No aggregation or optimization mechanisms are implemented outside the contract; therefore, all interaction and storage costs are borne directly by individual transactions. The total gas consumption for processing n reports is formulated in Equation (1):

$$C_{baseline} = \sum_{i=1}^{n} \left(G_{base} + G_{calldata,i} + G_{storage,i} \right) \quad (1)$$

Which can be approximately simplified into Equation (2):

$$C_{baseline} \approx n \times C_{per_{tx}} \quad (2)$$

In this formulation, $C_{baseline}$ represents the total gas consumed for all reports. The component G_{base} represents the fixed base cost of transaction execution. The component $G_{calldata,i}$ denotes the cost resulting from transmitting the parameters of the i-th transaction, which is influenced by the size of the transmitted data. Meanwhile, $G_{storage,i}$ represents the permanent storage cost of the i-th transaction through the SSTORE operation, which has a high value because it involves writing data to blockchain storage. Furthermore, $C_{per_{tx}}$ represents the estimated average gas cost for a single individual transaction in the baseline approach.

II.5.2 Algorithm 2: Transaction Aggregation via Merkle Tree

This approach reduces the number of on-chain transactions by grouping several reports into a single batch, and then storing only one representative hash value in the form of a Merkle Root in the smart contract [46], [47]. With this strategy, the number of transactions decreases from n (as in the baseline) to ⌈n/B⌉, where B denotes the batch size. Each batch is represented by the BatchCommit structure as shown in Algorithm 4, which stores the batch identity, the Merkle Root value, the number of reports, the range of report indices, the recording timestamp, and the address of the commitment sender. The aggregation procedure is illustrated in Algorithm 5 The Merkle Tree construction process is performed in a bottom-up manner, as illustrated in Algorithm 4.

```
struct BatchCommit { uint256 batchId; bytes32 merkleRoot; uint256 reportCount; uint256 fromIndex; uint256 toIndex; uint256 timestamp; address committer; }
```

Algorithm 4: BatchCommit Structure in MerkleAggregation Contract.
Source: Authors, (2026).

***Input**: n reports and batch size B*
***Output**: List of batch transaction receipts*
1. Determine the number of batches based on the total reports and the batch size *2. For each batch:* *a. Retrieve a group of reports according to its index range* *b. Convert each report into a hash (using KECCAK-256 over the report content)* *c. Arrange all hashes into a Merkle Tree structure* *d. Compute the root value of the tree (Merkle Root)* *e. Send the Merkle Root along with batch metadata to the smart contract through the commitBatch function* *f. Wait for transaction confirmation and store the transaction receipt* *3. Return all batch transaction receipts*

Algorithm 5: Algorithm: MerkleAggregation.
Source: Authors, (2026).

***Input**: List of report hashes in one batch*
***Output**: A single Merkle Root value*
1. Arrange all report hashes as the lowest level *2. Pair two adjacent hashes, then concatenate and hash them again to form a parent hash* *3. If the number of elements is odd, duplicate the last hash to maintain pairing* *4. Repeat the merging process until only one hash remains at the top* *5. The final hash becomes the Merkle Root*

Algorithm 6: Merkle Tree Construction Algorithm.
Source: Authors, (2026).

From a complexity perspective, constructing a Merkle Tree for a batch containing m reports requires O(m log m) because hashes are organized hierarchically from the leaf level to the root. With a fixed batch size B, the total off-chain computation for n reports becomes O (n log B). Meanwhile, on the on-chain side, the number of transactions decreases to O(n/B), thereby reducing the frequency of global blockchain state writes proportionally to the batch size. The membership of a report within a batch is verified using a Merkle Proof as shown in Algorithm 7, by reconstructing the hash path from the leaf to the root using proof elements, and then comparing the final result with the Merkle Root stored in the contract. If both values are identical, the report is proven to be valid as part of the corresponding batch.

```
function verifyReport( bytes32[] memory _proof, bytes32 _leaf, uint256 _batchId)
public view returns (bool valid) {
    bytes32 computedRoot = _leaf;
    for (uint256 i = 0; i < _proof.length; i++) {
        bytes32 proofElement = _proof[i];
        if (computedRoot <= proofElement) { computedRoot = keccak256(abi.encodePacked(computedRoot, proofElement)); }
        else { computedRoot = keccak256(abi.encodePacked(proofElement, computedRoot)); }
    } return computedRoot == batches[_batchId].merkleRoot;
}
```

Algorithm 7: verifyReport Function for Merkle Proof Validation.
Source: Authors, (2026).

The total gas cost for the aggregation approach is formulated in Equation (3):

$$C_{merkle} = \left\lceil \frac{n}{B} \right\rceil \times C_{store_{root}} \tag{3}$$

Approximately, when n is much larger than B, the total cost can be expressed as Equation (4):

$$C_{merkle} \approx \frac{n}{B} \times C_{store_{root}} \tag{4}$$

In these equations, C_{merkle} represents the total gas cost for processing n reports using aggregation. The variable n denotes the number of reports and B represents the batch size. The component $C_{store_{root}}$ represents the average cost of storing a single Merkle Root into the smart contract, including the overhead of executing the commitBatch function and the permanent storage operations within the BatchCommit structure. Theoretically, when $B > 1$, gas consumption decreases significantly because only a single fixed-size hash is recorded per batch. However, this efficiency introduces additional off-chain computation and requires a Merkle Proof-based verification mechanism when individual verification is needed. This trade-off between gas reduction and verification complexity is analyzed in the experimental stage.

II.5.3 Algorithm 3: Storage Optimization (Packed Struct + Enum Encoding)

This approach reduces gas consumption not by decreasing the number of transactions, but by compacting the representation of data stored in each transaction [48]. Dynamic data types such as string are replaced with more efficient fixed-length and numeric types: categorical attributes are encoded as `uint8`, while identifiers and hashes are represented as `bytes32`. Nine `uint8` fields are then packed into a single `uint128` variable using bitwise operations, allowing multiple attributes to share a single 32-byte storage slot. The optimized structure is shown in Algorithm8.

```
struct PackedAuditLog { bytes32 reportCode; bytes32 dataHash; uint256 timestamp; address actor; uint128 packedEnums; }
```

Algorithm 8: PackedAuditLog Structure in StorageOptimized Smart Contract.
Source: Authors, (2026).

The number of transactions remains linear with respect to the number of reports O(n), but each entry uses fewer storage slots compared with a dynamic string-based representation. The four primary components (`reportCode`, `dataHash`, `timestamp`, and `actor`) occupy individual slots, while nine categorical attributes share a single slot through `uint128`, thereby reducing the per-transaction cost constant. The total gas cost is formulated in Equation (5):

$$C_{packed} = \sum_{i=1}^{n} \left(G_{base} + G_{calldata,i}^{fixed} + G_{storage,i}^{optimized} \right) \tag{5}$$

Which can be approximately simplified into Equation (6):

$$C_{packed} \approx n \times C_{per_{tx}}^{optimized} \tag{6}$$

In this formulation, C_{packed} represents the total gas cost for n reports with the optimized structure. The component G_{base} still represents the base transaction cost. The value $G_{calldata,i}^{fixed}$ indicates a lower calldata cost because all parameters use fixed-length types. Meanwhile, $G_{storage,i}^{optimized}$ represents the reduced SSTORE operation cost due to the elimination of dynamic storage allocation and the implementation of a storage packing mechanism. Furthermore, $C_{per_tx}^{optimized}$ is the estimated average cost per transaction after the data structure optimization is applied.

II.5.4 Algorithm 4: Conditional Commit (Threshold-Based Batching)

This approach implements an off-chain buffering mechanism, in which reports are not immediately submitted to the blockchain but are first accumulated until a specified threshold value is reached [49], [50]. Once the number of reports in the buffer meets this threshold, the system submits a single commit transaction that records an aggregated hash representing all reports within the batch. Consequently, the number of on-chain transactions is reduced proportionally to the threshold value applied.

The metadata for each batch is recorded in the BatchRecord structure as illustrated in Algorithm 9, which contains the batch identifier, the aggregated hash, the number of reports included, the range of report identifiers, the threshold value applied at the time of commit, the recording timestamp, and the address of the transaction sender.

```
struct BatchRecord {
    uint256 batchId; bytes32 batchHash; uint256 reportCount; uint256 fromId; uint256 toId; uint256 threshold; uint256 timestamp; address committer; }
```

Algorithm 9: BatchRecord Structure in ConditionalCommit Smart Contract.
Source: Authors, (2026).

The initial threshold value is configured through the contract constructor as shown in Algorithm 10, which assigns the contract owner, initializes the total number of committed reports, and stores the initial threshold value as a system control parameter.

```
constructor(uint256 _initialThreshold) { owner = msg.sender; totalReportsCommitted = 0; currentThreshold = _initialThreshold; }
```

Algorithm 10: Constructor for Initial Threshold Configuration.
Source: Authors, (2026).

The procedural flow of the commit mechanism is presented in Algorithm 12.

***Input**: n reports and threshold value T*
***Output**: List of commit transaction proofs*
1. Prepare an empty buffer to store report hashes
2. For each report:
a. Compute the report hash as an integrity marker
b. Store the hash in the buffer
c. If the number of elements in the buffer reaches T:
- Concatenate all hashes in the buffer
- Compute a single aggregated hash from the concatenated data
- Submit the aggregated hash together with batch metadata to the smart contract
- Wait for transaction confirmation and store the transaction proof and then clear the buffer
3. After all reports have been processed, if any elements remain in the buffer, perform a final commit
4. Return all transaction proofs

Algorithm 12: ConditionalCommit Procedure.
Source: Authors, (2026).

From a computational perspective, each report is processed only once to generate its hash, resulting in an off-chain complexity of O(n). However, the number of on-chain transactions decreases to O(n/T), where T denotes the threshold value. Experimental evaluation for $n = 1000$ reports under several threshold values is presented in Table 5, demonstrating that increasing T reduces transaction frequency but increases commit latency, since reports must wait until the buffer reaches the defined threshold.

Table 5: Evaluated Threshold Parameters.

Threshold	On-chain Transactions (n=1000)	Reduction Ratio	Characteristics
5	200	5:1	More frequent commits with relatively low latency
10	100	10:1	Balanced trade-off between gas savings and responsiveness
25	40	25:1	High gas savings
50	20	50:1	Maximum gas savings with higher commit latency

Source: Authors, (2026).

The total gas cost is formulated in Equation (7):

$$C_{conditional} = \left\lceil \frac{n}{T} \right\rceil \times C_{commit} \tag{7}$$

If n is significantly larger than T, the total cost can be approximated as shown in Equation (8):

$$C_{conditional} \approx \frac{n}{T} \times C_{commit} \tag{8}$$

In these expressions, $C_{conditional}$ represents the total gas cost required to process n reports using the threshold-based mechanism. The variable n denotes the number of reports, T represents the threshold value per batch, and C_{commit} corresponds to the average gas cost of a single commit transaction that records an aggregated hash on the blockchain. The optimal threshold value is determined by calculating the effective gas per report, defined as the ratio between the total gas consumed and the number of processed reports. The value of T that produces the lowest average cost is selected as the optimal configuration, while also considering the trade-off between gas efficiency and increased commit latency.

III. RESULTS AND DISCUSSIONS

This chapter presents the performance evaluation results of various gas fee optimization approaches in the implementation of smart contracts for a blockchain-based sexual violence reporting system. The dataset used in the experiment consists of 1,000 simulated reports with an attribute structure as shown in Table 6, representing various report characteristics such as victim type, level of concern, incident location, and system action metadata. The experiments were conducted using a CPU-only computational environment without GPU acceleration, with hardware specifications consisting of an AMD Ryzen 5 6600H (12 CPUs) processor operating at approximately 3.3 GHz and 16 GB of RAM.

In this evaluation scenario, the Conditional Commit approach was implemented using a batching mechanism with a threshold of 50 reports, where a commit to the blockchain is executed once the number of reports in the buffer reaches the defined threshold. Subsequently, the performance of the Baseline, Merkle Tree Aggregation, Storage Optimized, and Conditional Commit methods was analyzed based on several key metrics, namely total gas consumption, transaction cost (ETH), transaction latency, and system execution time, across various report quantity scenarios.

The experimental results demonstrate clear performance differences between the baseline approach and the three proposed optimization methods in terms of gas consumption, transaction cost, latency, and execution time. As shown in Table 7, the baseline method consistently produces the highest gas consumption across all report quantity scenarios. The total gas increases from 38,430,050 gas for 50 reports to 770,899,033 gas for 1,000 reports, exhibiting a nearly linear growth pattern as the number of reports increases. This condition occurs because each report is processed as an independent on-chain transaction and stores several data fields in the smart contract storage. In the Ethereum Virtual Machine (EVM), storage write operations through the SSTORE instruction incur relatively high gas costs, particularly when the stored data has large size or uses dynamic data types. Consequently, as the number of processed reports increases, the number of storage operations also increases proportionally, directly affecting the total gas consumption and transaction cost. Statistical analysis using the Kruskal–Wallis test indicates that the differences between methods in the gas per transaction metric are significant across all scenarios; for example, in the 100-report scenario, a value of $H = 166.93$ with $p < 0.01$ was obtained.The Merkle Tree Aggregation method demonstrates a substantial reduction in gas consumption compared with the baseline. In this approach, multiple reports are first combined off-chain to form a Merkle Tree structure, after which only the Merkle Root value is recorded on the blockchain through a single commit transaction.

Through this mechanism, the number of on-chain transactions is reduced because a single transaction can represent multiple reports simultaneously. Data in Table 7 show that the total gas required for 1,000 reports reaches only 20,492,732 gas, which is significantly lower than the baseline. The Mann–Whitney test also indicates that the difference in gas consumption between the baseline and the Merkle Tree method is statistically significant across various scenarios; for instance, in the 500-report scenario, $p < 0.01$. The reduction in the number of transactions also contributes to lower latency and execution time, since fewer transactions need to be processed and confirmed by the blockchain network. The Storage Optimized approach reduces gas consumption through modifications to the data structure stored within the smart contract. This method replaces dynamic data types such as string with fixed-length types such as bytes32 and utilizes storage packing techniques to reduce the number of storage slots used. This optimization decreases the cost of data writing because fewer storage slots need to be updated. Experimental results indicate that the total gas consumption in the 1,000-report scenario is 177,566,016 gas, which is lower than the baseline but still higher than aggregation-based methods. Statistical testing also shows that the difference between the baseline and Storage Optimized approaches is significant in nearly all scenarios; for example, in the 100-report scenario, $p < 0.01$. This outcome arises from the characteristic of the method that continues to process each report as an individual transaction, resulting in the number of transactions still increasing linearly with the number of reports.

Table 7: Total Gas Consumption, Transaction Cost (ETH), Latency, and Execution Time for Each Scenario (50, 100, 500, and 1000) and Optimization Method.

Scenario	Method	Total Gas	Total Cost (ETH)	Total Latency (ms)	Total Exec Time (s)
50	Baseline	38,430,050	0.77	7066.71	7.07

The Conditional Commit method produces the lowest total gas consumption among all evaluated approaches. This mechanism collects several reports within a buffer until a specified threshold is reached before performing a commit to the blockchain. Each commit stores an aggregated hash representing a batch of reports, enabling a single transaction to record multiple reports simultaneously. By reducing the frequency of on-chain transactions, this method significantly decreases overall gas consumption and shortens the system execution time. In the 1,000-report scenario, the total gas consumption is 4,308,404 gas with an execution time of approximately 1.08 seconds, which is substantially lower than the baseline that requires 143.72 seconds. Statistical testing results also indicate that latency differences among methods are significant; for instance, in the 100-report scenario, a value of $H = 159.70$ with $p < 0.01$ was obtained, demonstrating that reducing the number of transactions has a substantial impact on improving the efficiency of blockchain system performance. The average per-transaction metric analysis in Table 8 provides additional insights into the execution characteristics of each method. The baseline approach exhibits an average gas consumption of approximately 768,000 to 770,000 gas per transaction, with relatively small variation across scenarios, indicating that the transaction operation structure remains relatively consistent. The Merkle Tree method reduces this average value to approximately 204,000 to 209,000 gas, because the transaction only stores batch metadata and the Merkle Root. The Storage Optimized approach produces an average of approximately 177,000 to 186,000 gas per transaction as a result of improved storage structure efficiency. The Conditional Commit method has an average of approximately 196,000 to 215,000 gas per transaction, slightly higher than Storage Optimized because each commit transaction stores additional metadata; however, the significantly smaller number of transactions ensures that the overall system gas consumption remains low.

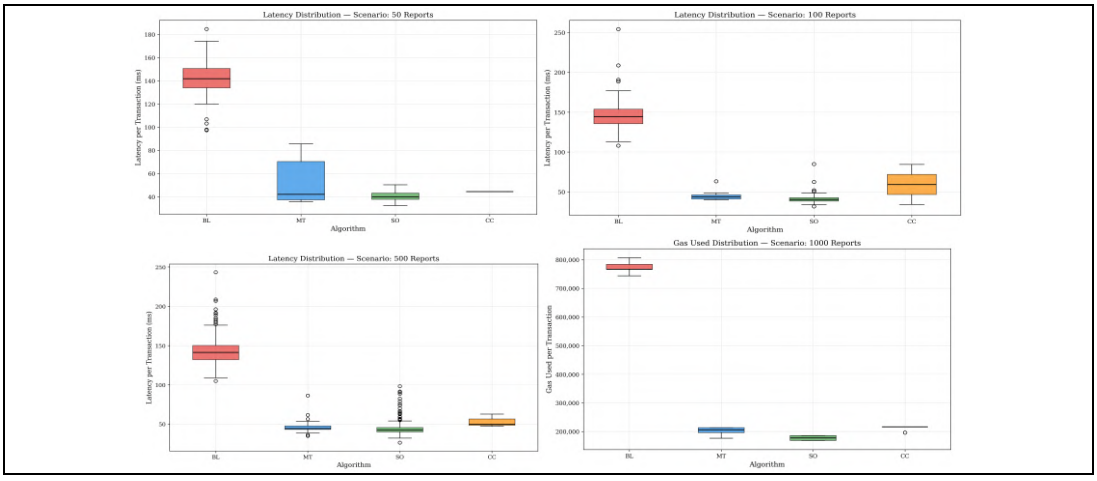

Figure 4: Boxplot of Transaction Latency Distribution (ms) Across Optimization Methods.
Source: Authors, (2026).

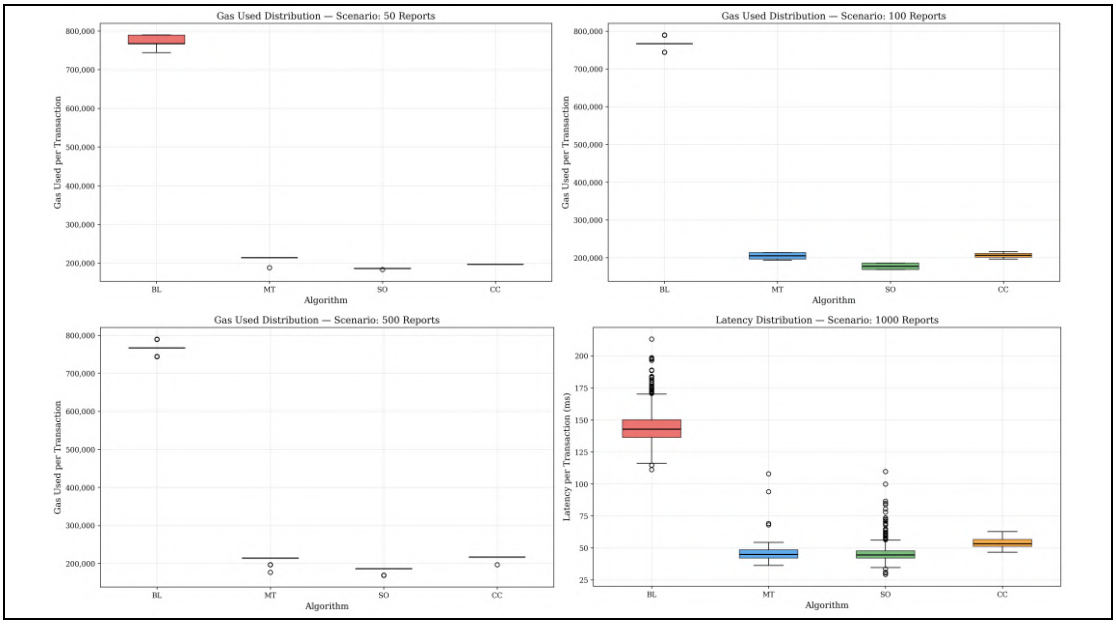

Figure 5: Boxplot of Gas Consumption Distribution per Transaction Across Optimization Methods.
Source: Authors, (2026).

The distribution of transaction latency visualized in Figure 4 shows distinct performance patterns among the evaluated methods. The baseline approach exhibits a median latency of approximately 140–145 ms with a wider interquartile range compared to the other methods, indicating relatively higher variability in execution time. This variation is associated with the larger calldata size and the greater number of storage operations performed in each transaction. The Merkle Tree and Storage Optimized methods demonstrate lower median latency values in the range of approximately 40–46 ms, with more concentrated distributions, reflecting lighter transaction execution processes. The Conditional Commit approach has a slightly higher median latency than these two methods, around 52–54 ms, yet it remains lower than the baseline and shows relatively small variation as the number of batches increases. The distribution of gas consumption per transaction presented in Figure indicates that the baseline method has the highest median value, approximately 766 thousand to 767 thousand gas. The Merkle Tree method reduces this value to approximately 205 thousand to 213 thousand gas per transaction, whereas the Storage Optimized approach shows a median of approximately 177 thousand to 186 thousand gas with relatively small variation. The Conditional Commit method has a median of approximately 196 thousand to 216 thousand gas, reflecting the storage of batch metadata within each commit transaction. The baseline approach shows a value of approximately 768 thousand gas per report across all scenarios, while Storage Optimized reduces it to approximately 177 thousand to 186 thousand gas. The Merkle Tree method produces a consumption of around 20 thousand gas per report because the transaction cost is distributed across all reports within a batch. The Conditional Commit approach demonstrates the lowest value, approximately 3,930 to 4,308 gas per report, since a single commit transaction represents multiple reports simultaneously.

This study provides an empirical contribution to the understanding of factors influencing the efficiency of blockchain-based reporting systems. By comparing several optimization approaches across different report quantity scenarios, the study demonstrates that strategies aimed at reducing the number of on-chain transactions can produce a greater impact on gas efficiency than data structure optimization alone. The evaluation conducted through metrics such as total gas consumption, average per-transaction metrics, and performance distribution analysis offers a more comprehensive overview of the performance characteristics of each method. This study has several limitations, primarily related to gas costs on the Ethereum network. Although the proposed optimization techniques significantly reduce gas consumption compared to the baseline approach, blockchain transaction costs remain relatively high, particularly as the number of reports increases. Furthermore, the experiments were conducted in a controlled testing environment, which does not fully represent the dynamic conditions of public blockchain networks, such as gas price fluctuations and transaction congestion levels. The evaluation in this study also focuses on primary metrics such as gas consumption, transaction cost, latency, and execution time, while other aspects that may influence cost efficiency, such as off-chain computation overhead and batch management, have not yet been analyzed in depth. Future research may explore more adaptive optimization strategies to mitigate the impact of high gas costs. One potential approach is the implementation of adaptive batching, which dynamically adjusts batch size or commit timing based on network conditions and gas prices. In addition, integration with layer-2 scaling solutions, such as rollups or sidechains, may further reduce transaction costs significantly [51]. Further evaluation on public blockchain networks with varying gas price conditions is necessary to obtain a more realistic understanding of system performance in real-world implementations.

IV. CONCLUSIONS

This study evaluated several smart contract optimization strategies to reduce gas consumption in a blockchain-based mobile reporting system for sexual violence cases on the Ethereum network. The findings indicate that the efficiency of blockchain applications is strongly influenced by how data storage and transaction submission are designed. Approaches that store detailed information directly on-chain result in high computational costs due to intensive storage operations, whereas strategies that minimize storage usage or reduce the frequency of on-chain transactions significantly improve scalability. In particular, aggregation and threshold-based batching mechanisms enable multiple reports to be represented through compact cryptographic commitments while preserving data integrity.

Scientifically, this research contributes a comparative experimental framework that integrates storage-level optimization, cryptographic aggregation, and transaction batching within a single evaluation environment, providing empirical evidence on how different design strategies affect gas efficiency and execution performance. Practically, the results provide guidance for developers and system architects in designing blockchain-based audit logging systems that remain economically feasible on public blockchain infrastructures. Nevertheless, the study is limited to experiments conducted in a controlled environment and focuses primarily on gas efficiency metrics without evaluating broader aspects such as security trade-offs or real network variability. Future studies should examine adaptive batching mechanisms, cross-platform blockchain implementations, and security implications of off-chain aggregation to further improve the scalability and reliability of decentralized reporting systems.

ABSTRACT

Flat plate solar collectors (FPCs) have significant thermal performance that is vital in improving the efficiency of solar thermal energy systems. Traditional absorber coating, including black paint, has limited optical and thermal behavior, and nanomaterial-based absorber coating has received interest in improving performance. The purpose of the study is to assess and compare the thermal performance of FPCs when coated with CuO, Al2O3 and graphene nanoparticles. A mathematical model simulator of the performance of the collector under dynamic solar and environmental conditions was created using transient lumped capacitance in MATLAB. The model computes the important thermal performance indicators, such as outlet fluid temperature, useful heat gain, and instantaneous efficiency, and it has been verified against literature data. Simulation findings indicate that nanomaterial coatings are much more efficient in terms of thermal conductivity with graphene showing the most dramatic efficiency improvement of up to 0.835 relative to 0.725 when using black paint and a maximum useful heat gain of 834 W relative to 724 W. Graphene-coated collectors on average increased efficiency by 15.2% and useful heat gain by 13.8%. The improvements of Al2O3 and CuO coating were around 9-11% higher than black paint. Such improvements are explained by the high thermal conductivity and optical absorption of nanoparticles. The results show the promise of advanced nanocoatings to enhance the efficiency of solar thermal systems and offer a solid basis to optimize and experimentally validate such systems in the future.

I. INTRODUCTION

Solar flat plate collector (FPSC) is a widely used solar thermal system that absorbs solar energy and transforms it into heat energy to be used in different ways, such as heating water and heating space. The FPSC consists of the core element, which is the absorber plate that directly affects the thermal efficiency of the system because it absorbs solar radiation and transfers heat to the working fluid [1–4].

The design parameters and material properties of the absorber plate have a considerable influence on the performance of the system. Materials with a high thermal conductivity, including copper and aluminum, increase the efficiency of heat absorption and transfer, which decreases thermal resistance [5] [6]. Also, surface alterations, including roughened surfaces, prolonged surfaces, and selective surface finishes are used to reduce radiative and convective heat losses to enhance heat retention [7] [8]. The geometrical arrangement of the absorber plate, plate thickness, channel structure, and fluid temperature increase are also further affected by the heat transfer efficiency and fluid temperature increase [1–3]. The optimization of these design parameters results in the achievement of high performance of FPSC and the system becomes efficient and effective in real-life applications. The development of absorber plate technology has greatly increased the efficiency of solar flat plate collectors (FPSC) through the enhancement of the mechanisms of heat absorption, retention and transfer. Surface modifications and innovations that include micro-grooved, V-corrugated, and selectively coated surfaces have been proposed to optimize optical absorption and reduce radiative and convective heat losses [1-8]. Absorber plates that have been integrated with nanomaterials, including carbon nanotubes, graphene, and metal oxide coating, have demonstrated increased thermal conductivity and solar energy conversion efficiency [9–11]. Geometric improvements, including the use of serpentine flow paths, spiral tubes, and multi-channel absorber designs, have improved the heat transfer through the increased surface contact between the working fluid and the absorber plate [1-12]. All these developments are aimed at enhancing the overall thermal performance and efficiency of FPSCs, and therefore, they become more suitable to sustainable and high-performance solar energy use. Improvement of solar thermal absorber plates by using different coatings, materials and structural changes is a common study in the quest to enhance efficiency, heat transfer and energy absorption. Coating modifications have shown to have great enhancements in thermal performance. Palanikumar et al. [13] discovered that a 0.1 mm black nickel thin film covering on copper absorber tubes reached a maximum absorptance of 0.98, reducing emissivity and maximizing thermal efficiency to 74.3%. In the same way, Nazari et al. [14] demonstrated that the coating of a cuprous absorber plate with CuO nanoparticles enhanced efficiency by 35.8% and exergy efficiency by 11.2. Coatings based on graphene also provided significant improvements, with Kumar et al. [15] reporting that graphene-doped black paint on a triangular plate solar air heater, and Mariraja et al. [16] reporting that graphene nanoplatelet (GNP) nano paint on solar still absorber plates, both raised thermal efficiency by 4.91 and exergy efficiency by 4.27. Moreover, Han et al. [17] found that the application of 15 wt% silicon (Si) particles to the plate of a solar still absorber increased the surface temperature by 65.81, which maximized the yield of the distillate.

Coatings that are enhanced by nanoparticles have also been widely researched. Katekar et al. [18] reported that the addition of 30% aluminum oxide nanoparticles to dull black paint enhanced heat transfer and thermal performance of absorber plates by a significant factor, whereas Gurbuz et al. [19] reported that nano-enhanced black paint with Fe3O4 and mesh tubes increased the efficiency of solar air collector by 40.45% and a payback period of 0.31-0.34 years. On the same note, Sivakumar et al. [20] demonstrated that CuO nanoparticle-coated absorber plates in a mixed-mode forced convection solar dryer enhanced collector efficiency by 4% and drying time by 6%. Performance has also been enhanced by structural and material changes to the absorber plates. Sakhaei et al., [21] reported that carbon-coated plates were the most efficient thermally (69.4%), which is 13 and 11.3% higher than the black chrome and black-painted plates, respectively. Sharma et al. [22] indicated that trapezoidal corrugated absorber plates in flat-plate solar collectors increased thermal efficiency by 12.85% and exergy efficiency by 23.31% and Kumar et al. [23] indicated that V-shaped rib roughness on absorber plates enhanced heat transfer despite higher friction factor properties. Also, Karthikeyan et al. [24] discovered that pin-fin absorber plates coated with Multi-Walled Carbon Nanotube (MWCNT) had 12% thermo-hydraulic efficiency and a 24% heat transfer enhancement. Cost-effective performance gains have also been realized by alternative absorber materials. Selikhov et al. [25] have shown that flat-plate solar collectors with polyethylene film absorbers had a maximum efficiency of 0.95 and were up to four times cheaper than aluminum absorbers. In addition, Ganesh Kumar et al. [26] emphasized that the combination of nano-coated conch shells and roughened corrugated copper absorber plates in a two-slope solar still enhanced the thermal efficiency by 35.53% and the water yield to 2193 ml/m2/day. In general, this paper point to the usefulness of nanoparticle-enhanced coating, structural changes, and alternative material to enhance the thermal efficiency, heat transfer, and economic viability of solar thermal absorber plates. The investigation of nanomaterials in solar thermal systems mainly focuses on steady-state conditions and simplified scenarios without adequate exploration of flat plate collector transient thermal responses under genuine solar and environmental fluctuations. The current investigation develops a complete transient thermal model through MATLAB that evaluates the dynamic characteristics of flat plate solar collectors using different nanoparticle materials. The model analyzes true-time solar irradiance and ambient temperature data points using Maxwell model calculations for effective thermal conductivity determination through nanoparticle selection and loading rates while implementing lumped capacitive energy modeling for time-based plate temperature and efficiency measurement. The simulation framework allows researchers to measure key performance indicators at instant efficiency rates, stagnation temperature levels and yearly energy production levels across various coating configurations thus creating a strong evaluation and material optimization environment.

II. MATHEMATICAL MODELING

The use of nanomaterials to improve thermal performance of flat plate solar collectors (FPCs) has received significant interest over the past few years. These surfaces are made of nanoparticles like graphene, CuO, and Al2O3 and are reported to have a tremendous effect on optical and thermal conductivity properties of the absorber plates. To measure such improvements and their effects on the performance of the system, a strict and dynamic mathematical model is necessary to capture the transient thermal behaviors at different solar and environmental conditions. This paper has constructed a MATLAB based simulation code to analyze the thermal efficiency and the energy production of flat plate collectors covered with different nanoparticle materials at varying concentrations. The code has first principles of heat transfer, with dynamic environmental inputs of solar radiation and ambient temperature, and computes key performance indicators of instantaneous collector efficiency, stagnation temperature and annual energy yield. This method offers a strong and scalable platform of comparative performance analysis of advanced coated absorbers in real-life operating environments.

II.1 KEY ASSUMPTIONS AND INPUT PARAMETERS

When formulating the thermal model of the nanoparticle-enhanced flat plate solar collector, a number of assumptions were made to reduce the complexity of the analysis without losing physical relevance. The incident of solar radiation on the collector surface was modeled as a sinusoidal curve, with the sunrise at 6:00 AM and the sunset at 6:00 PM, thus, representing the common diurnal variation in the solar irradiance. Likewise, the ambient temperature pattern was also sinusoidal with the lowest temperature at the beginning of the morning and the highest at the mid-afternoon, which closely approximates the natural environmental conditions. The absorber plate was assumed to be coated with graphene nanoparticles, whose thermal conductivity and solar absorptivity were considered to vary as functions of their concentration in the base material. In order to simulate the heat transfer behavior in the absorber plate, a lumped capacitance method was chosen. This assumes uniform temperature distribution across the plate thickness, which is valid given the small thickness of the plate and the relatively high thermal conductivity of the coated material. These assumptions collectively enabled a computationally efficient yet realistic simulation of the transient thermal behavior of the solar collector.

II.2 CODE DEVELOPMENT PROCEDURE

A simulation code was written in MATLAB to simulate the transient thermal performance of nanoparticle-enhanced flat plate solar collectors. The code is structured and modular, consisting of input definition, property enhancement, transient thermal simulation, performance analysis and result visualization. This systematic system enables the successful comparison of performance in different coating conditions.

- Input Module: Characterizes absorber geometry, coating parameters and environmental conditions (solar radiation and ambient temperature).
- Property Enhancement: Computes effective thermal conductivity, based on the Maxwell model and recalculates specific heat and density.
- Transient Module: Uses lumped capacitance model to model time-based temperature variation across the plate.
- Performance Module: Calculates instantaneous thermal efficiency, daily production and approximates yearly energy gain.
- Output and Visualization: Plots time-series data of irradiance, temperature and efficiency; compares materials and concentrations.
- Modular Design: Allows the flexibility of expansion and future upgrades or parametric studies.

II.3 CODE PERFORMANCE EVALUATION PROCEDURE

A systematic performance evaluation procedure was used to evaluate the accuracy and applicability of the developed MATLAB simulation code. This included comparing the numerical forecasts with benchmark data, sensitivity and parametric analysis and estimating long term energy production under different conditions. The steps are necessary to assure that the model is reliable to reflect the thermal behavior of nanoparticle-enhanced flat plate collectors and facilitate optimization studies.

- Result validation: Comparison of simulated temperature profiles and thermal efficiencies with published experimental data or literature values of similar nanoparticle coatings were used to verify the accuracy of the model.
- Sensitivity Analysis: The effect of nanoparticle thermal conductivity and volume fraction on thermal response of the collector was examined to determine the effect of the material.
- Annual Energy Estimation: Hourly energy gains were summed up over a daily cycle and extrapolated to give the total annual energy output of the collector system.
- Stagnation Analysis: The maximum temperature of the absorber plate (stagnation temperature) was calculated, which provided information on the highest thermal loading, by assuming zero flow conditions.
- Parametric Study: A series of simulations were performed to produce contour plots and the impact of optical (absorptance a) and thermal (emittance e) property variations on the performance metrics was observed.

III. NUMERICAL METHODOLOGY

III.1 OVERVIEW OF NUMERICAL MODELING

The numerical analysis in this study was conducted using a MATLAB-based finite difference method (FDM) to simulate the transient thermal behavior of a nanoparticle-enhanced flat plate solar collector absorber. The model accounts for conduction within the absorber plate, convective and radiative heat losses from the top surface, and thermal energy absorption from incident solar radiation. The impact of adding nanoparticles to the absorber coating is captured through modified thermophysical properties. The simulation includes time-dependent ambient and solar conditions to closely mimic realistic operating scenarios.

III.2 GOVERNING EQUATION

The primary equation governing the energy dynamics in the absorber plate is based on the first law of thermodynamics, applied to a control volume given by Eq. (1):

$$mC_p \frac{dT_p}{dt} = Q_{in} - Q_{loss} \quad (1)$$

T_p is the average plate temperature, C_p is the specific heat, Q_{in} is the absorbed solar energy, and Q_{loss} includes convective and radiative heat losses from the top surface. To assess thermal performance at any instant, instantaneous thermal efficiency is defined as Eq. (2):

$$\eta(t) = \frac{Q_{useful}}{I \cdot A} = \frac{Q_{in} - Q_{loss}}{I \cdot A} \quad (2)$$

Where *I* is solar irradiance and *A* is the collector area. The effective thermal conductivity of the nanoparticle-enhanced coating is estimated using the Maxwell model as given in Eq. (3):

$$k_{eff} = k_{base} \cdot \left(\frac{k_{np} + 2k_{base} + 2\phi(k_{np} - k_{base})}{k_{np} + 2k_{base} - \phi(k_{np} - k_{base})} \right) \quad (3)$$

This accounts for the influence of nanoparticle volume fraction ϕ on thermal conductivity.

III.3 BOUNDARY CONDITIONS

In the present study, the thermal behavior of the absorber plate coated with nanoparticle-enhanced paint is simulated by applying realistic boundary conditions that represent actual operating environments of flat plate solar collectors. Top Surface Boundary Condition The top surface of the absorber plate is exposed directly to the solar irradiance, resulting in a heat gain, while simultaneously losing heat through convection to the ambient air and radiation to the surroundings. This is modeled using a combined heat flux boundary condition expressed as Eq. (4):

$$-k\left(\frac{\partial T}{\partial y}\right)_{\text{top}} = \alpha I(t) - h_{\text{conv}}(T_s - T_{\text{amb}}) - \varepsilon\sigma(T_s^4 - T_{\text{amb}}^4) \quad (4)$$

This boundary condition ensures the simulation captures the transient and competing effects of solar heat gain and environmental heat loss. The inclusion of both convective and radiative terms allows the model to handle a wide range of environmental conditions and surface modifications. Bottom Surface Boundary Condition The bottom surface of the absorber plate is assumed to be thermally insulated, representing either a well-insulated bottom or negligible heat loss through the backside. This is mathematically expressed as an adiabatic boundary condition – Eq. (5):

$$\left(\frac{\partial T}{\partial y}\right)_{\text{bottom}} = 0 \quad (5)$$

This implies no heat transfer occurs across the bottom boundary, allowing the model to focus on upward heat exchange with the working fluid or air. Lateral Edges Boundary Conditions The lateral sides of the absorber plate are modeled using symmetry or adiabatic conditions, depending on the physical layout and insulation characteristics of the system. For a large or center-symmetric absorber plate, symmetric conditions are suitable and simplify the problem – Eq. (6):

$$\left(\frac{\partial T}{\partial x}\right)_{\text{left/right}} = 0 \quad (6)$$

This indicates that there is no net heat flow across the lateral boundaries, which is a valid assumption when the geometry or physical design suggests negligible lateral heat loss. Initial Condition The entire absorber plate is assumed to be at ambient temperature at the beginning of the simulation – Eq. (7):

$$T(x, y, t = 0) = T_{\text{amb}} \quad (7)$$

This defines the starting point for the transient simulation and ensures that the heat build-up due to solar exposure is captured from the beginning of the day.

III.4 NUMERICAL SCHEME AND GRID DISCRETIZATION

The absorber plate is discretized into a 2D finite difference grid, with nodes representing small control volumes. At each node, transient heat conduction is solved using either an explicit or implicit time-stepping scheme, based on the energy conservation principle. The general form of the heat conduction equation is (Eq. 8):

$$\frac{\partial T}{\partial t} = \alpha\left(\frac{\partial^2 T}{\partial x^2} + \frac{\partial^2 T}{\partial y^2}\right) \quad (8)$$

Where α is the thermal diffusivity. The time-marching algorithm updates nodal temperatures iteratively, and convergence is verified using the following criterion (Eq. 9):

$$\max|T^{n+1} - T^n| < \varepsilon \quad (9)$$

Where ε is a user-defined tolerance for convergence. The program exits once thermal equilibrium is reached for all nodes within the tolerance.

III.5 THERMAL PERFORMANCE METRICS

To comprehensively evaluate and compare the thermal behavior of the nanoparticle-enhanced solar absorber plates and different solar still configurations, several thermal performance metrics were used. These metrics capture instantaneous, daily, and annual system responses under varying ambient and operational conditions.

1. Useful Heat Gain

The useful heat gain (Q_{useful}) is the amount of thermal energy effectively absorbed and utilized by the system to raise the fluid (or plate) temperature. It is calculated as (Eq. 10):

$$Q_{\text{useful}} = \dot{m} C_p (T_{\text{out}} - T_{\text{in}}) \tag{10}$$

This parameter is essential for quantifying the energy that contributes to desalination or heating processes.

2. Instantaneous Thermal Efficiency

The instantaneous thermal efficiency ($\eta(t)$) defines the efficiency of the absorber plate or solar still at a particular moment, based on the ratio of useful energy gain to the incident solar energy (Eq. (11)):

$$\eta(t) = \frac{Q_{\text{useful}}(t)}{I(t) \cdot A} \tag{11}$$

This metric helps assess system performance under dynamic sunlight conditions.

3. Average Daily Efficiency

To evaluate system performance over an entire day, the time-integrated thermal efficiency is computed as (Eq. 12):

$$\eta_{\text{day}} = \frac{\int_0^{t_{\text{day}}} Q_{\text{useful}}(t)\ dt}{\int_0^{t_{\text{day}}} I(t) \cdot A\, dt} \tag{12}$$

This measure smooths out short-term fluctuations and is useful for comparing systems under realistic daily cycles.

4. Annual Energy Output

The annual thermal energy output can be estimated by extrapolating daily performance to a yearly scale, assuming typical daily operation (Eq. (13)):

$$E_{\text{annual}} = Q_{\text{daily}} \times 365 \tag{13}$$

This allows for economic analysis, including cost per liter of water and energy payback period.

5. Stagnation Temperature

Stagnation temperature is the theoretical maximum temperature the absorber can reach when no heat is extracted. It provides insight into system safety and material constraints (Eq. (14)):

$$T_{\text{stag}} = T_{\text{amb}} + \frac{I \cdot \alpha}{U_L} \tag{14}$$

A higher stagnation temperature indicates better insulation or surface absorption but may also raise material degradation concerns.

6. Empirical Collector Efficiency – Hottel–Whillier–Bliss Equation For model validation, the thermal performance is also compared using empirical efficiency correlations (Eq. (15)):

$$\eta = \eta_0 - a_1 \left(\frac{T_m - T_a}{I} \right) - a_2 \left(\frac{(T_m - T_a)^2}{I} \right) \tag{15}$$

These coefficients are commonly used in standard testing (e.g., ASHRAE, ISO) for flat plate collectors. A detailed set of governing parameters-thermal, optical, and geometrical should be specified and measured to provide accurate simulation and evaluation of the thermal performance of nanoparticle-coated flat plate solar collectors. The input parameters used in the developed transient heat transfer model were the key parameters in MATLAB as shown in Table 1. These are basic performance measures like instantaneous efficiency, useful heat gain, stagnation temperature, and annual energy output, which are calculated using energy balance equations and transient fluid temperature profiles. Also, thermal and physical characteristics of the base absorber material (copper), such as thermal conductivity, specific heat, and density are added to model real-world collector behavior. Both conventional and nanoparticle coatings are defined in optical terms of absorptance and emittance to describe radiative interactions. The dimensions and material characteristics chosen are in line with typical commercial flat plate collector designs and thereby increase the practical applicability of the model and allow comparison with experimental and literature-reported data

Table 1: Key Parameters Used in the Transient Performance Analysis of Nanoparticle-Coated Flat Plate Solar Collector.

Category	Parameter	Value(s)	Source/Notes
Performance Parameters	Instantaneous Efficiency	0–100	Calculated from energy balance
	Useful Heat Gain	Dynamic	Based on fluid temperatures and flow rate
	Stagnation Temperature	60–160 (varies by case)	Analytical expression
	Annual Energy Output	Computed for each case	Integrated from daily transient results
Collector Unit Size	Collector Area	2	Typical experimental flat plate collector
	Plate Thickness	0.003	Based on commercial copper absorber plates

Base Material Properties	Base Thermal Conductivity	385	Copper (standard absorber material)
	Specific Heat	385	Copper
	Density	8960	Copper
	Absorptance	0.9	For black paint / selective coatings
	Emittance	0.05 – 0.65	Varies with coating (selective to normal paint)
Nanoparticles Used	Thermal Conductivity Graphene	-	-
	Thermal Conductivity – CuO	33	Common nanofluid additive
	Thermal Conductivity – Al_2O_3	36	Common nanofluid additive
	Volume Fraction	0.01, 0.03, 0.05	1%, 3%, 5% considered

Source: Authors, (2026).

A parametric study was performed with the aim of investigating the effect of material properties and environmental parameters on collector performance. The most important parameters were systematically changed to determine their influence on transient efficiency, absorber plate temperature, and total thermal output as summarized in Table 2. These are the values of nanoparticle thermal conductivity of CuO, Al2O3, and graphene, volume fraction 1-5%, and optical characteristics, solar absorptance, and thermal emittance. Time-dependent profiles of the solar irradiance and ambient temperature are also integrated in the simulation through the use of sinusoidal functions to simulate realistic diurnal operating conditions. Moreover, the effective thermal conductivity of the nanoparticle-enhanced plate is computed dynamically by the Maxwell model. The model ensures a common performance baseline by keeping all the parameters constant (plate thickness, collector area, and mass flow rate) throughout the simulations. This parameter model enables a strong insight into the effect of coating composition and environmental inputs on collector performance, thus enabling the data-driven optimization of advanced absorber coatings.

Table 2: Parametric Study – Input Parameters and Their Levels.

Parameter	Levels / Values Considered	Purpose of Variation
Nanoparticle Thermal Conductivity	33 (CuO), 36 (Al_2O_3), 3000 (Graphene)	To analyze material influence on heat transfer enhancement
Nanoparticle Volume Fraction	0.01, 0.03, 0.05	To assess effect of concentration on collector performance
Solar Absorptance	0.85, 0.90, 0.95	To compare optical performance of coatings
Thermal Emittance	0.05, 0.20, 0.65	To evaluate thermal losses for various coating materials
Solar Irradiance	Transient (0–1000, sinusoidal profile)	To simulate realistic daily solar input
Ambient Temperature	Transient (15–35, sinusoidal profile)	To replicate diurnal weather conditions
Plate Thermal Conductivity (Effective)	Computed via Maxwell Model	To dynamically update heat transfer properties
Plate Thickness	0.003	Fixed – standard plate design
Mass Flow Rate	0.02	To maintain consistent comparison across test cases
Collector Area	2	Fixed size for baseline comparison

III.6 SIMULATION SETUP AND COATING CONFIGURATIONS

This paper analyses thermal performance of a flat plate solar collector under different nanoparticle-enhanced absorber coating under controlled simulation conditions using a MATLAB-based transient thermal model. The main aim is to examine how various nanoparticle coating and mass flow rates affect the outlet temperature of the working fluid and consequently the thermal efficiency of the collector. The simulation model is based on the basic principles of energy conservation, and the equation of energy balance is considered to take into consideration useful heat gain, time-varying solar irradiance, ambient temperature, and heat losses due to convection and radiation. In order to consider the thermal enhancement of nanoparticles, the effective thermal conductivity of the coating layer was calculated through classical Maxwell model with the adjustment of the volume fraction and intrinsic thermal conductivity of the dispersed nanoparticles. Four absorber surface coatings were modeled: conventional black paint, copper oxide (CuO), aluminium oxide (Al_2O_3), and graphene. Each coating was evaluated at a fixed nanoparticle concentration to maintain consistency across cases and to isolate the effect of material thermal properties. The simulations were conducted for three different flow rates i.e. 0.01 kg/s, 0.02 kg/s, and 0.03 kg/s to examine the impact of mass flow rate on the system's thermal response and outlet temperature profile. This setup allowed a fine comparison of thermal performance in terms of coating types and operating conditions and provided information on the interaction between material selection and fluid dynamics to influence solar thermal collector efficiency

IV. NUMERICAL ALGORITHM

A simulation framework of a customized MATLAB was used to conduct the thermal analysis of nanoparticle-enhanced absorber plates. The transient two-dimensional heat conduction equation in the absorber plate domain was solved by the finite difference method (FDM). The general computational procedure can be summarized in the flowchart shown in Figure 1. The simulation starts with the initialisation and input of key parameters such as the geometry of the plate (length, width, and thickness), material characteristics of the base material and nanoparticles (thermal conductivity, density, specific heat), nanoparticle volume fraction (ϕ), solar radiation intensity (G), ambient temperature (Tamb), convective heat transfer coefficient, and plate surface emissivity. Stefan-Boltzmann constant is used to include radiation losses. Boundary conditions are then applied. The top surface of the absorber plate is subjected to combined solar radiation and convective–radiative heat losses, while the bottom surface is thermally insulated. The edges of the plate are treated as either adiabatic or symmetric, depending on symmetry considerations. Next, effective thermophysical properties of the nanocomposite plate are calculated.

These are the effective thermal conductivity (keff), which is calculated by a modified Maxwell model that considers the coupling between base material and nanoparticles, and the effective density (reff) and specific heat (Cp_eff), calculated by volume-weighted averages. This is because the computational domain is discretized with a finite difference grid, which allows calculation of the temperature at each node on discrete time steps. A time-marching loop is then initiated to solve the transient heat conduction problem using either explicit or implicit schemes. At each time increment, nodal temperatures are updated and checked for convergence. The iterative loop continues until the maximum temperature difference between two successive time steps satisfies the convergence criterion,

$$\max|T^{n+1} - T^{n}| < \varepsilon \tag{16}$$

The outputs of the program on convergence are the temperature distribution of the absorber plate with time, spatial temperature profiles, heat flux and thermal efficiency. Thermal efficiency is determined as the ratio of useful heat gain to the total incident solar energy, which is a complete measure of thermal performance of the plate.

V. RESULTS AND DISCUSSIONS

V.1 VARIATION OF SOLAR RADIATION AND AMBIENT TEMPERATURE DURING TEST HOURS

Figure 2 and Figure 3 represent the variation of the solar radiation and ambient temperature of the day at the time of experiment between 9:00 AM to 2:30 PM. The solar radiation was of a normal bell-shaped pattern with the lowest value of 500 W/m2 at the start of the day at 9:00 AM and the highest value of about 1000 W/m2 at 10:40 AM to 11:10 AM. Subsequently, it started to decrease gradually, to about 670 W/m2 at 2.30 PM. This symmetrical pattern is consistent with the natural cycle of solar altitude and it proves the good conditions of radiation to do thermal testing in the middle of the day. Simultaneously, ambient temperature also increased with time with an initial value of 30°C and reaching a peak of 40°C at noon (12:00 PM). After noon, there was a small decrease as a result of the lowering solar elevation and a lower irradiance. The ambient temperature pattern follows the solar radiation peak slightly, which means the thermal inertia of the environment. These realistic variations are needed to model transient boundary conditions in a numerical model and to predict the thermal behavior of solar collector systems. These environmental inputs were dynamic forcing functions to the heat transfer simulations and allowed accurate determination of absorber plate temperatures, thermal losses and efficiency measures in further analysis.

V.2 VARIATION OF OUTLET FLUID TEMPERATURE WITH TIME

Figure 4(a)-4(d) show the change in the temperature of the outlet of the working fluid with time in the case of absorber plates painted with black, CuO, Al2O3, and graphene at mass flow rates of 0.01 kg/s, 0.02 kg/s, and 0.03 kg/s. Based on the graphs, it is clear that at every flow rate, graphene-coated absorber plates always record the highest outlet temperatures, then CuO, Al2O3, and black paint in that order of thermal performance. The graphene-coated collector achieves the highest outlet temperature of 59.29°C at the lowest flow rate of 0.01 kg/s, which is about 4.54, 5.86 and 9.4 higher than CuO (56.69°C), Al2O3 (55.98°C) and black paint (54.18°C). The improvement in performance of graphene coatings is mostly because of its high thermal conductivity and optical absorptivity. The large thermal diffusivity of graphene allows quick heat transfer over the absorber surface, minimizing hotspots locally and ensuring a uniform temperature gradient. CuO and Al2O3 also provide better thermal response than traditional black paint because of their nanostructured structure that increases the effective surface area to transfer heat and the convective heat transfer coefficient at the absorber-fluid interface. The outlet temperature decreases significantly as the flow rate rises between 0.01 kg/s and 0.03 kg/s in all the types of coatings. This is a direct effect of the lower thermal residence time of the working fluid within the collector tube, which restricts the quantity of heat absorbed. To illustrate, the temperature of the outlet of graphene decreases to 54.92°C at 0.02 kg/s and to 51.62°C at 0.03 kg/s - a relative decrease of 6.3 and 12.9%, respectively, of its maximum value at 0.01 kg/s. On the same note, the black paint coating drops are reduced by almost 9.2% and 14.7% respectively as the flow rate increments. This validates the assertion that low flow rates are better suited to higher outlet temperatures because of extended heat exchange whereas higher flow rates are more advantageous in regards to total thermal energy removal because of greater fluid volume. Furthermore, the average temperature of the outlet measured throughout the whole time of the experiment also proves the better thermal performance of graphene. The average temperature of graphene at a rate of 0.01 kg/s is 55.17°C, whereas the average temperature of CuO, Al2O3, and black paint are 52.89°C and 50.47°C respectively. This pattern is always preserved at increased flow rates, but the temperature differences become a little smaller as a result of greater convective dominance. In general, the findings indicate clearly the high thermal performance of graphene as an absorber coating material, particularly when flow rate conditions are low and the properties of the absorber surface dominate the heat transfer processes.

V.3 EFFECT OF NANOPARTICLE MATERIAL ON HEAT GAIN

Figure 5 shows the change in useful heat gain of flat plate solar collectors coated with black paint, CuO, Al2O3 and graphene at a constant mass flow rate of 0.01 kg/s. The results indicate a strong improvement in thermal performance when nanomaterial-based coating, especially graphene is used instead of the standard black paint. The useful heat gain of all the coatings increased steadily as the solar radiation increased during the morning, reaching its highest point in the middle of the day and then decreasing in the afternoon as the sun faded. This day/night cycle is common to solar thermal systems, but the degree of heat gain differs greatly across the various coatings, suggesting the importance of improved thermal and optical characteristics. The graphene-coated absorber recorded the highest heat gain during the entire test period with the peak of 834W recorded at 11:00 AM. Comparatively, the highest values obtained on Al2O3, CuO and black paint were 794W, 784W and 724W respectively. This is equivalent to a maximum increase of about 15.2% of graphene against black paint, 5.0% of graphene against CuO and 5.0% of graphene against Al2O3. These high-performance properties of graphene can be explained by its high thermal conductivity that increases the heat transfer rate between the absorber plate and the working fluid. Also, graphene has high solar absorptance and low emittance, which enhance solar energy capture and retention. Its two-dimensional lattice structure is unique and enables fast phonon transport, which lowers interfacial thermal resistance and enables energy conversion to be more efficient. There were also significant improvements with CuO and Al2O3 coatings, Al2O3 always slightly better than CuO. These metal oxide nanoparticles have a moderate thermal conductivity and higher surface absorptivity than black paint, which explains the fact that these nanoparticles perform better. Graphene continued to have a visible advantage in useful heat gain over the entire time range, suggesting that it does not just enhance peak performance, but also allows it to remain in higher energy conversion efficiency even in sub-optimal solar conditions. These findings support the importance of the coating material choice in maximizing the collector efficiency, especially in low flow rate conditions where thermal inertia is stronger.

V.4 COMPARISON OF USEFUL HEAT WITH DIFFERENT ABSORBER PLATE COATINGS

Figure 6 shows the variation of instantaneous thermal efficiency of the various absorber plate coatings at constant flow rate of 0.01 kg/s. The coatings that have been studied are conventional black paint and nanomaterial-based coatings which are CuO, Al2O3, and graphene. The thermal efficiency is evidently correlated with the nature of coating as a result of variations in optical and thermal characteristics. Graphene was the most efficient of all the coatings and it was also the most efficient during the day with a peak of 0.8353 at around 11:20 AM. This high performance is explained by the outstanding thermal conductivity and high solar absorptivity of graphene that increase the rate of heat transfer between the absorber surface and the working fluid. CuO and Al2O3 were also more efficient than the black paint coating with maximum values of 0.7853 and 0.7953 respectively, which were obtained at the same period of high radiation. These nanomaterials of metal oxide enhance the surface area and thermal diffusivity, which results into the lessening of thermal resistance between the coating and the fluid. Comparatively, the traditional black paint coating had the lowest efficiency of 0.7253 and hence was the least efficient of the four. CuO, Al2O3 and graphene had a percentage improvement in peak efficiency of approximately 8.27, 9.64 and 15.17 respectively as compared to black paint. The overall pattern of Figure 6 is that efficiency gradually rises between 9:00 AM and about 11:30 AM and then gradually decreases because of the decreasing solar irradiance and a decrease in the temperature gradient between the plate and the fluid. Nevertheless, less efficient coatings (particularly graphene) remained more efficient in the later hours because they could extract and transfer heat more efficiently at lower irradiance. This shows that nanomaterial-based coating does not only improve peak performance but also provides sustained thermal performance over a broader operating range.

VI. CONCLUSIONS

This work provides detailed numerical research on the improvement of thermal performance of flat plate solar collectors (FPCs) with nanoparticle-based absorber coating, such as CuO, Al2O3, and graphene. A transient MATLAB-based model was developed and validated to assess the effect of nanoparticle coatings on outlet fluid temperature, useful heat gain, and thermal efficiency under varying operating conditions. Key conclusions drawn from the study are:

- The performance of nanoparticle-coated absorber plates was far superior to that of conventional black paint in all the measures of thermal performance.
- Collectors covered with graphene had the highest thermal efficiency with a maximum of over 0.83, about 15% higher than black paint.
- Al2O3 and CuO coating also offered significant gains in useful heat gain of about 8-10% and 6-8% respectively over black paint.
- The increase in performance has been credited to the fact that the nanomaterials have better optical absorption and thermal conductivity that minimizes thermal losses and enhances the heat transfer.
- The graphene-coated collector retained a higher performance even at lower irradiance periods, which showed an increased thermal inertia and heat retention.

The next step in research should be experimental validation and stability analysis of nanomaterial coating in the real outdoor conditions in the long-term.

ABSTRACT

In this work, a novel Lyapunov backstepping control law (LBC) is introduced, which allows for robust and stable regulation of the mechanical power produced by an induction motor (IM). The stator variables supply this induction motor through two converters. One, a motor converter (two-level inverter), allows for exact control and optimization of the energy flow during motor operation; the other, a mains converter (two-level rectifier), makes it easier to manage the direct current (DC) bus and increases the mains power factor. We demonstrated the modeling of our motor and its converters in the first section. The control structure that was suggested to regulate and maximize the mechanical energy produced by our motor (speed, torque) in order to attain optimal efficiency and transfer quality was presented in the second section. The outcomes of the numerical simulations show how well the new Lyapunov control system achieves these goals: electromagnetic torque below the nominal torque and mechanical speed side its references.

I. INTRODUCTION

Induction machines play a key role in industry and are currently widely used for variable speed or positioning applications [1-3]. These machines have the advantage of being robust and inexpensive. However, despite these advantages, the control of induction machines is very complicated because their basic mathematical model is non-linear and their parameters are only approximately known and can vary over time. Current research is aimed at making the control of these machines simpler and more reliable [4-6]. The induction machine has several control techniques (scalar control, sliding mode control, vector control.). Each control technique poses a problem in terms of guaranteeing the stability of the system because its basic model is non-linear and highly coupled, which is the opposite of the simplicity of its structure. This model is also complicated by the fact that the parameters of the induction motor are only approximately known and can vary over time. In our work, we use a new control technique called BACKSTEPPING to improve the control of the machine [7] [8]. The backstepping technique is one of the new methods in this field. It provides a systematic method for designing a controller for nonlinear systems. The main advantage of this method is that it guarantees the stability of the control system [9] [10]. This paper develops a new Lyapunov control technique to control the mechanical power produced by the induction motor. This control technique guarantees the robustness and stability of our control system with a remarkable improvement in the convergence of the errors towards zero. The rest of this article is structured as follows: The next section presents the mathematical model of the induction motor and its converters. In section 2, we present the DPC control based on PI controllers. In section 3, we present simulation results that show the efficiency and robustness of the control developed to control the mechanical power generated by our induction motor. Finally, the paper will conclude with a conclusion.

II. MODELLING OF THE INDUCTION MOTOR AND ITS CONVERTERS

To simulate the behavior of the IM and develop a control technique for it, we need to model both the motor and its converters separately.

- The induction motor;

- The motor-side converter;
- The grid-side converter.

II.1 INDUCTION MOTOR MODEL

The induction machine is a very complex non-linear system, so applying our control to our machine requires more precise mathematical modelling to represent its behaviour in a satisfactory and realistic way [11-13].

$$\begin{cases} V_{s\alpha} = R_s i_{s\alpha} + \frac{d}{dt}\Phi_{s\alpha} \\ V_{s\beta} = R_s i_{s\beta} + \frac{d}{dt}\Phi_{s\beta} \\ V_{r\alpha} = 0 = R_r i_{r\alpha} + \frac{d}{dt}\Phi_{r\alpha} + \omega_r \Phi_{r\beta} \\ V_{r\beta} = 0 = R_r i_{r\beta} + \frac{d}{dt}\Phi_{r\beta} - \Phi_r \Phi_{r\alpha} \end{cases} \quad (1)$$

$$C_{em} = \frac{PM}{L_r}\left(\Phi_{r\alpha} i_{s\beta} - \Phi_{r\beta} i_{s\alpha}\right) \quad (2)$$

$$J\frac{d}{dt}\Omega + f\Omega = C_{em} - C_r \quad (3)$$

The aim is to obtain a system of equations written as an equation of state. The model will have the form :

$$[\dot{X}] = [A][X] + [B][U] \quad (4)$$

With:

$$\begin{cases} [X] = \left[i_{s\alpha}\ i_{s\beta}\ \Phi_{r\alpha}\ \Phi_{r\beta}\right]T \\ [V] = \left[V_{s\alpha}\ V_{s\beta}\right]T \end{cases} \quad (5)$$

$$[A] = \begin{bmatrix} -\left(\frac{1}{\sigma T_S} + \frac{M^2}{l_r T_r}\right) & 0 & \frac{M}{\sigma l_S l_r T_r} & \frac{M}{\sigma l_S l_r}\omega_r \\ 0 & -\left(\frac{1}{\sigma T_S} + \frac{M^2}{l_r T_r}\right) & -\frac{M}{\sigma l_S l_r}\omega_r & \frac{M}{\sigma l_S l_r T_r} \\ \frac{M}{T_t} & 0 & -\frac{1}{T_r} & -\omega_r \\ 0 & \frac{M}{T_r} & \omega_r & -\frac{1}{T_r} \end{bmatrix} \quad (6)$$

$$[\boldsymbol{B}] = \begin{bmatrix} \frac{\mathbf{1}}{\boldsymbol{\sigma l_s}} & \mathbf{0} \\ \mathbf{0} & \frac{\mathbf{1}}{\boldsymbol{\sigma l_s}} \\ \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{bmatrix} \quad (7)$$

II.2. MOTOR SIDE CONVERTER MODEL

The voltage inverter is a converter that makes it possible to obtain an AC voltage of fixed or adjustable frequency and RMS value from a DC voltage source. It consists of switching cells, generally transistors for high power [14] [15].

$$\begin{bmatrix} V_A \\ V_B \\ V_C \end{bmatrix} = \frac{E}{6}.\begin{bmatrix} 2 & -1 & -1 \\ -1 & 2 & -1 \\ -1 & -1 & 2 \end{bmatrix}\begin{bmatrix} S_1 \\ S_2 \\ S_3 \end{bmatrix} \quad (8)$$

II.3. GRID SIDE CONVERTER MODEL

In addition to its bidirectional power flow capability, the grid-side converter has the advantage of maintaining a stable DC bus voltage and setting the reactive power reference to zero. This helps to maintain grid quality by maintaining a unity power factor [16] [17].

$$\frac{d}{dt}\begin{bmatrix} i_1 \\ i_2 \\ i_3 \end{bmatrix} = \begin{bmatrix} -\frac{R}{L} & 0 & 0 \\ 0 & -\frac{R}{L} & 0 \\ 0 & 0 & -\frac{R}{L} \end{bmatrix}\begin{bmatrix} i_1 \\ i_2 \\ i_3 \end{bmatrix} + \frac{1}{L}\begin{bmatrix} V_1 - V_{an} \\ V_2 - V_{bn} \\ V_3 - V_{cn} \end{bmatrix} \quad (9)$$

$$\begin{bmatrix} V_A \\ V_B \\ V_C \end{bmatrix} = \frac{Uc}{3}.\begin{bmatrix} 2 & -1 & -1 \\ -1 & 2 & -1 \\ -1 & -1 & 2 \end{bmatrix}\begin{bmatrix} S_1 \\ S_2 \\ S_3 \end{bmatrix} \quad (10)$$

$$\frac{U_C}{i_S} = \frac{R_{Ch}}{1 + R_{Ch}.C.p} \quad (11)$$

This inverter can be cascade controlled, with two inner loops to control the phase currents and an outer loop to control the output voltage [18] [19].

$$\begin{cases} V_{pd} = V_d - R\, i_d - L\frac{di_d}{dt} + L\omega i_q \\ V_{pq} = V_q - R\, i_q - L\frac{di_q}{dt} - L\omega i_d \end{cases} \tag{12}$$

$$\begin{cases} P = \frac{3}{2}.\left[V_d I_d + V_q I_q\right] \\ Q = \frac{3}{2}.\left[V_q I_d - V_d I_q\right] \end{cases} \tag{13}$$

We pose:

$$P_{ref} = U_{cmes}\, I_{red\_ref} \tag{14}$$

$$Q_{ref} = 0 \tag{15}$$

III. LYAPUNOV BACKSTEPPING CONTROL

Backstepping control for nonlinear systems enables the design of a control law that ensures stability throughout the process. By expressing the states in a purely parametric form, the process's subsystems become more apparent. For each subsystem, a control is derived using a Lyapunov function to achieve stability. This involves treating the preceding state as the controllable variable. The order of the subsystem is then incremented, and the procedure is repeated. Ultimately, this approach yields a control law for the entire process [20] [21].

III.1. PRINCIPLE OF OUR CONTROL

The main idea behind Backstepping is to calculate a control law to ensure that the derivative of a certain (Lyapunov) function is defined as positive and that this derivative is always negative. The system is broken down into a set of nested subsystems of decreasing order. The Lyapunov function is then calculated recursively from inside the loop [22] [23].

III.2. APPLICATION OF OUR ORDER TO OUR IM

The application of the backstepping control to the induction machine requires the use of its model in the (α,β) reference frame in order to avoid the use of Park transformations. This approach is based on three steps to determine the control law given by the machine's stator voltages; before starting the calculation of the various steps, we group together the electrical, magnetic and mechanical equations in the following system.

$$\begin{cases} \frac{d\Omega}{dt} = \frac{\mu}{J}\left(\Phi_{r\alpha} i_{s\beta} - \Phi_{r\beta} i_{s\alpha}\right) - \frac{C_r}{J} \\ \frac{di_{s\alpha}}{dt} = \alpha\beta\Phi_{r\alpha} + P\beta\Omega\Phi_{r\beta} - \eta i_{s\alpha} + \frac{1}{\sigma.L_s} V_{s\alpha} \\ \frac{di_{s\beta}}{dt} = \alpha\beta\Phi_{r\beta} - P\beta\Omega\Phi_{r\alpha} - \eta i_{s\beta} + \frac{1}{\sigma.L_s} V_{s\beta} \\ \frac{d\Phi_{r\alpha}}{dt} = -\alpha\Phi_{r\alpha} - P\Omega\Phi_{r\beta} + \alpha M i_{s\alpha} \\ \frac{d\Phi_{r\beta}}{dt} = -\alpha\Phi_{r\beta} + P\Omega\Phi_{r\alpha} + \alpha M i_{s\beta} \end{cases} \tag{16}$$

With:

$$\alpha = \frac{R_r}{L_r},\ \beta = \frac{M}{\sigma L_s L_r},\qquad \eta = \frac{M^2.R_r + L_r^2.R_s}{\sigma L_s L_r^2},\quad \mu = \frac{PM}{L_r}$$

Rotor flux is given by:

$$\overline{\Phi_r} = \Phi_{r\alpha} + j.\Phi_{r\beta} = \sqrt{{\Phi_{r\alpha}}^2 + {\Phi_{r\beta}}^2}.\left[\frac{\Phi_{r\alpha}}{\sqrt{{\Phi_{r\alpha}}^2+{\Phi_{r\beta}}^2}} + j.\frac{\Phi_{r\beta}}{\sqrt{{\Phi_{r\alpha}}^2+{\Phi_{r\beta}}^2}}\right] \tag{17}$$

$$\overline{\Phi_r} = \sqrt{{\Phi_{r\alpha}}^2 + {\Phi_{r\beta}}^2}.[\cos(\theta_s) + j.\sin(\theta_s)] \tag{18}$$

The modulus of the flow and its derivative are given by:

$$\emptyset_r = \Phi_r^2 \tag{19}$$

$$\dot{\emptyset}_r = 2(\dot{\Phi}_{r\alpha}\Phi_{r\alpha} + \Phi_{r\beta}\dot{\Phi}_{r\beta}) \tag{20}$$

Step 1

In this step we consider the errors "e1 ","e2 " between the speed "Ω" and its reference "Ωref" and the rotor flux" $\emptyset_r$"and and its reference " $\emptyset_{ref}$".

$$\begin{cases} e_1 = \Omega_{ref} - \Omega \\ e_2 = \emptyset_{ref} - \emptyset_r \end{cases} \tag{21}$$

So the derivative of "e1", "e2" is given by:

$$\begin{cases} \dot{e}_1 = \dot{\Omega}_{ref} - \dot{\Omega} = \dot{\Omega}_{ref} - \frac{\mu}{J}\left(\Phi_{r\alpha} i_s - \Phi_{r\beta} i_{s\alpha}\right) + \frac{C_r}{J} \\ \dot{e}_2 = \dot{\emptyset}_{ref} - \dot{\emptyset}_r = \dot{\emptyset}_{ref} + 2\alpha\emptyset_r - 2\alpha M(i_{s\alpha}\Phi_{r\alpha} + i_{s\beta}\Phi_{r\beta}) \end{cases} \quad (22)$$

The chosen Lyapunov function is defined as follows:

$$V_1 = \frac{1}{2}(e_1^2 + e_2^2) \quad (23)$$

Then the stabilisation functions are given by:

$$\begin{cases} i_{s\beta} = \frac{J}{\mu\,\Phi_{r\alpha}}\left(k_1 e_1 + \dot{\Omega}_{ref} + \frac{C_r}{J}\right) + \frac{\Phi_{r\beta}}{\Phi_{r\alpha}} i_{s\alpha} \\ i_{s\alpha} = -\frac{J}{\mu\,\Phi_{r\beta}}\left(k_1 e_1 + \dot{\Omega}_{ref} + \frac{C_r}{J}\right) + \frac{\Phi_{r\alpha}}{\Phi_{r\beta}} i_{s\beta} \end{cases} \quad (24)$$

To obtain a negative derivative of the Lyapunov function, the reference currents must be chosen as follows:

$$\begin{cases} (i_{s\alpha})_{ref} = -\frac{J\sin(\theta)}{\mu\Phi_r}\left(k_1 e_1 + \dot{\Omega}_{ref} + \frac{C_r}{J}\right) + \frac{\cos(\theta)}{2\alpha M\Phi_r}\left(K_2 e_2 + \dot{\emptyset}_r + 2\alpha\emptyset_r\right) \\ \left(i_{s\beta}\right)_{ref} = \frac{J\cos(\theta)}{\mu\Phi_r}\left(k_1 e_1 + \dot{\Omega}_{ref} + \frac{C_r}{J}\right) + \frac{\sin(\theta)}{2\alpha M\Phi_r}\left(K_2 e_2 + \dot{\emptyset}_r + 2\alpha\emptyset_r\right) \end{cases} \quad (25)$$

The error dynamics must be chosen by:

$$\dot{e}_1 = -k_1 e_1 \;\; et \;\; \dot{e}_2 = -k_2 e_2 \quad (26)$$

Then the derivative of the Lyapunov function with respect to time becomes:

$$\dot{V}_1 = -k_1 e_1^2 - k_2 e_2^2 < 0 \quad (27)$$

With: $k_1 > 0$ and $k_2 > 0$

Step 2

In this step, we consider the errors "e3 ","e4 " between the currents "isq"and "isqref " and the currents " isd" and "isdref".

$$e_3 = (i_{s\beta})_{ref} - i_{s\beta} \quad (28)$$

$$e_3 = \frac{J\cos(\theta)}{\mu\Phi_r}\left(k_1 e_1 + \dot{\Omega}_{ref} + \frac{C_r}{J}\right) + \frac{\sin(\theta)}{2\alpha M\Phi_r}\left(K_2 e_2 + \dot{\emptyset}_r + 2\alpha\emptyset_r\right) - i_{s\beta} \quad (29)$$

$$e_4 = (i_{s\alpha})_{ref} - i_{s\alpha} \quad (30)$$

$$e_4 = -\frac{J\sin(\theta)}{\mu\Phi_r}\left(k_1 e_1 + \dot{\Omega}_{ref} + \frac{C_r}{J}\right) + \frac{\cos(\theta)}{2\alpha M\Phi_r}\left(K_2 e_2 + \dot{\emptyset}_r + 2\alpha\emptyset_r\right) - i_{s\alpha} \quad (31)$$

Then the derivative of the errors "e1" and "e2" become:

$$\begin{cases} \dot{e}_1 = -k_1 e_1 - \frac{\mu}{J}\emptyset_r(e_4\sin(\theta) - e_3\cos(\theta)) \\ \dot{e}_2 = -k_2 e_2 + 2\emptyset_r\alpha M(e_4\cos(\theta) - e_3\sin(\theta)) \end{cases} \quad (32)$$

Then the derivative of the errors "e3"," e4" will be of the form:

$$\begin{cases} \dot{e}_3 = (\dot{i}_{s\beta})_{ref} - \dot{i}_{s\beta} = (\dot{i}_{s\beta})_{ref} - \delta_2 - \frac{1}{\sigma L_s} V_{s\beta} \\ \dot{e}_4 = (\dot{i}_{s\alpha})_{ref} - \dot{i}_{s\alpha} = (\dot{i}_{s\alpha})_{ref} - \delta_1 - \frac{1}{\sigma L_s} V_{s\alpha} \end{cases} \quad (33)$$

We pose

$$\begin{cases} \delta_1 = \alpha\beta\Phi_{r\beta} - P\beta\Omega\Phi_{r\alpha} - \eta i_{s\beta} \\ \delta_2 = \alpha\beta\Phi_{r\alpha} + P\beta\Omega\Phi_{r\beta} - \eta i_{s\alpha} \end{cases} \quad (34)$$

Step 3

To calculate the control laws (stator voltages), we choose the Lyapunov function dependent on all the previous errors. This function is given by:

$$V_2 = \frac{1}{2}(e_1^2 + e_2^2 + e_3^2 + e_4^2) \quad (35)$$

The derivative of this function is:

$$\dot{V}_2 = e_1\dot{e}_1 + e_2\dot{e}_2 + e_3\dot{e}_3 + e_4\dot{e}_4 \quad (36)$$

By replacing the derivatives of the errors by their respective values, we obtain:

$$\dot{V}_2 = -k_1 e_1^2 - k_2 e_2^2 + e_3\left(\left(i_{s\beta}\right)_{ref} - \delta_1 - \frac{1}{\sigma L_s} V_{s\beta} + 2\alpha M\Phi_{r\beta} + \frac{\mu\,\Phi_{r\alpha}}{J} e_1\right) + e_4\left(\left(i_{s\alpha}\right)_{ref} - \delta_2 + 2\alpha M\Phi_{r\alpha} e_2 - \frac{1}{\sigma L_s} V_{s\alpha} - \frac{\mu\,\Phi_{r\beta}}{J} e_1\right) \quad (37)$$

Finally, to obtain the derivative of the negative Lyapunov function, we choose the following control law

$$\begin{cases} V_{s\alpha} = \sigma L_s \left(k_4 e_4 + (i_{s\alpha})_{ref} - \delta_2 + 2\alpha M \Phi_{r\alpha} e_2 - \frac{\mu \Phi_{r\beta}}{J} e_1 \right) \\ V_{s\beta} = \sigma L_s (k_3 e_3 + (i_{s\beta})_{ref} - \delta_1 + 2\alpha M e_2 \Phi_{r\beta} - \frac{\mu \Phi_{r\alpha}}{J} e_1) \end{cases} \quad (38)$$

With: $k_3 > 0$ and $k_4 > 0$
The derivatives of the errors "e3", "e4" will be as follows:

$$\begin{cases} \dot{e}_3 = -k_3 e_3 - 2\alpha M \Phi_{r\beta} - \frac{\mu \Phi_{r\alpha}}{J} e_1 \\ \dot{e}_4 = -k_4 e_4 - 2\alpha M \Phi_{r\alpha} e_2 + \frac{\mu \Phi_{r\beta}}{J} e_1 \end{cases} \quad (39)$$

So from equation (32), (39) we can write:

$$\dot{e} = A.e \quad (40)$$

With:

$$A = \begin{bmatrix} -k_1 & 0 & \frac{\mu}{J}\Phi_r \cos(\theta) & -\frac{\mu}{J}\Phi_r \sin(\theta) \\ 0 & -k_2 & 2\alpha M \Phi_r \sin(\theta) & 2\alpha M \Phi_r \cos(\theta) \\ -\frac{\mu}{J\Phi_r}\cos(\theta) & -\frac{2\alpha M}{\Phi_r}\sin(\theta) & -k_3 & 0 \\ \frac{\mu}{J\Phi_r}\sin(\theta) & -\frac{2\alpha M}{\Phi_r}\cos(\theta) & 0 & -k_4 \end{bmatrix} \text{ and } e = \begin{bmatrix} e_1 \\ e_2 \\ e_3 \\ e_4 \end{bmatrix}$$

It can be seen that the elements of the matrix A contain variable terms cos(θ) and sin(θ) which can cause instability in the system. The following figure shows the block diagram of the backstepping control of the asynchronous machine in the (α,β) frame of reference.

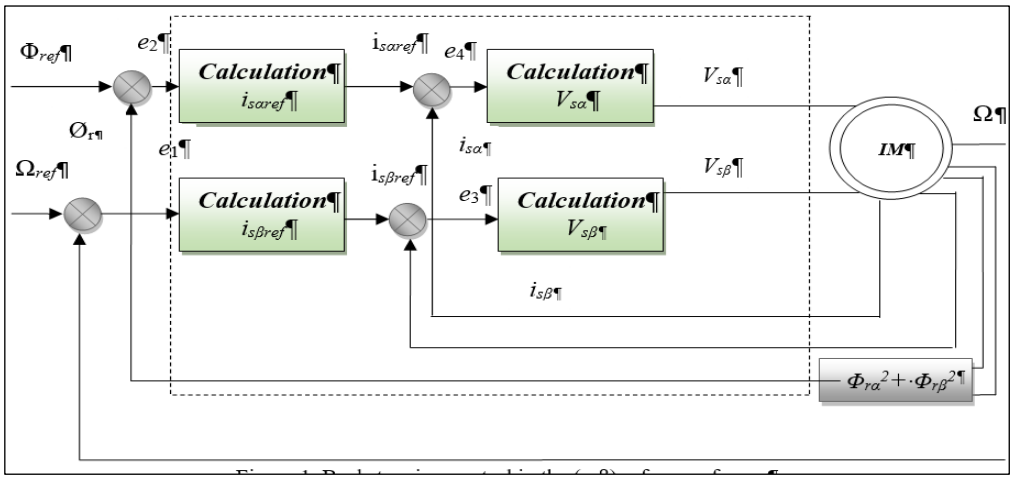

Figure 1: Backstepping control in the (α β) reference frame.
Source: Authors, (2026).

III.3. SIMULATION RESULTS

These results obtained through simulating our motor within the MATLAB SIMULINK environment, using the new backstepping control developed. We carried out the test by implementing a resistive torque (Cr = 6 N.m) as an external variation of the instants (t=2.5s and t=3.5s) and a speed setpoint equal to the nominal speed of the IM (157 Rad/s).

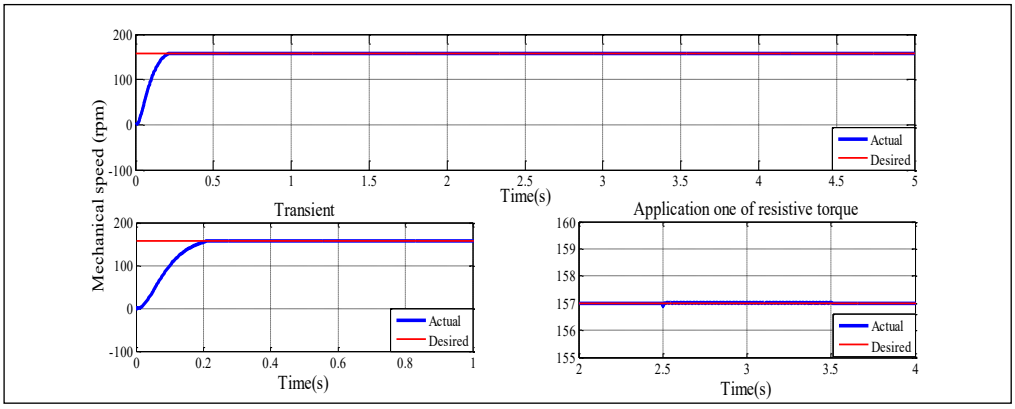

Figure 2: Mechanical speed produced for the new lyapunov backstepping control with a zoom (external variation).
Source: Authors, (2026).

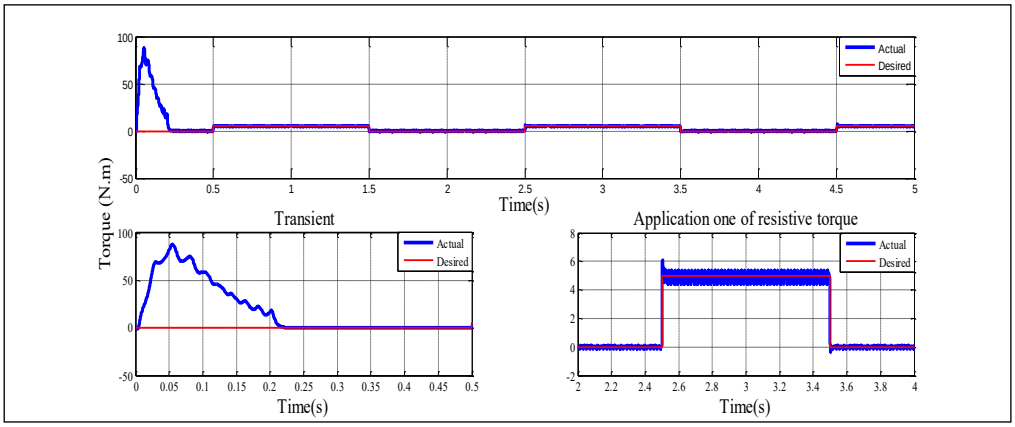

Figure 3: Torque produced for the new lyapunov backstepping control with a zoom (external variation).
Source: Authors, (2026).

The simulation results show that the mechanical speed closely follows its reference with the developed control technique. The response time, the overshoot and the convergence of the exponential error to the steady state are all optimal, even when external variations (resistive torque) are applied and removed and the torque peaks at the first starting moment, then reaches the value of the resisting torque before and after the load is applied. This control technique demonstrates high efficiency and strong performance.

IV. CONCLUSION

In this study, we develop a control system based on Lyapunov stability theory, which is backstepping control. This method solves the parametric and external variation problems to obtain positive mechanical power output with error convergence to zero. It also guarantees the closed-loop stability of the induction machine at all times. The chosen model of the machine is in the (α,β) reference frame, which does not require a Park transformation. These excellent results obtained with the new Lyapunov backstepping control should be taught in academic circles and also applied in industrial environments.

ABSTRACT

Accurate stock price prediction is vital for investors and analysts to make informed decisions and mitigate risks. Traditional methods like ARIMA struggle with the complex, non-linear patterns of stock market data, leading to less precise forecasts. This study addresses the gap by leveraging advanced deep learning methods, specifically Generative Adversarial Networks (GANs) and Long Short-Term Memory (LSTM) networks, for stock price forecasting. Using historical stock data and 32 influencing features, we trained GANs and LSTMs, with Root Mean Square Error (RMSE) as the evaluation metric. The data was split into 80% training and 20% testing. Our results show that the GAN model achieved a lower RMSE of 5.36, outperforming the LSTM model (RMSE of 6.6) and traditional ARIMA models, demonstrating GAN's superior ability to capture complex patterns. While computational challenges exist, GAN's accuracy underscores its potential for stock price prediction. Future research could explore hybrid models and sentiment analysis to further improve prediction accuracy.

I. INTRODUCTION

Forecasting prices of stock market is a complex and demanding task because of the highly dynamic as well as non-linear characteristics of financial markets. Precise forecasts can provide significant benefits for investors as well as traders which enables them to make informed decisions, handle risks efficiently along maximize returns. Traditional methods of the prediction of stock price like ARIMA models often fail to capture accurately the intricate along with the unpredictable patterns inherent in market data. These limitations have promoted the investigation of advanced methods. Deep Learning approaches have gained popularity for their capacity to model complex patterns as well as the interconnections in time-series data. Methods like GANs as well as LSTM networks handle large volumes of data as well as uncover hidden connections within the data. They also provide more precise as well as reliable predictions comparing conventional data. GANs which can generate synthetic data and LSTMs are known for their proficiency in handling sequential data which provides promising results for the challenges presented by the stock market's volatility as well as complexity. Researchers want to improve the precision as well as robustness of stock price predictions by using these advanced DL techniques which leads to better investing strategies along with financial decision-making. Many researchers have explored deep learning (DL) models for stock price prediction. By [1] introduced the S_I_LSTM technique, combining traditional and non-traditional data like stock posts and financial news, enhancing accuracy in the Shanghai A-share market. In turn [2] evaluated DL techniques using Google's daily closing price, finding GANs superior to LSTM and GRU. According to [3] proposed a GAN with an economics-driven loss function for predicting financial time series. In turn [4] tested multiple DL models, highlighting GRU and addressing overfitting with GANs. By [5] improved accuracy by combining empirical mode decomposition with LSTM and GAN architectures. According to [6] developed the GAF-EWGAN method, integrating enhanced WGANs with Gramian Angular Fields. By [7] introduced GAN-TrellisNet, which combined TrellisNet and CNN for better stock prediction accuracy. In turn [8] created a GAN-based model with piecewise linear representation to forecast stock trading actions. By [9] used BERT and GAN for sentiment analysis to predict Apple Inc.'s stock, achieving high accuracy. According to [10] combined neural networks and GANs for S&P 500 predictions, achieving superior results with the G-LSTM+D-LSTM technique.

By [11] developed TSGAN, integrating ACNN, LSTM, ARIMA, and CNN for accurate stock predictions. In turn [12] combined Phase-space Reconstruction and GAN for effective forecasting. According to [13] introduced a BiLSTM and WGAN approach to predict stock prices for newly listed companies with limited data. By [14] reviewed various stock prediction techniques, noting the rise of DL methods from 2020 to 2023. In turn [15] highlighted the shift from traditional methods to advanced DL techniques, including Transformers, GANs, and GNNs. Financial news and social media have been shown to enhance prediction accuracy [16], while GANs and LSTMs often outperform traditional methods in capturing the non-linear dynamics of financial data [17]. Addressing overfitting and improving model robustness are common themes, with various studies exploring artificial data generation and hybrid approaches [18]. However, there is still a research gap in the comparative analysis of GANs as well as LSTMs, especially for the prediction of the stock market. Several research focuses on the utilization of a single DL technique with less exploration of the synergistic potential of combining GANs as well as LSTMs. Previous researches often suffer limitations like overfitting, lack of integration of diverse data sources as well as a limited focus on certain markets or stocks.The motivation of this study is to utilize advanced DL methods especially LSTM networks as well as GANs to enhance the predictions of the stock market. Traditional techniques often face difficulties when dealing with complex unpredictable characteristics of financial data. The main motivation of this research is the potential of utilizing advanced methods to combine various data sources like historical prices, technical indicators as well as sentiment analysis from news to create a more holistic as well as accurate prediction model. The objective is to demonstrate the practical applications as well as the benefits of these complex modeling methods by focusing on Apple Inc., a stock that is highly influential as well as volatile. The objective of this study is to enhance the accuracy of stock price prediction by utilizing advanced structures of LSTM as well as GAN. This study aims to contribute to expanding the literature on the utilization of DL methods in financial market analysis. This research focuses on the utilization of advanced DL techniques like LSTM networks and GANs to forecast stock prices which especially examines the stock price of Apple Inc.

II. MATERIAL AND METHODS

II.1 MATERIALS AND METHODS

Materials:

The first step in building a technique involves obtaining a dataset that includes the essential features required for training the model. In DL the dataset contains the target values that are used during the training process. In this particular scenario, the dataset comprises continuous feature extractions that are presented in a time series format. In this study, the daily closing price of the APPLE stock data is used. The series covers 497 trade days from 2nd January 2020 to 19th July 2024. Overall, 497 observations are present in the data set.While there are around 1187 trading days in this timeframe, the 497 trade days considered are based on specific criteria relevant to the study, such as days with significant market movements or availability of complete data.Figure 1 provides a comprehensive analysis of AAPL stock performance showing the closing prices, moving averages, daily returns, and their distribution. The detailed analysis helps in understanding the stock's behavior over the selected period.

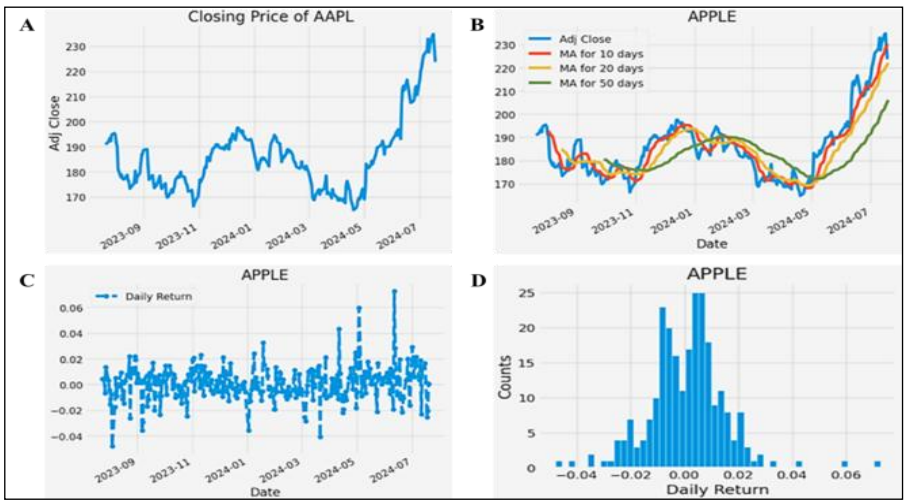

Figure 1: Analysis of AAPL Stock Performance. (A) Closing prices over the 497 trade days, illustrate the overall trend and key fluctuations. (B) Moving averages for 10 days, 20 days, and 50 days, highlighting long-term and short-term trends. (C) Daily returns, showing the day-to-day changes in stock price. (D) Distribution of daily returns, providing insights into the frequency and magnitude of daily changes. Graphs were generated using Python.

II.1.1 Long Short-Term Memory (LSTM):

LSTM is a type of recurrent neural network (RNN) designed by Hochreiter and Schmidhuber in 1997 to handle sequential data more effectively than standard feed-forward networks. To control information flow, it has an outputgate, an input gate and a forget gate in addition to feedback loops. The main novelty of LSTM is that it can retain or discard data according to its current cell state, which helps to alleviate the vanishing gradient issue that standard RNNs frequently encounter while training. This unique design addresses issues related to vanishing and exploding gradients, making LSTM a robust tool for tasks involving time series data, such as sequence prediction and classification.

II.1.2 Generative Adversarial Network (GAN):

GANs are structured as a zero-sum game, where two components—a generator and a discriminator—compete against each other. The generator is crafted using GRU layers and is designed to produce data that appears convincingly real. Meanwhile, The discriminator's job is to differentiate between generated and genuine data. The loss function for the discriminator is:

$$V_D = \frac{1}{m}\sum_{i=1}^{m} \log D(y^i) + \frac{1}{m}\sum_{i=1}^{m} (1 - \log D\ (G(x^i)))$$

The loss function for the generator is:

$$V_G = \frac{1}{m}\sum_{i=1}^{m} (1 - \log D\ (G(x^i)))$$

GAN framework utilizes cross-entropy loss to align the generated data distribution with the real data distribution, effectively minimizing the Kullback-Leibler-Jensen-Shannon (KL-JS) divergence.

II.2 FEATURE EXTRACTION FROM DATA:

Technical Indicators:

In this research, we calculated several key technical indicators used by investors:exponential moving averages, 7-day and 21-day moving averages, Bollinger Bands, momentum, and the Moving Average Convergence Divergence (MACD). The formulas and their significance are:

7-day and 21-day Moving Average (MA):

$$\mathrm{MA}_n = \frac{1}{n}\sum_{i=0}^{n-1} P_{t-i}$$

Moving Average smooth out price data to identify the trends by averaging past prices over a significant period. The 7-day MA captures short-term trends while the 21-day MA provides insights into medium-term trends.

Exponential Moving Average (EMA):

$$\mathrm{EMA}_t = (P_t \times \frac{2}{n+1}) + (\mathrm{EMA}_{t-1} \times (1 - \frac{2}{n+1}))$$

These indicators are particularly sensitive to recent price changes, allowing for a faster reaction to new market data. It helps in identifying the direction of the current trend along with potential reversals.

Momentum:

$$P_t - P_{t-n}$$

It measures the rate of price change. The rising trend is known as positive momentum and a declining trend is known as negative momentum. This helps traders gauge the strength of a price movement.

Bollinger Bands:

Bollinger Bands consist of two outside bands that are positioned ±2 standard deviations apart from the center and a middle band that is made up of the 20-day moving average. This tool is used to gauge market volatility and outlines a range within which the price is expected to fluctuate. Prices may be overbought when they approach the top band, while they may be oversold when they approach the lower band.

Moving Average Convergence Divergence (MACD):

EMA_{12} - EMA_{26}
Signal Line: 9-day EMA of MACD

Market momentum is reflected by the MACD, which shows a bullish trend when its value is positive and a bearish trend when its value is negative. The MACD line indicates possible buy or sell signals when it crosses above or below the signal line.

News Sentiment Analysis:

Stock price changes may be impacted by news. We gathered daily news stories on Apple Inc. and assessed each article's mood using the FinBert model. With a sentiment score ranging from -1 to 1, our analysis classified the news as good, neutral, or negative. These sentiment scores were then integrated into the model as additional features, allowing the model to incorporate the impact of market sentiment on stock price predictions.

Fourier Transforms:

The study employed Fourier transforms to identify long-term and short-term trends in Apple stock. By decomposing the data into sine wave components, Fourier transforms help in reconstructing the original signal, enabling the model to discern patterns and trends more accurately for predictive purposes.

II.3 DATA STRUCTURE:

This study prepared the dataset for supervised learning by dividing it with a rolling window equal to 1. The original dataset is two-dimensional and reshaped the data to three dimensions according to the timesteps as shown in Figure2.The specific steps taken to prepare the data for the many-to-many model:

Rolling Window Approach: The rolling window technique involves creating overlapping subsets of the data where each window shifts by one-time step. For a rolling window of size 1, each subset contains the data point at time ttt and its previous data points.

Original Data:the dataset starts as a two-dimensional array with rows representing time steps and columns representing features.

Reshaping Process: For each rolling window, the data is split into input sequences (features at time ttt) and output sequences (features at time t+1t+1t+1). This process transforms the data into three dimensions: [samples, timesteps, and features]. Each sample corresponds to a rolling window, each timestep within a sample corresponds to a specific time point in that window, and each feature corresponds to the various data attributes at that time point

Many-to-Many Model Preparation: Input Data: For the LSTM and GAN models, the input data is structured as [number of samples, number of timesteps, number of features].

Output Data: The output for each input sequence is also a sequence, allowing the model to predict multiple future time steps (many-to-many). Example: If the rolling window size is 5, each input sequence will have 5 timesteps, and the corresponding output sequence will also have 5 timesteps. Figure 2 illustrates how the original dataset is reshaped into a three-dimensional structure suitable for the many-to-many model.

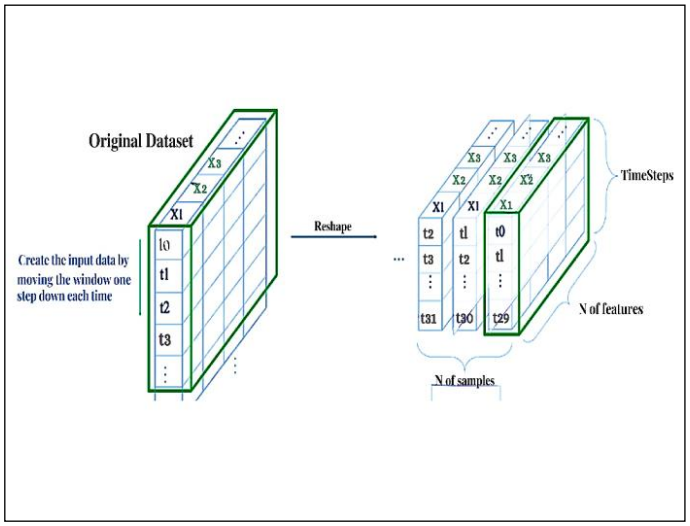

Figure 2: Reshaping the Original Dataset for Input Data Preparation.
Source: Authors, (2026).

This research developed a model that uses a many-to-many approach, utilizing a 30-day time step to forecast stock prices for an output step of 3, as depicted in Figure 3.

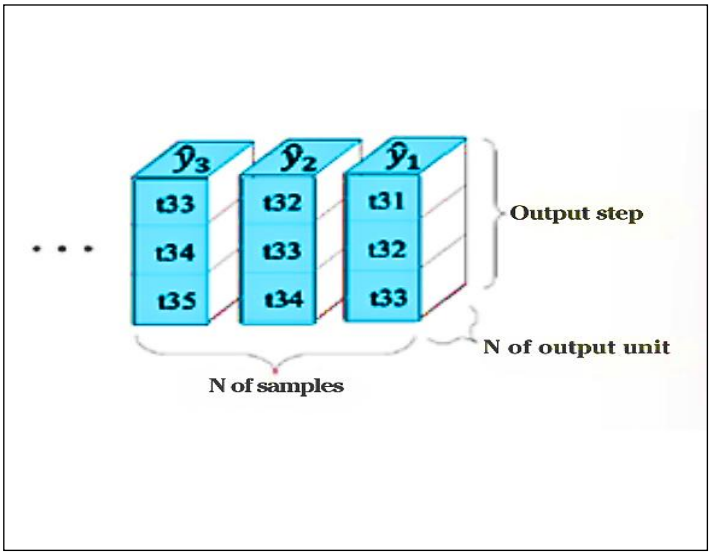

Figure 3: Many-to Many Models with Timestep of 30 and an Output Step of 3.
Source: Authors, (2026).

II.4 METHODOLOGY

Generator:

The study used a GRU as the generator component in the GAN model, chosen for its stability and effectiveness in handling sequential data. The dataset spans a decade of historical stock prices and includes 32 distinct features such as Open, High, Low, Close, Volume, and various global indices like NASDAQ, NYSE, S&P 500, and others.

Additional metrics such as Crude Oil prices, Gold prices, VIX, USD index, and technical indicators (e.g., moving averages, MACD, Bollinger Bands) are also part of the dataset, alongside news sentiment data. We perform multi-step ahead prediction.The generator model receives input data in three dimensions, consisting of batch size, input steps, and features, and it produces output based on the batch size and output steps.

Generator Architecture:

GRU Layer 1:

- Neurons: 1024
- Activation Function: ReLU
- Dropout Rate: 0.2
- Regularization: L2 regularization with a coefficient of 0.01

GRU Layer 2:

- Neurons: 512
- Activation Function: ReLU
- Dropout Rate: 0.2
- Regularization: L2 regularization with a coefficient of 0.01

GRU Layer 3:

- Neurons: 256
- Activation Function: ReLU
- Dropout Rate: 0.2
- Regularization: L2 regularization with a coefficient of 0.01

Dense Layer 1:

- Neurons: 128
- Activation Function: ReLU

Dense Layer 2:

- Neurons: Number matching the output step to be predicted (e.g., if predicting 10 steps ahead, this layer has 10 neurons)
- Activation Function: Linear

Input and Output Dimensions:

- Input Dimensions: [batch size, input-step, number of features (32)], where batch sizeis the number of samples in a batch; input-step = number of timesteps in each input sequence.
- Output Dimensions: [batch size, output-step], where the batch size is the same as the input batch size, and the output-step is the number of future time steps to predict.

This detailed architecture ensures that the generator can effectively capture temporal dependencies and generate accurate multi-step ahead predictions.

Discriminator:

The discriminator in this GAN model is a Convolutional Neural Network (CNN) designed to differentiate between real and generated data, as depicted in Figure 4. It accepts both genuine and synthetic data as input. The architecture features three one-dimensional convolutional layers with 32, 64, and 128 neurons, followed by three dense layers with 220, 220, and 1 neuron, respectively. With the exception of the last layer, which employs a linear activation for WGAN-GP or a sigmoid activation for GANs, all of these layers utilize leaky ReLU as their activation function.

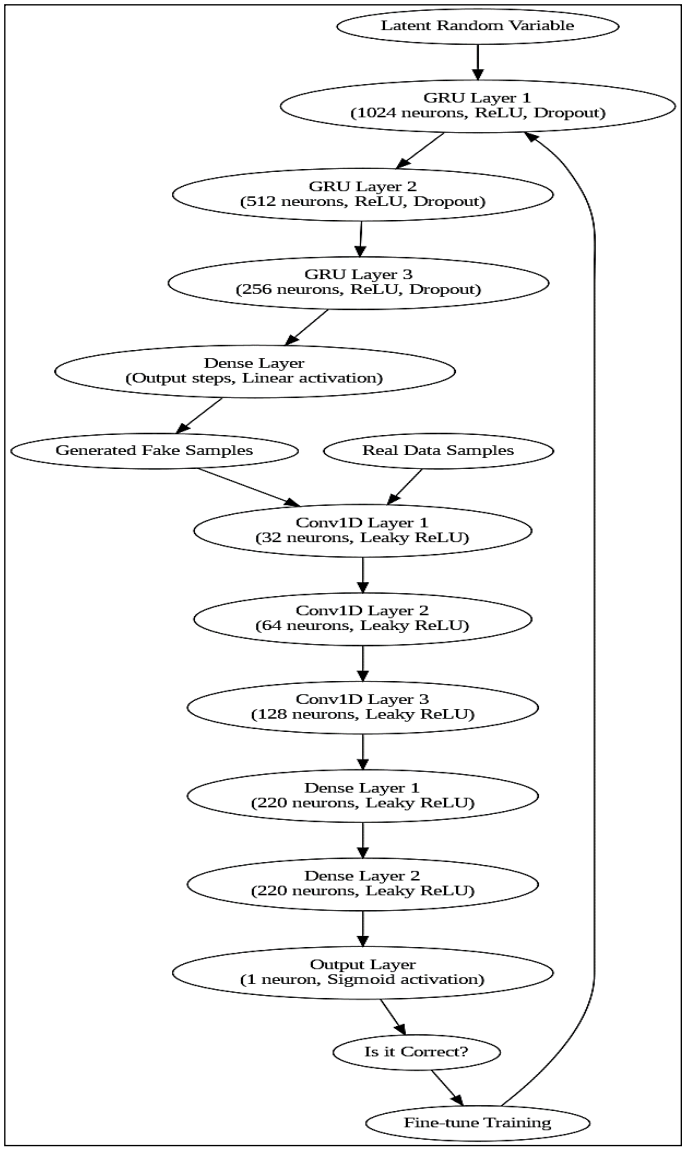

Figure 4: Flowchart of GAN Model.
Source: Authors, (2026).

Activation Functions:

Leaky ReLU:

This function successfully mitigates the dying ReLU issue, where neurons might stop learning, by allowing for a little positive slope (often set to 0.01) while the neuron is not active. By preventing neurons from staying dormant, this method encourages continuous learning. All of the discriminator's layers—aside from the output layer—are subject to Leaky ReLU.

Sigmoid:

The Sigmoid function squashes outputs to the range [0, 1], suitable for binary classification by representing probabilities. In GANs, the Sigmoid function in the discriminator's output layer indicates the likelihood that input data is real or fake. This combination of Leaky ReLU and Sigmoid activations enables the discriminator to effectively differentiate between genuine and fake data, enhancing the GAN model's performance.

Architecture of GAN:

Combining the generator and discriminator structures, we define our proposed GAN model. The model uses cross-entropy to calculate the loss for both the generator and discriminator. In the discriminator, as shown in Figure5 this study combines the generated stock price with the historical stock price of input steps, enhancing data length and increasing accuracy in classification.

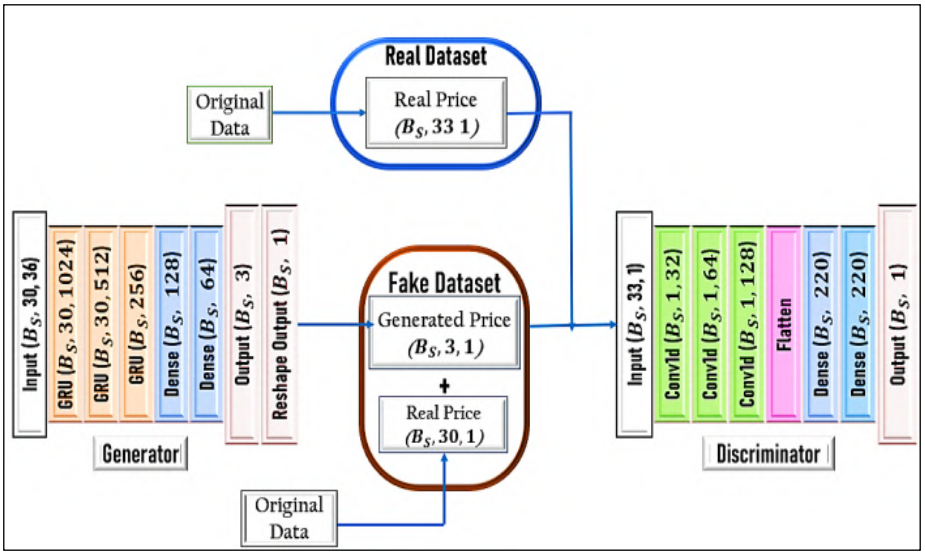

Figure 5: The architecture of the GAN model.
Source: Authors, (2026).

Training Process of GAN:

The training process of the GAN involves iterative updates to both the generator and discriminator components. Here's a detailed explanation of the process, including the number of epochs, batch size, and optimization algorithms used:

(1) Initialization

- *Generator and Discriminator Networks:*The weights of both networks are initialized independently.
- *Hyperparameters:*Important parameters like the batch size, learning rate, and number of training epochs are configured at the start.

(2) Training Loop

- *Epochs:* The GAN is trained for 500 epochs, which defines how many times the entire training dataset is passed through the network.
- *Batch Size:* During each epoch, the training data is divided into smaller batches. The batch size used in this study is 32.

(3) Discriminator Training

- *Real Data:* A batch of real stock prices is selected from the historical dataset.
- *Generated Data:* The generator produces a batch of fake stock prices.
- *Training:*It involves the discriminator being exposed to both actual and synthesized data, aiming to differentiate between the two correctly. The cross-entropy loss function measures the performance of the discriminator by evaluating its accuracy in classifying real versus fake data.

(4) Generator Training

- *Noise Input:* The generator receives a batch of random noise as input.
- *Fake Data:* The generator produces a batch of fake stock prices from the noise.
- *Discriminator Feedback:* The fake data is then passed to the discriminator.
- *Training:*The generator is trained to maximize the discriminator's error in classifying fake data as real. The cross-entropy loss function is used to calculate the generator's loss.

(5) Optimization

Both the generator and discriminator are optimized using the Adam optimization algorithm, with a learning rate set to 0.0002 and a beta1 of 0.5.

(6) Evaluation

After each epoch, the performance of the GAN is evaluated based on the accuracy of the discriminator and the quality of the generated stock prices.

(7) Convergence

The training continues until the specified number of epochs is reached or until the model converges, indicated by stable loss values and realistic generated stock prices.

Summary of GAN Training Architecture:

Generator Architecture:

- Input Layer: $(B_S, 30, 36)$
- GRU Layers: 1024, 512, 256 units
- Dense Layers: 128, 64 units
- Output Layer: $(B_S, 3, 1)$

Discriminator Architecture:

- Input Layer: $(B_S, 3, 1)$, $(B_S, 30, 1)$
- Conv1d Layers: 32, 64, 128 filters
- Flatten Layer
- Dense Layers: 220, 220 units
- Output Layer:$(B_S, 1)$

II.5 PROPOSED SYSTEM:

The proposed system integrates advanced LSTM and GAN architectures to predict stock prices using technical indicators, news sentiment analysis, and Fourier transforms.

- LSTM Networks: Capture long-term dependencies and trends in historical stock price data by processing sequences, modeling temporal dynamics crucial for accurate predictions.
- Generative Adversarial Networks (GANs): Enhance predictive power through synthetic data generation. The GAN architecture includes a generator for creating plausible stock price sequences and a discriminator for differentiating between real and synthetic data, refining the model's accuracy.
- Technical Indicators: Incorporates moving averages, RSI, and Bollinger Bands to enrich the feature set and provide deeper insights into market trends and price movements.
- News Sentiment Analysis: Uses sentiment extracted from financial news and social media to account for market psychology's impact on stock prices.
- Fourier Transforms: Analyzes stock price data in the frequency domain to detect cyclical patterns and periodicities not visible in the time domain.

Integration and Prediction:

The system combines outputs from the LSTM network, GAN-generated data, technical indicators, sentiment scores, and Fourier transform features. This comprehensive approach ensures a robust predictive model by capturing diverse aspects of market behavior and improving prediction accuracy.

III. RESULTS AND DISCUSSIONS

III.1 TRAINING OF OUR MODEL:

This research attempts to predict the closing price of the stock for the following five days based on data from the last 60 days. In addition to historical closing prices, the model will be trained using 32 other potential price-influencing parameters. Data augmentation techniques, such as the addition of noise and the generation of artificial data using GANs, are employed to increase the variation in the training set. 20% data is used for testing and rest 80% data is used for training. To avoid overfitting, several strategies are implemented, including early stopping, dropout regularization, and cross-validation.

Experimental Results:

The research evaluated each model's performance using Root Mean Square Error (RMSE) which is defined as follows:

$$\text{RMSE} = \sqrt{\frac{\sum_{i=1}^{N}(x_i - \widehat{x_1})^2}{N}}$$

In this project the research evaluated the models through comparing their RMSE on testing data for each of the N data points, x_i being the actual stock price, and $\widehat{x_1}$ being the predicted stock price.

Table 1: Calculations using the ARIMA model.

Dep. Variable	D.GS	No. Observations	1144
Model	ARIMA (2, 1, 0)	Log Likelihood	-4589.254
Method	css-mle	S.D. of innovations	3.789
Date	20.07.2024	AIC	998.245
Time	09.05.58	BIC	8956.785
Sample	1	HQIC	8936.458

Source: Authors, (2026).

Table 1 illustrates the ARIMA(2,1,0) model fit to the differenced GS series using 1144 observations. To evaluate the fit of the model information criteria (AIC, BIC, HQIC) can be used with lower values suggesting a better model. Additional insights into the performance of the model can be obtained from the standard deviation of innovations and the log-likelihood. To ensure that the chosen model accurately captures the underlying patterns in the time series data the selection and evaluation process of models is crucial.

ARIMA:

Based on Figure6 ARIMA approximates the real stock price very well. The predicted price will be used as an input feature into the LSTM because as this research mentioned previously the study wants to capture as many features and patterns as possible about AAPLE.

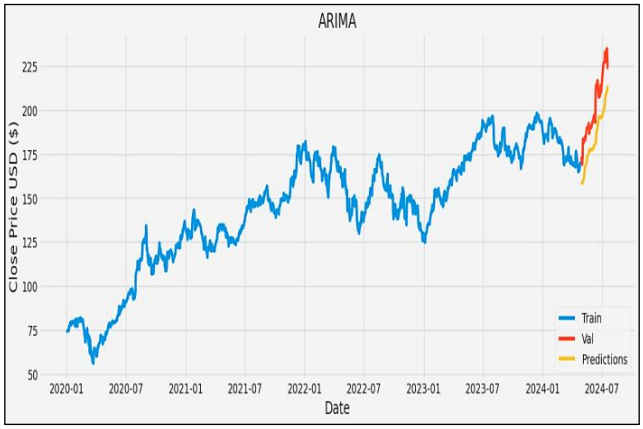

Figure 6: Forecasts based on ARIMA.
Source: Authors, (2026).

LSTM:

In this work, Bidirectional LSTM was used in the first layer of the LSTM model. Adam algorithm is used as the optimizer in this work with a learning rate of 0.001. A batch of 64 is trained on a stock price dataset followed by 50 epochs. The GAN model in this baseline model uses historical data from the past 4.7 years along with 24 correlative features as input. Following the split of the data into the train set and the test set. Figure7 shows how an LSTM model performs in predicting stock prices with the x-axis representing the timeline from January 2020 to July 2024 and the y-axis representing closing prices in USD. In the blue line stock prices are shown in a historical context showing a general upward trend but with fluctuations.

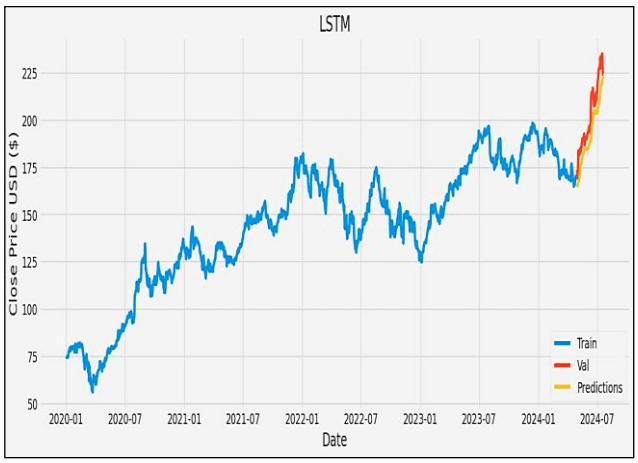

Figure 7: Stock price prediction using an LSTM model.
Source: Authors, (2026).

In Figure7 the orange line represents the validation dataset which overlaps with the yellow prediction line to demonstrate the performance evaluation of the model. Based on the close alignment between the validation data and predictions it appears that the model has accurately captured the trend and continues to make accurate predictions. A model that forecasted stock prices well predicting a continued rise based on historical data trends indicates a model that performs well.

Basic GAN:

It has been proposed that the GAN model in this paper will follow the structure suggested in the methodology section. This paper utilizes the Adam algorithm with a learning rate of 0.00016 as the optimizer for our models. This dataset was trained for 165 epochs on 128 samples over 165 epochs. Figure 8 shows the basic GAN loss curves for training and validation, which were generated using TensorFlow for training the GAN model and Matplotlib for visualization. During training, loss values for both the generator and discriminator were recorded at each epoch. These values were plotted using Matplotlib to create the loss curves, displaying training (blue) and validation (orange) performance over time. The analysis and plotting were done using Python. The x-axis represents epochs, and the y-axis represents loss values.

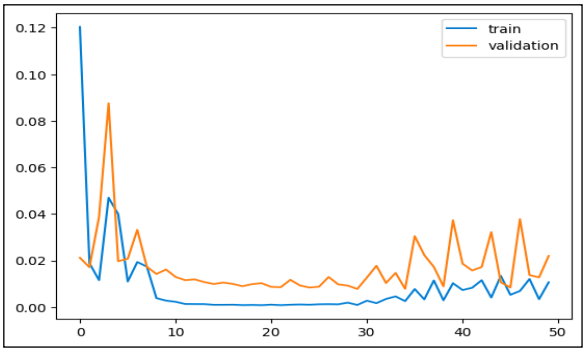

Figure 8: Basic GAN loss curves for training and validation.
Source: Authors, (2026).

Based on 50 epochs of training and validation Figure8 illustrates the loss curves of a Basic GAN (Generative Adversarial Network) model. Blue is the loss associated with training while orange is the loss associated with validation. In the first 10 epochs, both training and validation losses are high. However, they decrease significantly indicating rapid model learning. Following this initial phase, the training loss gradually decreases, stabilizing and fluctuating around a lower value. The validation loss by contrast shows a greater degree of variability fluctuating between 0.02 and 0.04 suggesting that the model may have overfitted to the training data. Plotting the first 50 epochs reveals the model's learning dynamics as well as the balance between generator and discriminator improvements. Low and stable losses indicate that the model has been effectively trained and generalized. A chart of GAN's historical and forecasted closing prices in USD is shown in Figure9.

Figure 9: Forecasting GAN closing prices using ARIMA.
Source: Authors, (2026).

The plot is divided into three sections: training data (blue) from January 2020 to January 2023 validation data (red) from January 2023 to July 2024 and predictions (orange) for the same period. The training data shows initial growth, volatility, and later stabilization of stock prices. Validation data shows an upward trend with volatility. A close alignment of the orange prediction line with the red validation data suggests that the ARIMA model has a high degree of robustness in forecasting future price trends. A visualization such as this illustrates the model's accuracy and its utility in predicting future trends and making informed investment decisions.

Table 2: Predictive Model Performance Based on RMSE.

Model	RMSE-of Training Dataset	RMSE-of Testing Dataset
ARIMA	2	7.5
LSTM	1.52	6.6
GAN	1.64	5.36
RF [1]	1.8	6.4

Source: Authors, (2026).

The GAN model has the lowest RMSE, indicating high predictive accuracy and effective generalization on the testing dataset, as shown in Table 2. LSTMs also perform well showing relatively low RMSE values. The ARIMA model performs moderately poorly with the highest RMSE on the testing dataset and the Random Forest model outperforms the GAN and LSTM models. GAN and LSTM models perform better in this particular prediction task. Confidence intervals provide a range within which the true RMSE values are expected to fall, offering insight into the variability and reliability of the model's performance. For instance, a narrow confidence interval indicates low variability and high stability, while a wide interval suggests higher variability.

Performance Variability and Implications for Real-world Trading:

Calculating confidence intervals for RMSE values helps assess model consistency and reliability. A model with a narrow confidence interval is more stable, producing predictions consistently close to actual values. This stability is crucial for real-world trading, where reliable performance is essential for making informed decisions and managing risk effectively. Models with lower RMSE and narrow confidence intervals offer more dependable predictions, which can lead to better decision-making and potentially higher returns.

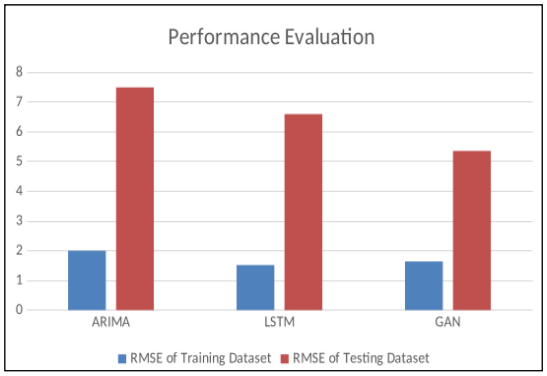

Figure 10: Comparison of model performance based on RMSE.
Source: Authors, (2026).

While GAN and LSTM models demonstrate lower RMSE values, their robustness, as indicated by confidence intervals, is also important. Traders might prefer models with greater stability and lower variability, even if it means slightly lower accuracy. In dynamic market conditions, models with consistent performance and lower variability are better suited for adapting to changes and maintaining reliability over time. According to Figure10, the GAN model exhibits the highest predictive accuracy on the testing dataset with the lowest RMSE. A LSTM model that has a relatively low RMSE value also performs well suggesting that generalization is effective. A higher RMSE on the testing dataset indicates poor performance in predicting unseen data suggesting overfitting in the ARIMA model. According to these results, the GAN and LSTM model is superior at predicting future value generalization and accuracy. GANs, with their adversarial training mechanism, can generate highly accurate predictions by learning the underlying distribution of the data. LSTM models, which are designed to process sequential data, are particularly effective at capturing both long-term dependencies and time-based patterns, making them ideal for forecasting time series data.

Discussion

This work employs GAN and LSTM networks to predict stock market closing prices using historical data and various influencing factors. The GAN model achieved the lowest RMSE of 5.36 on the testing dataset, indicating superior predictive accuracy compared to other models. This aligns with [2], who found GANs excel in stock price prediction with evenly distributed error rates. The LSTM model also performed well, with an RMSE of 6.6, effectively capturing temporal dependencies, consistent with [5], who noted LSTM's enhanced accuracy when combined with empirical mode decomposition. The study incorporated 32 features affecting stock prices, enabling the model to capture complex patterns, similar to the approach by [1], who used both traditional and non-traditional data to improve accuracy. The GAN model's ability to generalize on new data outperformed traditional models like ARIMA, which had higher RMSE values, supporting [4], who demonstrated GANs' effectiveness in reducing overfitting. The models' performance aligns with the economic-driven GANs (Fin-GAN) approach by [3], showing practical value in financial markets with higher Sharpe Ratios. Comparatively, the GAN model's RMSE of 5.36 shows significant improvement over other studies, such as [15] with an RMSE of 6.2. The LSTM model's RMSE of 6.6 also compares favorably with [19] RMSE of 7.1, highlighting the superior performance of the models used in this study. The high accuracy achieved in this study requires large datasets, which can be a limitation when data is scarce or poorly labeled. The dataset used, while comprehensive, may contain biases or gaps that affect the model’s generalizability. Future research should address these issues by using more diverse data sources and thorough data cleaning and labeling.

Although the GAN model showed good generalization, the fluctuating validation loss compared to the training loss suggests potential overfitting. Techniques like dropout, regularization, or cross-validation could mitigate this. Dropout prevents units from co-adapting by randomly omitting them during training. Regularization, such as L2 regularization, adds a penalty to the loss function based on model parameter magnitudes, and cross-validation helps assess how well the model generalizes to new datasets. This study focused on short-term predictions, but future research should explore different prediction cycles, including long-term forecasts, to provide a broader understanding of model performance over time. By [1] suggested that analyzing various cycles could reveal insights into model performance across different time horizons. While the current study used 32 features, it did not incorporate sentiment analysis from financial news and social media, which has been shown to enhance prediction accuracy. By [2] emphasized the importance of including sentiment analysis to improve model performance. Future studies should integrate sentiment data to better capture market sentiment’s impact on stock prices. Training GANs and LSTMs is computationally intensive, posing challenges for real-time applications. By [15] noted that deep learning models often struggle with complexity and high computational demands. The reliance on large datasets for high accuracy could be a drawback in cases of data scarcity, as discussed by [14]. In turn [6] also found that while enhanced WGAN models performed well, they were computationally expensive and prone to overfitting.

IV. CONCLUSION

This study explored the effectiveness of GANs and LSTM networks for predicting stock market closing prices using historical data and 32 significant factors. The GAN model achieved a low RMSE of 5.36 on the testing dataset, indicating high accuracy in stock price prediction. Using a wide range of factors allowed the models to capture complex patterns in the stock market. The bidirectional LSTM model showed robustness with an RMSE of 6.6, outperforming the ARIMA model but still facing some overfitting issues. The study identified areas for improvement, such as addressing potential overfitting and enhancing the integration of sentiment analysis. This research highlights the potential of GANs and LSTMs in predicting stock market trends, demonstrating their superior performance and robustness.

Future research must give importance to addressing the identified limits by optimizing computational efficiency, exploring hybrid models as well as integrating more diverse data sources which include sentiment analysis. The accuracy of DL models as well as practical applicability in financial market analysis and stock price prediction can be enhanced. Future research should include sentiment analysis from financial news as well as social media data to build accuracy. Investigating the hybrid models that use the strengths of several DL models like integrating GANs with GRU or Transformer networks could improve performance. Using GANs can mitigate overfitting as well as improve generalization. Incorporating more diverse features, such as economic indicators and sector-specific data, will help capture broader market trends. Creating models that could forecast and manage large amounts of streaming data will improve practical usefulness, especially during financial crises.

ABSTRACT

FSW - Friction stir welding has extended recognition as an effective non-fusion welding process for dissimilar materials, offering a solution to the limitations commonly encountered in conventional fusion welding techniques. This review paper focuses on the FSW of magnesium to steel, which has gained significant attention in different industries, like energy sector, aerospace, marine, automotive, etc. The paper presents an overview of the magnesium and steel materials, discusses the challenges and considerations specific to their dissimilar FSW, and provides insights into the mechanical characteristics, microstructural development, process parameters, and joint performance of the magnesium to steel welded joints. This paper highlights the current state of research, identifies knowledge gaps, and suggests future research directions. This information will be valuable for researchers, engineers, and practitioners involved in the development and application of dissimilar material joining techniques in various industries. The present review paper outlines FSW parameters including tool design, rotating speed, feed, tilt angle, pin offset, and the positioning of workpiece in a clamp for dissimilar FSW systems.

I. INTRODUCTION

It is a challenging task and a topic of interest for scientists, engineers, and researchers to find an effective and reliable weld joint of different material. Recently, there has been a lot of focus on lowering carbon dioxide emissions, and one effective way to combat this is to make cars lighter. Thus, it is desirable to employ light metals aggressively to address these environmental problems. However, in order to ensure their safety, all of the structures need to be strong enough. To satisfy these requirements, a dissimilar joint of strong and light metals is required [1]. Steels are utilised extensively for structural components because of their great absolute strength and good cost-effectiveness, while aluminium and magnesium are preferred light metals. Friction Stir Welding (FSW), as is widely known, is a helpful technique for creating a variety of dissimilar joints, and numerous studies have been published [1-11]. To achieve strong Mg–steel joints through fusion welding, coated steels or Cu/Ni interlayers are used as fillers. These promote beneficial interface structures and intermetallic compounds (IMCs), enhancing mechanical strength compared to conventional Mg–steel jointsb [12-22]. Manufacturing costs are raised by the use of coated steels and filler metals. Moreover, it is challenging to form strong magnesium–steel joints using traditional fusion welding because of their wide melting point differences (Fe: 1538 °C, Mg: 649 °C) and immiscibility in solid and liquid states. Weldability is further limited by the Mg–Fe binary system, which exhibits zero solubility of Mg in Fe and only 0.00041 at % solubility of Fe in Mg [4], [23-33]. Because of its environmental friendliness, energy economy, and adaptability, FSW is being used extensively [4], [16], [23], [34-35]. FSW joins similar and dissimilar materials such as Al, Mg, Cu, Pb, Zn, steel, and Ti without melting, for thicknesses of 1-50 mm. As a result, FSW avoids common fusion welding issues such as alloy segregation, wide heat-affected zones, residual stresses, weak joints, partial melting, hot cracking, porosity, oxidation, and slag inclusions [23], [35-41]. The UK's The Welding Institute (TWI) first introduced friction stir welding (FSW), a solid-state joining technique for aluminium alloys, in 1991 [11], [42-48]. Figure 1 presents the FSW setup in a butt joint configuration.

A non-consumable rotating tool is inserted at the plate edges and traversed along the joint line. The tool rotates anticlockwise, with its advancing side moving in the same direction as the traverse and the retreating side moving opposite [49-52].

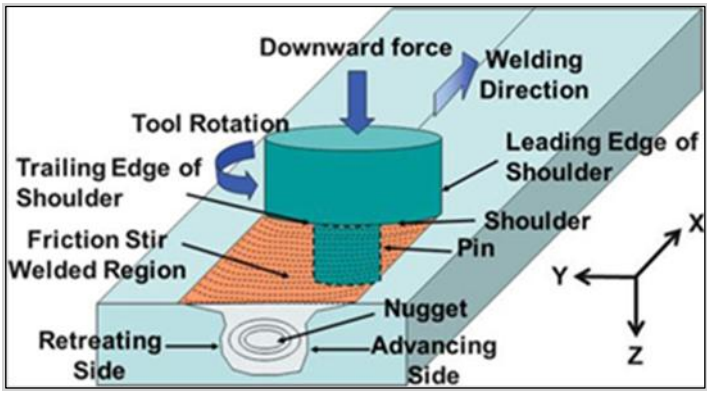

Figure 1: Illustration of friction stir welding in a butt joint configuration.
Source: [49].

Many industries, including aerospace, automotive, marine, railway, and construction, use friction stir welding [5], [49], [51]. The problems associated with joining of magnesium alloys must be resolved because of their increasing usage in industrial applications. Various Solid state welding and resistance welding methods like Friction Stir Welding [23], [53-66], Friction Stir Spot Welding [31], [67-74], Resistance spot Welding [69-77], Arc Spot Welding (ASW) [78], Resistance Element Welding (REW) [79], Resistance Rivet Welding (RRW) [80], Ultrasonic Spot Welding [12], [81-96], Ultrasonic Welding [91], Explosive Welding [92], Diffusion Bonding [93], fusion welding methods like Laser Welding [13], [97-104], Laser Welding–Brazing [99], [100-112], Laser-TIG [14-18], [21], [113-130], MIG – GMAW [125-129], MIG welding-brazing [130], TIG welding-brazing [131], TIG–MIG hybrid welding [132], Vacuum Electron Beam Welding [133], Cold Metal Transfer (CMT) [134-139], Cold Metal Transfer Spot (CMTS) [140], Diffusion-brazing [20], [141-147], Eutectic bonding [142], Impact welding - vaporizing foil actuator welding [143], Liquid Phase Bonding [144] Reactive transient liquid phase bonding [145], have been employed in the progress of magnesium to steel joints. The papers [35], [146-174]. This paper critically examines the current state of dissimilar material FSW, highlighting its challenges and opportunities. They extend a variety of alloy systems, such as different types of aluminium alloys [148], [150], [153], [175] aluminium/ magnesium [149], [176-178], and aluminium alloy/steel pairs [179-188]. It can be concluded from the literature that there hasn't been much work done to strengthen steel connecting in lap and butt configuration using FSW. So, this literature has been prepared to explore more about FSW of mg to steel.

II. MATERIALS AND METHODS

Several transportation industries are now more interested in using lightweight materials due to the need to reduce fuel consumption and component net weights [71], [189-199]. A nationwide survey indicated that cutting vehicle weight by 10% can improve fuel efficiency by about 5%. [195], [200-212]. A 100 kg weight loss in a car can lead to a 20 g/km drop in CO_2 [198]. Currently, steel makes up more than 50% of the weight of a typical automobile [199]. The average car uses 900 kg of steel, which is split up into 23% for the drive train, 12% for the suspension, 34% for the body construction, and 31% for the rest [200]. So, one easy way to make the car lighter is to use lighter materials for manufacturing instead of steel.

Table 1: Physical characteristics of steel, magnesium, and aluminium.

Metals	Fe	Al	Mg
Melting point °C	1536	660	650
Density (at 20 °C) (g/cm^3)	7.86	2.70	1.74
Tensile strength (MPa)	350	320	240
Modulus of elasticity (×10^6 MPa)	206.842	68.947	44.126
Thermal expansion coefficient (×10^6/°C)	11.7	23.6	25.5
Lattice structure	HCP	FCC	BCC

Source: [213-215].

The automotive industry makes extensive use of polymers, magnesium, and aluminium to address weight-related issues [15], [20], [201], [202]. Magnesium and its alloys are well-suited for automotive applications due to their low density, good ductility, high specific strength and stiffness, and superior damping capacity [15], [201-203], [209-214]. However, because to the high cost of magnesium alloys, more aluminium alloys have been used than magnesium alloys [210], [211] and are particularly susceptible to corrosion [212].The physical characteristics of magnesium, aluminium, and steel are listed in Table 1 [213], where it is evident that magnesium alloys can provide significant weight reductions when compared to steel and aluminium. Many industries, including shipbuilding, automotive, and aerospace, are interested in adopting hybrid constructions that produce desired weight savings because of the different properties of magnesium alloys [25], [27], [30], [109], [214].Although magnesium alloys are the lightest structural metals, they show potential as alternatives to steel in automotive applications where weight reduction is desired. It becomes challenging to join or weld two dissimilar metals that have distinct melting conditions, flow strengths, and no congruent melting phases. They are also immiscible in both solid and liquid states. Strong magnesium-steel bonding is therefore challenging.

In order to determine if it is feasible to establish mechanical interlocking or metallurgical bonding for structural applications, FSW has recently been investigated on magnesium to steel dissimilar joint in lap configuration. It is unlikely that IMC will happen between magnesium and steel when welding two different metals together. However, there have been reports of IMC happening between aluminium and steel or magnesium and zinc. These depend on the conditions of the welding, the coating on the steel, and the amount of aluminium in the magnesium alloy [59], [216-218]. In the butt joint setup, steel was placed on the advancing side (AS) and magnesium on the retreating side (RS) during FSW [57]. The rotating pin was put into the magnesium plate [56]. In the lap joint, the AZ31B sheet was placed above the steel sheet, with overlap width set by design requirements and its rolling direction oriented transverse to welding [26-28]. In butt configuration, the magnesium side was favoured by the tool pin offset from magnesium/steel interface [57]. The base materials selected for the lap configuration experiments [23], [26-28], [50], [53], [55], [58], [60] and butt configuration [59], [62], [65-66] with Mg and Steel sheets; the dimension, and thicknesses were summarised in Table 2.

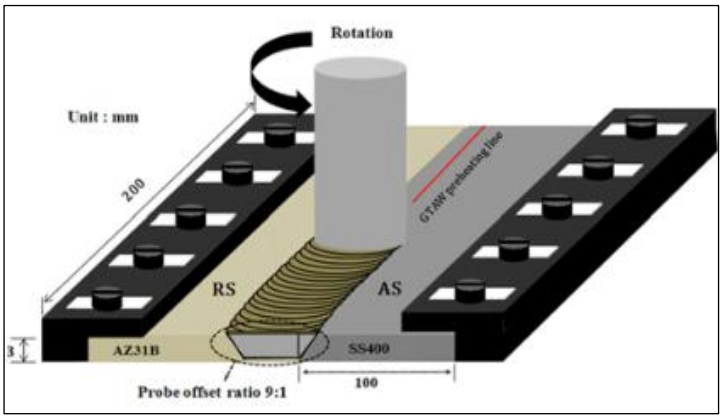

Figure 5: Schematic diagram of the HGTAFSW process.
Source: [54].

Figures 2 and 3 represent the precise welding configuration and arrangement [60]. Figure 4 illustrates the experimental configuration. As shown in Figure 4, the mg alloy has been compelled onto the steel in a lap pattern. As seen in Figure 5, the mild steel (MS) plate surface had previously GTAW preheated at a 60° angle adjacent to the intersection. This procedure guarantees improved material flow during welding and less tool wear. An anticlockwise (CCW) rotating tool was used to perform the welding operation. Positioning magnesium on the RS and mild steel on the AS produced higher joint strength compared to using a clockwise (CW) tool rotation. With tool rotation aligned to the welding direction, this configuration intensified stirring in the MS on the advancing side [54]. A high-stiffness, precision FSW machine was used to perform the welding in position-controlled mode [53].

III. FSW TOOL

In FSW, the tool plays a vital role. It generates heat and softens the workpiece to form a solid-state joint by transporting material around the pin. The tool's material and geometry are the two key factors governing its performance [11], [43-44], [46-48], [219]220]. In FSW, a non-consumable tool with a shoulder and pin generates heat, softens the workpiece, and directs material flow, thereby influencing joint formation, weld quality, mechanical properties, and process speed. [44][220-223].Tool design is the most critical factor in advancing the FSW process. A general process development flow chart is shown in Figure 6. Reliable welds require the removal of all welding flaws, including voids and insufficient root penetration.

Despite the fact that the knowledge has mostly been empirical, appropriate tool material and tool geometry can be determined for a given joint (types of w/p material, thickness, and joint design). It is easy to achieve good metallurgical bonding between workpieces for similar material FSW. FSW of different materials is even harder when their melting or thermal properties and physical or chemical properties are very different. Weldability and tool life are affected when different workpieces are positioned on the AS or RS side in butt welding and lower or upper sheet in for lap welding, and the rotating tool is plunged to a specific location in relation to the joint interface. An optimized tool design helps suppress liquid film formation and limits brittle IMC generation when dissimilar materials exhibit strong chemical affinity at elevated temperatures. This facilitates the formation of eutectic structures at low melting temperatures and speeds up the growth of IMCs. Recent studies on FSW of dissimilar materials have largely focused on joining aluminum alloys with both low- and high-melting-point materials to evaluate joint structural performance. Several studies have also examined dissimilar FSW of high-melting-point materials, including steels and titanium alloys. For dissimilar FSW, the next sections mostly address tooling materials and tool shape design [216].

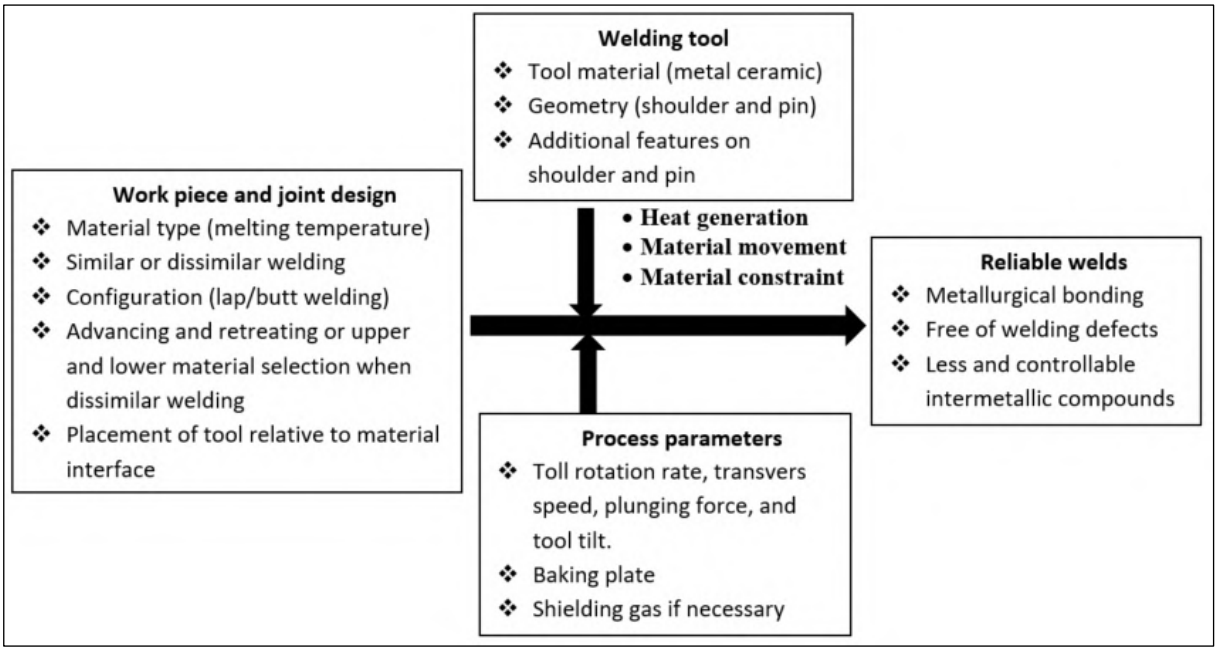

Figure 6: A typical flow chart for the development of the FSW process.
Source: [49].

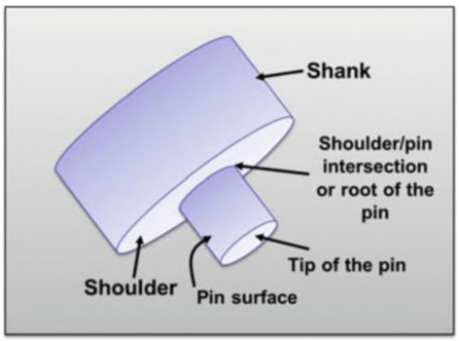

Figure 7: A friction stir welding tool.
Source: [49].

Figure 7 clearly illustrates the various features of the tool [49]. Table 2 summarizes the recommended FSW tool parameters, including tool material, shoulder profile, shoulder diameter, pin diameter, pin profile, pin length, shoulder-to-pin ratio, pin bottom diameter, and tip diameter.

III.1 TOOL MATERIAL

The right tool material must be used for the intended application in order to produce a satisfactory FSW joint. The need for welding materials like titanium, steel, and metal matrix composites has created new difficulties. An effective FSW tool must retain dimensional stability without failure or property loss during welding. The tool material should exhibit six key traits: strength at both room and process temperatures, high fatigue life, fracture toughness, wear resistance, thermal endurance, and chemical stability [49], [221]. Researchers have achieved FSW of steel to Mg alloys using H13 tool steel for the shaft and W-Re alloys for the pin [28]. Common tool materials include quenched and tempered steels, PCBN, and SKD61. For dissimilar FSW of steel to Mg, SKD61 and WC are often preferred; however, the high rotational speeds and intense forging action between steel and magnesium cause rapid tool wear and degradation. Therefore, careful selection of tool material, tool design, and process parameters is essential, as wear resistance and thermal stability limitations at high speeds remain the primary factors reducing tool life [24], [61], [223-226].

III.2 TOOL DESIGN AND GEOMETRY

FSW tool geometry strongly influences weld integrity, material flow, thermal input, and defect control. The tool has two main parts: the shoulder, which creates frictional heat and confines softened material, and the pin, which stirs and promotes mixing and recrystallization in the weld zone. Together, these factors affect flow behavior, heat distribution, force, torque, and defect prevention. A schematic of the tool is provided in Figure 8. [60]. Material flow behavior is primarily governed by the dimensions of the tool shoulder and probe. Thus, the tool profile is considered a critical factor in the FSW joining process [226], [227]. In figure 9, the stir pin was a WC rotary burr 6 mm dia. and on the cylindrical surface and 15 spiral cutting edges. The welding tool, PL=2.9, SD=25, was constructed by inserting the rotary burrs into an H13 steel holder. A penetration depth of tool 3.2 mm was applied for FSLW [50].

Figure 8: Schematic of FSW tool
Source: [60].

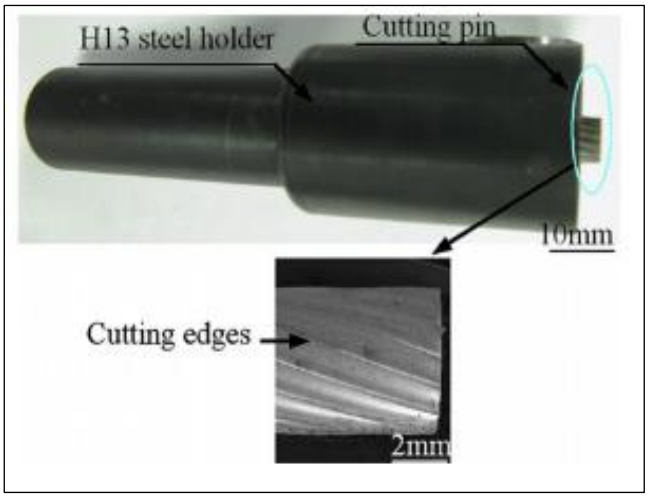

Figure 9: Appearances of the FSW tool with the design of the cutting pin.
Source: [50].

III.3 TOOL SHOULDER

The tool shoulder generates frictional heat in the surface and subsurface regions of the workpiece. In thin-sheet welding, it contributes most of the deformation and heat input [221]. In FSW, the shoulder diameter is the primary contributor to heat generation, with nearly 87% of the total heat produced through friction between the shoulder surface and the workpiece. Tool shoulder diameter and geometry surface characteristics have an impact on the FSW weld quality as they increase heat generation. Selecting the appropriate shoulder diameter is critical for producing high-quality FSW joints [48], [219], [220]. Early tool designs often used a shoulder-to-pin diameter ratio of 4:1. More recently, this ratio has been reduced to 3:1 or even 2:1 to better control heat input.

III.4 TOOL PROBES (PIN)

The tool probe generates both frictional and deformational heat. It shears material at the front, transports it to the rear, and influences the contact surfaces of the joint. The probe governs deformation depth and welding speed, while its geometry affects plasticized material flow and weld quality. Common probe designs include threadless, whorl, MX-triflute, truncated cone, triflute, trivex, and cylindrical types [44], [48], [221]. The ratio of shoulder to pin diameter (SPR) depends on the thickness of the workpiece. In dissimilar FSW, the SPR is generally higher than in similar joints, particularly for steel–magnesium alloys, where values are much greater than those for steel–steel or magnesium–magnesium welds. This is attributed to the higher hardness and lower thermal conductivity of steel compared to other materials of similar strength. Consequently, many researchers have adopted SPR values in the 4:1–10:1 range for steel–Mg dissimilar welding [228].

IV. FSW PROCESS PARAMETERS

The essential parameters of FSW are tool speed, welding speed, axial force, tilt angle, and pin offset. In addition to the criteria used for similar material systems, dissimilar FSW is further influenced by tool pin offset and the placement of base materials in the fixture [219]. Table 2 summarizes the recommended FSW tool parameters, including rotational speed, welding speed, tilt angle, plunge depth, plunge force, tool pin offset.

IV.1 ROTATIONAL SPEED

Rotational speed, defined as the revolution rate of the tool about its axis, is a key parameter influencing weld quality [229]. It accounts for nearly 40–50% of the overall effect in dissimilar FSW [44]. Higher speeds enhance the joint contact area and thermal input [30]. In dissimilar welding, tool rotation governs (i) plastic deformation through frictional heating and (ii) the plunge force, which impacts material flow, defect formation, stir zone (SZ) size, joint integrity, and tool wear. Conversely, insufficient rotation generates low heat and poor mixing, particularly in steel–Mg welds, making speed optimization essential [184], [224], [228], [229].

IV.2 WELDING SPEED OR TRAVEL SPEED

Welding or travel speed refers to the forward movement of the tool along the joint line. This parameter greatly affects the weld quality and microstructure in steel–Mg FSW, making its selection complex [230-232]. Alterations in travel rate often produce uncertain effects on joint properties [233]. Therefore, considerations such as joint configuration (butt or lap), tool rotation, plunge depth, and base material are crucial when determining the appropriate speed [228], [234-236].

IV.3 TOOL PIN OFFSET OR TOOL ECCENTRICITY

Tool pin offset is a critical parameter in dissimilar steel–Mg FSW. It refers to the displacement of the tool toward one of the base materials. In conventional (similar-material) welding, the pin is aligned at the joint center; however, applying this approach to dissimilar systems often leads to defective joints [59], [61], [69], [217], [237-242]. The distinct mechanical, chemical, and thermal characteristics of steel and magnesium-such as melting point and recrystallization temperature make zero offset unsuitable, as it results in inadequate plastic flow and bonding [59], [228], [242-244]. Research shows that shifting the pin toward the softer or lower-conductivity Figure 10 (a) illustrates a central pin position (0 mm offset), while Figure 10 (b) shows a displacement of h mm toward the Mg side. With no offset, heat and deformation are insufficient due to property mismatches. Moving the tool toward magnesium increases heat generation on that side, while the steel side retains less due to its higher thermal expansion coefficient, promoting balanced stress distribution [219].

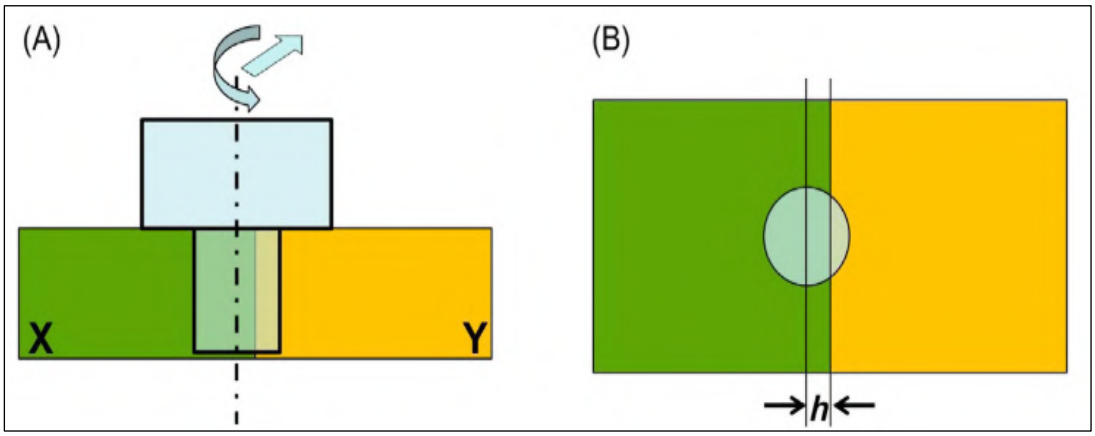

Figure 10: Tool pin offset concept (A) TPO 0 mm (B) TPO h mm w.r.t, weld centreline.
Source: [216], [219].

IV.4 TOOL TILT ANGLE

The tilt angle refers to the inclination of the FSW tool (e.g., 0°, 1°, 2°, or perpendicular to the workpiece surface) [219]. This parameter is critical for producing defect-free welds [245-248]. An optimized tilt angle provides two key benefits: (i) it confines the forged material beneath the tool shoulder with assistance from the pin [44]; and (ii) it enhances stirring, enabling uniform flow from front to rear and top to bottom, thereby ensuring proper mixing and joint quality [44], [228], [246].

V. MICROSTRUCTURES AND INTERMETALLIC COMPOUNDS

In FSW joints, the microstructure describes the grain arrangement, phase distribution, and defects observed at the microscopic scale. These features vary across weld zones as a result of heat input, plastic flow, and dynamic recrystallization. At the interface of dissimilar materials, diffusion and chemical reactions can lead to the formation of intermetallic compounds (IMCs), which significantly influence joint behavior. These compounds typically exhibit ordered atomic structures and possess properties that are distinct from those of the parent metals. Fractured surfaces from tensile specimens can be characterized using several analytical methods. Following ASTM E3-11 (2017), samples were prepared through sequential polishing with 220–2000 grit emery papers and diamond finishing to enable observation of microstructural changes induced by welding [249]. The polished samples were microetched in accordance with ASTM E407-07 [250] [251]. Metallographic characterization was performed using optical microscopy (OM), scanning electron microscopy (SEM), and transmission electron microscopy (TEM) coupled with energy-dispersive X-ray spectroscopy (EDS) [23], [50], [53-59], [251]. Post-tensile test fracture surfaces were further examined by X-ray diffraction (XRD) [55], [58], [251]. All interfaces showed bending, with dispersed steel fragments embedded in the magnesium. The probe action generated a fresh surface on the steel plate. Microstructural analysis revealed that iron was absent on the Mg side regardless of IMC thickness, while an Fe–Al intermetallic layer formed at the interface when Mg contained Al, and Mg was identified on the steel side. Thus, formation of the Fe–Al IMC layer occurs through new surface generation on the steel plate, requiring direct probe contact with the steel butt face [59].

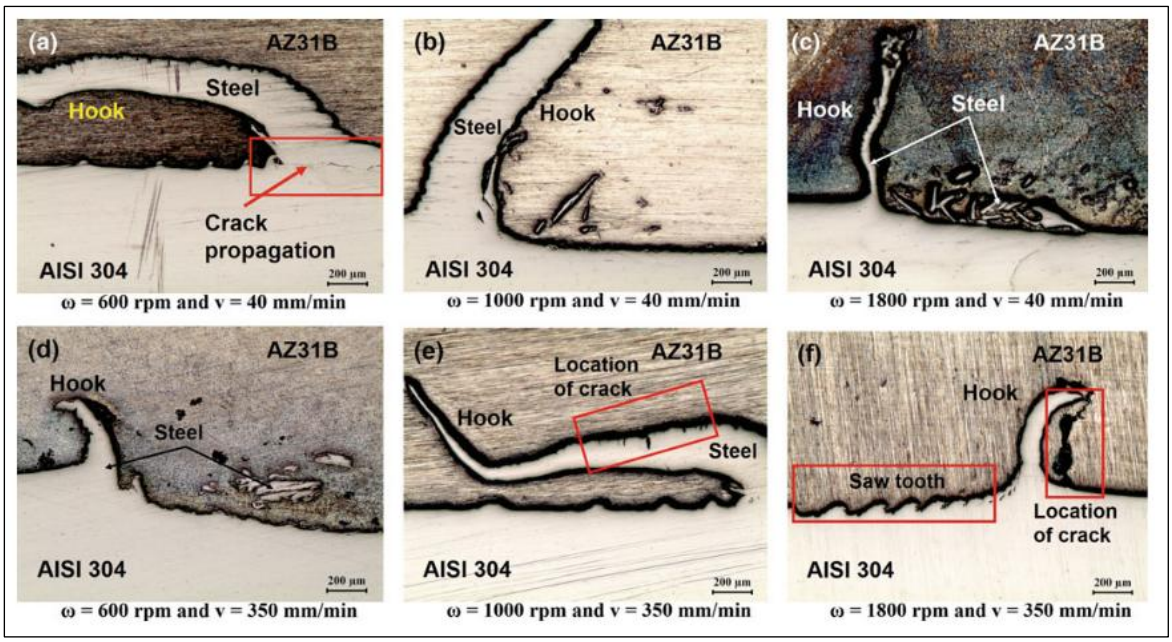

Figure 11: Optical micrographs for different ω and υ.
Source: [59].

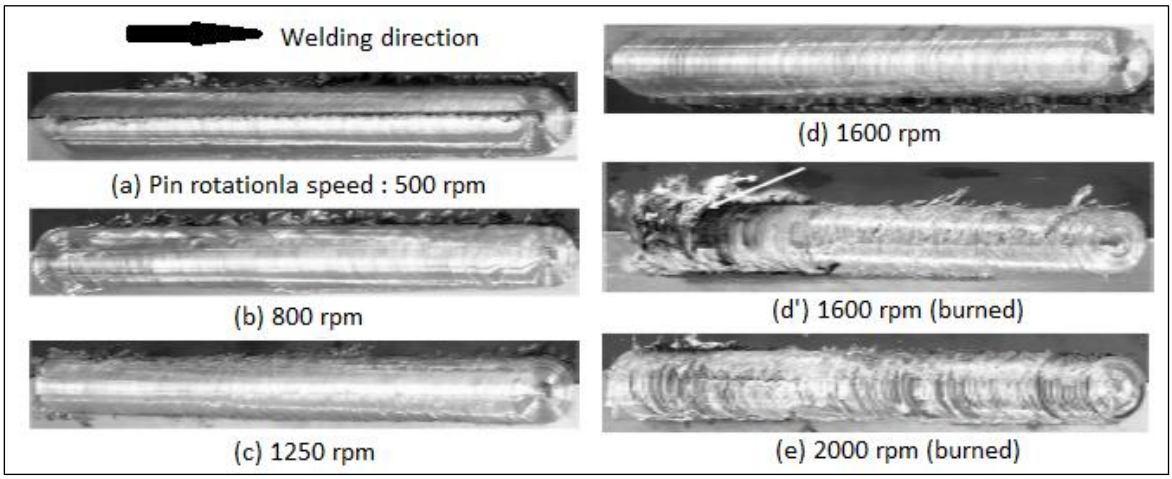

Figure 12: Effects of pin rotating speed on the surface view.
Source: [56].

Figure 12 presents weld surface features and cross-sectional morphologies. At 500 rpm, a groove-like defect appeared along the weld line due to insufficient plasticization of Mg caused by low heat input, precluding tensile evaluation. Conversely, at 2000 rpm, excessive heat led to severe ignition, producing a major root defect and resulting in very low tensile strength [56]. As indicated by the arrow in Figure 12(d′), magnesium ignition frequently occurred at a rotation speed of 1600 rpm, where the weld temperature approached its ignition limit. At 1250 rpm, the joint showed reduced tensile strength compared to 1600 rpm, with defects appearing near the root region [60]. At 800 rpm, inadequate plastic flow of magnesium produced flaws within the Mg zone, while fracture consistently propagated along the Fe–Mg interface. Alongside regions where Mg bonded to the Fe surface, flat zones were also observed (indicated by the arrow) where Mg failed to adhere. These unbonded regions are likely responsible for the reduced joint efficiency of about 70% [56]. The HGTAFS weld nugget showed a fully bonded structure without unjoined regions at the joint bottom, unlike FS welds, due to a composite of scattered mild steel fragments and recrystallized Mg grains. In the HAZ and TMAZ, Mg grains were slightly coarser in assisted FS because GTAW preheating provided additional gradual heating. Recrystallized grains in the stir zone resulted from intense plastic deformation. The steel nugget displayed finer grains at the top than the bottom, suggesting upper-section hardening from the combined influence of the rotating tool shoulder and GTAW preheating [54]. Section views of a group weld produced by FSLW at various travel speeds are displayed in Figure 13. The macrostructure characteristics of the connecting interfaces differ greatly from those of other typical FSLW (the pin without cutting the bottom metal) [252]. The steel surface layer was broken up into metal fragments and flashes by the stirring pin, which then transferred them into the magnesium base. It's possible that the pin rotation created the flower-like flashes. Figure 13.a illustrates these phenomena in vivid detail. The smooth joining interface with a few lengthy flashes remained after the scraps dropped and were destroyed as the transit speed increased. The evolution of the joining interface's macro-morphology could be attributed to the decreased friction heat input [253].

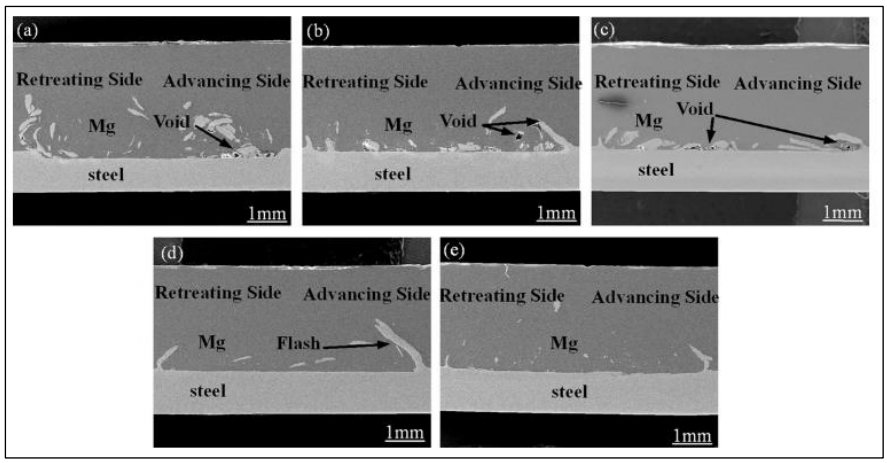

Figure 13: Interfacial macro-morphology by FSLW at welding speeds of (a) 60 mm/min, (b) 118 mm/min, (c) 150 mm/min, (d) 190 mm/min, and (e) 300 mm/min.
Source: [50].

As seen in Figure 13.e, the flashes decreased with increasing travel speed. The thinned flashes are easier for the stirring pin to cut away from the interface because less metal has been softened by friction heating at high travel speed. As shown in Figure 13.a–c, voids were discovered near the interface; however, as seen in Figure 13.d and e, they vanished when the transit speed was increased. Due to the oncoming filler metal's inadequate extrusion force at low travel speed, voids tend to form at the advancing side, as one may have observed. This phenomenon is somewhat analogous to the production of voids in FSW joints [254]. However, the joining strength may be somewhat enhanced by the decreased voids at high travel speeds [50]. As the probe length increased, the microstructure at the joining interface changed dramatically [58].

VI. MECHANICAL PROPERTIES OF DISSIMILAR MG-STEEL FSW SYSTEM

The mechanical behavior of Mg–steel dissimilar FSW joints differs markedly from similar-material welds due to the unequal properties of the base metals.Summary of recommended remarkable properties of joint welded by FSW systems, like IMCs, UTS, YS, TS, JE, Elongation, etc. shown in Table 2. Studies show that the ultimate tensile strength (UTS) of Mg–steel dissimilar FSW joints is typically lower than that of the base metals, indicating reduced efficiency compared with the weaker alloy. The UTS depends on IMC formation and joint microstructure, both of which are strongly affected by FSW process parameters. The majority of defects are caused by incorrect material flow between the steel matrix and magnesium particles, which is caused by non-optimized process parameters, and its lowers the UTS. Conversely, a reinforcing action that enhances the joint's ultimate tensile strength is conferred by small steel particles exhibiting suitable material flow inside the magnesium matrix. Thus, in order to achieve a greater UTS, the size of the steel particles is crucial. Furthermore, grain refining is strengthened by the vigorous stirring motion, which also raises the UTS. Owing to the inhomogeneous microstructure and unavoidable IMCs, these strengthening effects are insufficient to achieve a UTS greater than that of the base metals. The inherent characteristics of IMCs lower joint ductility within the stir zone, thereby reducing yield strength and fracture-to-elongation ratios [219]. Many studies employ fractography to examine the reduced fracture-to-elongation ratio, often linked to brittle fracture or finely recrystallized grains. Broken tensile specimens with flat surfaces and cracks demonstrate a mixed fracture mechanism characterised by both brittle and ductile patterns. Since a tensile specimen typically fractures in the TMAZ zone. Due to the existence of IMCs in these regions, TMAZ of the Cu side is thought to be responsible for brittle fracture [219], [247], [255], [256]. Future studies may focus on improving the tensile characteristics of dissimilar Cu–Al FSW [219].

VI.1 TENSILE STRENGTH

A UTM machine was used to test the tensile specimens. As shown in Figure 14, the AZ31B magnesium alloy was fixed in the driven crosshead to evaluate specimens under advancing side (AS) loading. Specimen dimensions followed ASTM E8M-04 standards, as illustrated in Figure 15 [54]. For testing, samples were prepared with the tensile axis oriented perpendicular to the weld line [59].

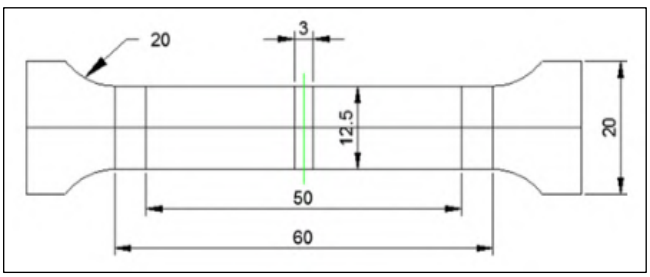

Figure 15: Geometry of the tensile test specimens.
Source: [54].

.

Figures 16 and 17 illustrate the relationship between RS (ω rpm) and TS (MPa), as well as WS (υ mm/min) and TS (MPa), respectively. The TS of the joint diminishes as RS increases, while it consistently rises with an increase in WS. A maximum joint strength of 198.75 MPa, about 79% of the Mg base alloy was achieved at 600 rpm and 350 mm/min. All tensile samples fractured in the transition zone between the advancing side (AS) and the stir zone [60]. Joint strength is adversely affected by increased heat input and reduced cooling rates. The microstructure gets coarser with high heat input, which makes dislocation movement easier. Weld strength gradually decreased [60].

Source: [60].

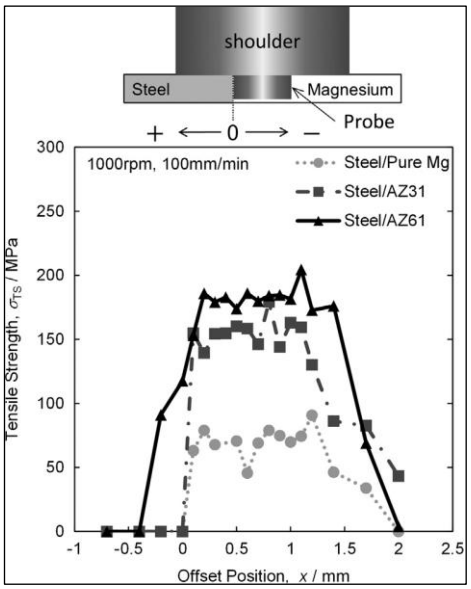

Figure 18: Relationship between joint tensile strength and tool pin offset position.
Source: [59].

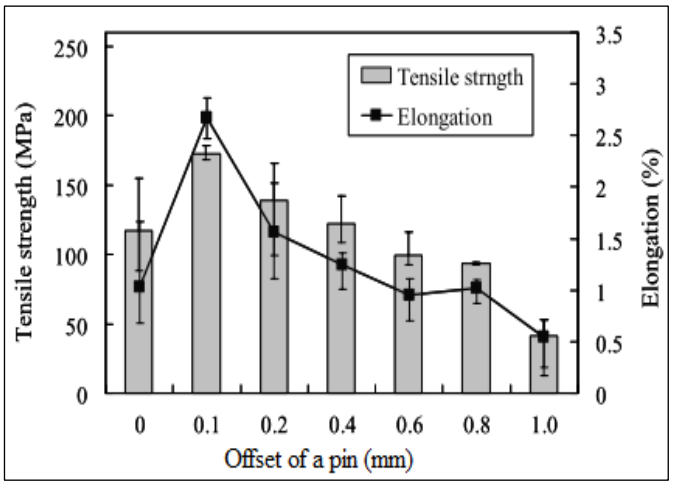

Figure 19: Relation between tensile strength, pin offset and elongation of joint.
Source: [56].

Figure 18 illustrates the correlation between tool offset position and TS at speed 1000 rpm and feed 100 mm/min. The joint between steel and various magnesium alloys, with an offset of +0.1 to +1.1 mm, demonstrated optimal high tensile strength. Numerous voids were present in the SZ when offset was excessively big in the direction of the steel-AS. In contrast, an intermetallic compound layer cannot develop when the offset position is negative (towards mg-RS). Thus, to achieve a suitable IMC layer and ensure bonding between steel and magnesium, the tool probe must contact the steel butt face [59]. Joint strength and elongation were investigated in relation to different pin offsets towards the Fe faying surface. Figure 19 shows the effect of tool pin offset on tensile strength and elongation at a welding speed of 100 mm/min and a rotation speed of 1250 rpm, with offsets between -0.2 mm and 1.0 mm. Maximum strength and elongation were achieved at a 0.1 mm offset, whereas tensile performance declined as the offset increased. At 0 mm offset strength was low, likely due to inadequate removal of the oxide film on the Fe surface. In all cases, fracture occurred along the Mg–Fe interface. Between 0.2 and 0.8 mm offsets, UTS was reduced because cracks initiated at the interface between Fe fragments dispersed in the Mg matrix and the surrounding Mg, compared with the 0.1 mm offset. At 1.0 mm, tool wear occurred, resulting in poor joint strength with bonding limited to the upper region [56]. For pure mg, and its alloy AZ31, and AZ61 plates, the average tensile strength is 170, 260, and 280 MPa, respectively. As the mg alloy's Al content increased, the joint strength increased because Al was being depleted at the mg side close to the interface. UTS of the steel/mg joint was substantially associated with the Al depletion on the mg side close to the joint edge. Under the optimal FSW conditions, the steel to mg joint failed on the mg side close to the joint interface. The improved TS resulted from the FSW's low heat input, which prevented Al depletion [59].

Figure 20 illustrates the relationship between RS, elongation, and joint TS. The fracture happens at the joint interface, and the maximum TS of a joint was approximately 70% of that of mg base metal. When the pin rotated slowly, the magnesium matrix of the joint developed a number of defects due to inadequate plasticization of the mg. Joint strength increased with pin rotation. As the mg plasticised, pushing it into an active steel surface produced pressure. However, excessive pin rotation speed caused magnesium to burn, reducing joint strength [56].

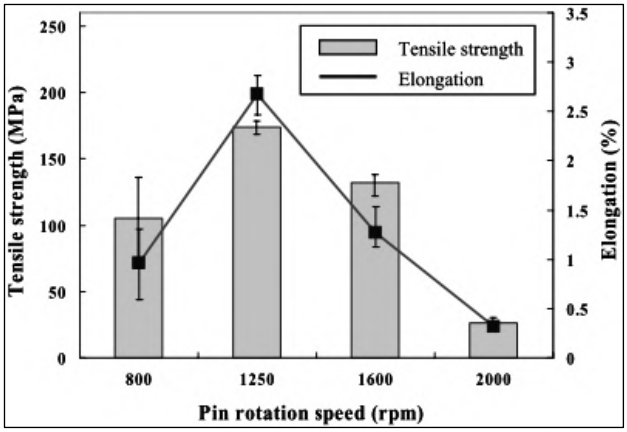

Figure 20: Relationship between TS, speed, elongation.
Source: [56].

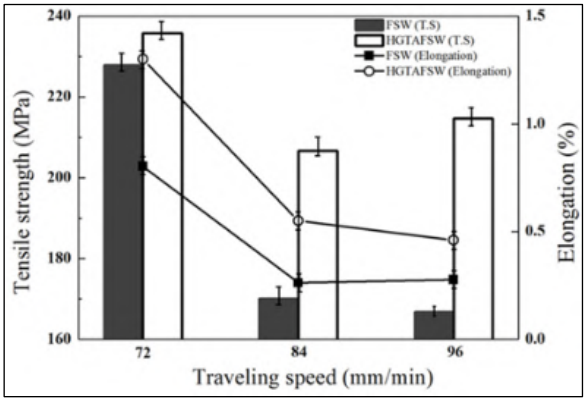

Figure 21: TS of the FSW and HGTAFSW welds.
Source: [54].

Figure 21 shows the effect of travel speed (72–96 mm/min) on the tensile strength (TS) of FSW and HGTAFSW joints. At the same speeds, HGTAFSW achieved higher TS than FSW, reaching a maximum of 237 MPa (~91% of Mg base metal) at 72 mm/min, compared with 226 MPa (~86%) for FSW. FS welds weakened with increasing speed, while HGTAFSW displayed a fluctuating trend. In FS welds, cracks often initiated at the lower joint region and propagated along the Mg–steel interface, whereas in HGTAFSW, fracture followed a similar path but with better elongation due to improved material flow and partial annealing. These findings highlight the role of steel-side preheating in enhancing joint strength [54]. Tensile properties of AZ31-SS316 and WE43-SS316 dissimilar welds were compared with their base metals, showing no significant difference between the two systems. The joints exhibited a UTS of ~160 MPa, about 73% of the Mg alloys. In both cases, fracture occurred at the weld interface due to the mismatch in elastic modulus between steel and Mg, leading to stress concentration. The presence of intermetallic compounds slightly reduced joint strength. Thermodynamic and kinetic simulations further suggested anomalous Al diffusion into Mn-Mo rich particles within SS316 during butt-welding of AZ31 and stainless steel 316 [57]. Steel and magnesium alloy are mechanically bonded together, with the bonding land only falling within the probe diameter's domain. As a result, brushed finish steel joints don't show much of failure load. AZ31–zinc-coated steel joints exhibited higher failure loads than AZ31–brushed steel joints, indicating that the zinc layer enhanced Mg–steel weldability.

A fresh metal surface was exposed as a result of the low melting eutectic phase's emergence and extrusion at the interface, increasing the mutual diffusion between steel and magnesium alloy [23]. As welding speed increases, the fracture strength (as illustrated in Figure 22) rises, and samples coated with zinc have a higher fracture strength than samples without coating. The true fracture strength of the steel–magnesium interface is greater than the measured values since all specimens fractured within the stir zone. During welding, the zinc coating on steel forms a liquid eutectic layer and acts as a flux, enhancing surface reactivity [28]. Figure 23 shows the effect of probe length on tensile strength and fracture location in AZ31–steel lap joints. Tensile testing revealed that probe length strongly influences joint properties under identical welding conditions. In zinc-coated steel joints, void defects in the stir zone limited the benefits of longer probes, while short probes produced defect-free, high-strength joints. For brushed finish steel, increasing probe length significantly improved failure loads. Similar tensile strengths for both zinc-coated cases indicated that probe extension had little effect. With a 1.5 mm probe, steel and Mg were mechanically bonded, whereas a 1.8 mm probe penetrated the steel underside, enabling stirring to create a new steel–Mg interface and promote thin diffusion bonding [58].

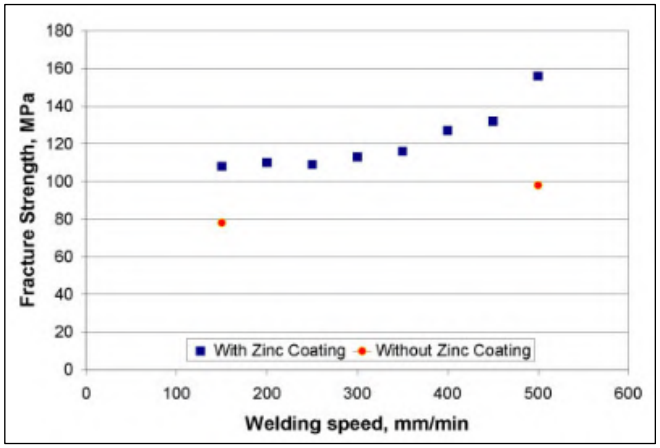

Figure 22: Influence of welding speed on fracture strength.
Source: [28].

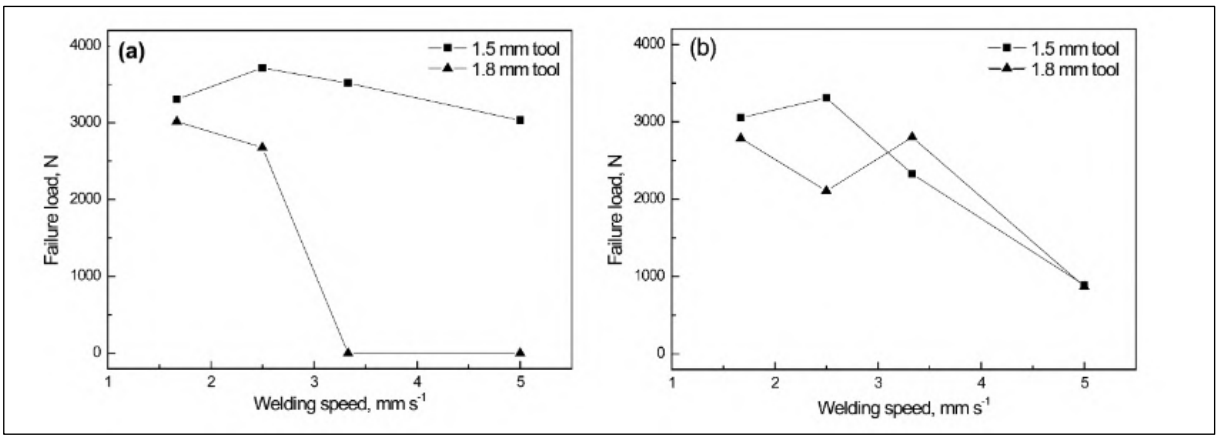

Figure 23: Effect of tool design on tensile strength: (a) brushed finish steel joints; (b) zinc-coated steel joints.
Source: [58].

Because of the intrinsic strength differential, joints manufactured of HSLA steel (1.5 mm) have a much higher failure load than joints made of MS (0.8 mm). Nevertheless, MS (0.8 mm) weld specimens sustained a significant amount of elongation before failure. All four lap shear specimens failed through interfacial separation between the top and bottom sheets. The principal mode of failure was determined as the fracture of the top magnesium layer. When tensile specimens are examined transversely, the percentage of elongation to failure decreases noticeably. Nonetheless, the percent elongation to failure is improved for the tensile specimens. In transverse tensile specimens, a reduction in yield strength and elongation indicates a compromised region within the weld cross-section. The research indicates that the weaker region is located on the advancing side [26].

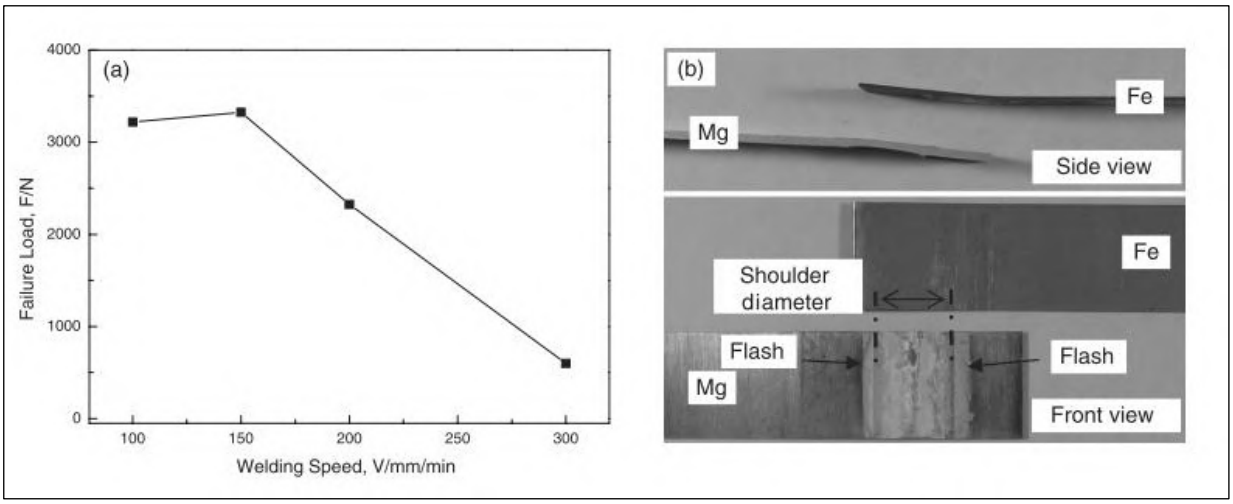

Figure 24: (a) welding speed to failure loads, and (b) fracture location.
Source: [55].

Figure 24 shows joint failure loads and fracture sites. At a WS 150 mm/min, the maximum failure load was 3.4 kN, which is about 65% of the zinc-coated steel base material. Increasing welding speed lowered the load, confirming that proper parameters are essential for strong Mg–steel lap welds. All fractures occurred at the interface, as seen in Figure 24(b). The bonded region extended beyond the probe and shoulder diameters, with solidified flash at its edges, but its width decreased sharply with higher welding speeds [55]. In friction stir welding, heat input is inversely related to travel speed and directly related to tool rotation. Thus, at constant rotation, heat input decreases as welding speed rises. Insufficient heat during higher travel rates reduces joint strength by limiting interaction between the magnesium alloy and zinc-coated steel. In contrast, excessive heat at lower speeds produces a thick reaction layer, diminishing mechanical performance. The zinc coating promotes eutectic formation at the Mg–Zn interface due to its low melting point [55].

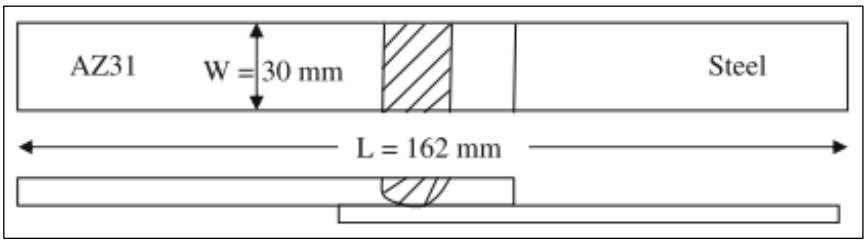

Figure 25: An illustration of the lap shear specimen.
Source: [27].

Figure 25 shows the lap shear specimen schematic. Average joint strengths were 5.1 ± 1.5 kN for AZ31 (0.8 mm) EG steel and 6.3 ± 1.0 kN for AZ31 (1.5 mm) HDG steel, with unguided lap shear tests showing peak loads of ~6 kN. FSW joints reached up to 80% of base metal strength, particularly in thinner 0.8 mm steel welds. Both failed by interfacial separation. Under the tool tip, the Mg/steel bond contained few Zn–Mg phases. Heat from welding melted the Zn layer, dissolving Mg and creating a Zn–Mg alloy, but much of this liquid was expelled, leaving a hardened layer without strong bonding. Thus, the thin Zn coating was ineffective as a brazing medium [27]. To guarantee that the complete shear force is applied to the joining contact, two notches were meticulously cut from the welded steel and mg, and the sample was sectioned parallel to the weld line, as shown in figure 26 [50]. Figure 27 illustrates the variation of tensile shear strength with travel speed. Strength increased with speed, peaking at 96.3 MPa at 190 mm/min, after which it declined. A dashed line marks the 88 MPa strength of an AZ31B FSW butt joint, while a horizontal line represents the 144 MPa shear strength of the AZ31 base metal [50].

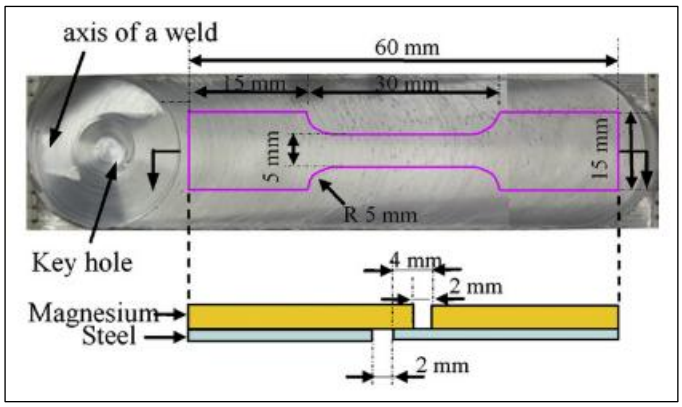

Figure 26: Tensile shear test sampling and weld appearance.
Source: [50].

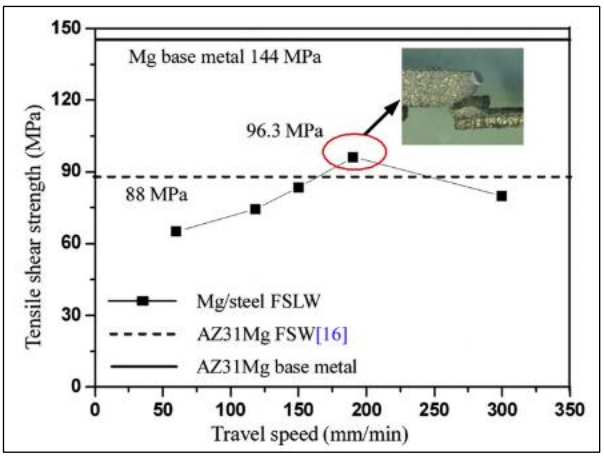

Figure 27: Joint tensile shear strength as a function of transit speed.
Source: [50].

The average minimum joint efficiency for AZ31/MS welds exceeds 60%, while for AZ31/HSLA welds using tool 1 (convex scrolled shoulder and a stepped spiral pin), it is approximately 40%. Process parameters showed an influence on joint efficiency. For AZ31/MS welds using tool 2 (Convex scrolled shoulder and a stepped spiral pin plus a short hard WC insert on the tool pin bottom), the combination of 500 RPM, 100 mm/min travel speed, and 2.47 mm plunge depth produced a weld efficiency of > 90%. The AZ31/HSLA weld's weld efficiency, at the same process parameters, was around 52%, the highest in its class [53].

VI.2 HARDNESS

Microhardness of the weld zones was evaluated with a Vickers hardness tester following ASTM E384-16 standard [251]. From the mg surface to the steel surface, microhardness measurements were made in the thickness direction. When measuring hardness from the top magnesium surface, it was found that the hardness progressively increased until it reached the interface between magnesium and steel, after which it decreased when measured in steel. The hardness rises as we proceed from AS to RS. This effect may be attributed to grain refinement. The increased rate of cooling was the cause of the increase in magnesium hardness. Smaller grains with a higher hardness are produced by the faster cooling rate [60]. As shown in Figure 28, the stir zone (SZ) has higher hardness than the TMAZ, HAZ, and base metal (BM) of magnesium alloys in AZ31–SS316 and WE43–SS316 joints. No significant hardness variation was observed between AZ31 and WE43. In steel, the TMAZ exhibited greater hardness than its base material. The hardness rise in the SZ is attributed to recrystallization, whereas in the steel TMAZ it stems from work hardening followed by recrystallization [57].

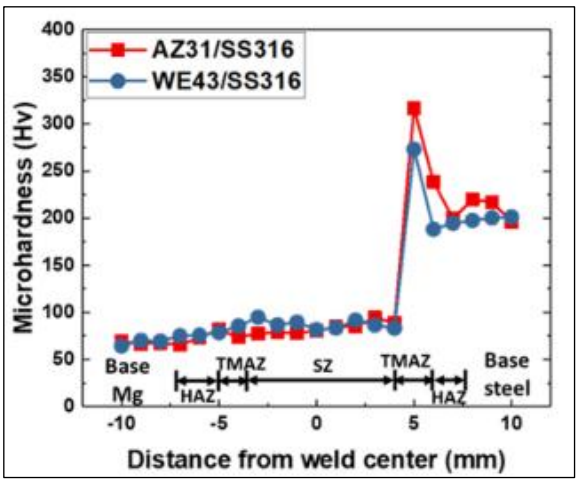

Figure 28: Microhardness profile of AZ31 to SS316 and WE43 to SS316 across the weld cross section.
Source: [57].

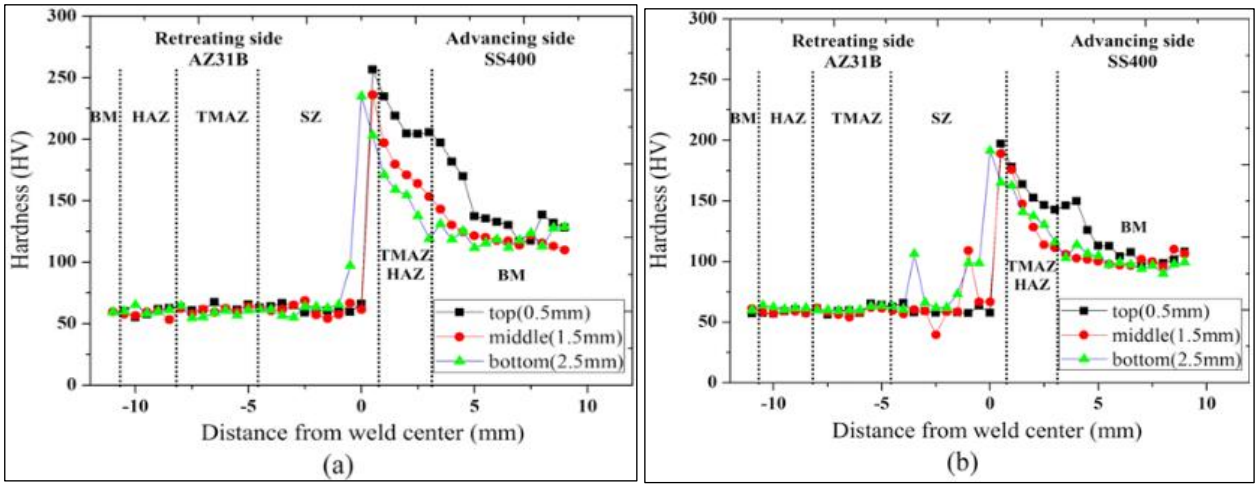

Figure 29: Cross-sectional hardness profiles (a) FS, (b) HGTAFS welds.
Source: Authors, (2026).

Figure 29 presents hardness profiles across the weld cross-section at 0.5 mm, 1.5 mm, and 2.5 mm from the top surface. Maximum values were ~250 HV in FS welds and ~190 HV in HGTAFS welds on the steel side. Hardness on the Mg retreating side was comparable to the base alloy. In steel, work hardening raised hardness in the TMAZ and HAZ, but values were slightly lower in HGTAFS than FS welds. This decrease was attributed to coarser recrystallized grains from GTAW preheating and higher frictional heat on the steel side. [54].

VII. WELDING DEFECTS OF DISSIMILAR MG-STEEL FSW SYSTEM

The various types of joining defects are caused by the incorrect joining approach and the use of non-optimal dissimilar FSW working constraints [44], [257]. Due to improperly deformed metal flow patterns and insufficient material inclusion in the FSW zone, both identical and dissimilar FSW welds are susceptible to a number of defects, including tunnel flaws, pinholes, kissing bonds, fractures, and pipe defects, among others [258-260]. A trustworthy technique for locating a number of concealed defects in the weld produced after FSW is the X-ray detection test [261]. Onion-ring defects are commonly observed in both steel and magnesium alloy with comparable FSW, frequently aggregating around the weld nugget zone (WNZ). The dark and light alternating bands that define onion ring microstructures must have the same spacing between them as the tool moves forward in each revolution. Within the onion-ring microstructure, band discontinuity increases with weld length and is directly affected by tool rotation and material flow capacity [228], [262]. The primary cause of tunnelling defects is insufficient material mixing and forging action, which occurs when Welding variables including traverse speed, rotational speed, tilt angle, etc., are incompetent to generate necessary heat input for joining. In order to prevent tunnelling and void flaws during FSW, the ideal welding speed must be chosen. Future research in this area has to be properly investigated [228], [263-266]. Another type of FSW defect that can be found across the bonding surface is crack formation. Crack formation is mostly caused by small plunging depth, inappropriate pin offset, tool design, and incorrect w/p placement [267]. Cracks are typically detected in the SZ during different FSW and are classified as macro and micro-cracks. Cracks in the weld region are also likely to be caused by the development of IMCs and worse weld bonding in the SZ [268]. It is important to use appropriate parameters in FSW in order to prevent these kinds of flaws while connecting via FSW.

Defects involving fragmented or microscopic particles are uncommon in the Steel–Mg alloy welds produced by FSW and are often not present in FSW of similar and low-strength materials. Steel fragments within the Mg-Al metal matrix are regarded as defect formations. An uneven material flow fails to distribute the fine steel fragments uniformly, leaving sharp edges and surfaces unbonded, leading to voids and microcracks. This is caused by the high hardness, and reduced UTS in the stir zone. Optimizing process parameters, especially tool pin offset and feed rate can minimize fragmentation-related defects [30], [228], [269].

Lack of penetration is a common defect in dissimilar material FSW. This type of defect is typically located at the weld joint's lowest surface, and when the workpiece is isolated or lacks appropriate joints, the welds produce a weak joint. Under stress corrosion, crack initiation reduces fatigue toughness and tensile strength (weld efficiency), ultimately causing deformation or fracture. Factors like improper tool design, incorrect pin length, shallow plunging depth, varying plate thickness, and poor tool alignment influence FSW butt joints and worsen defects. Bend tests, which examine a material's ductility and soundness, can be used to find these kinds of defects [47], [228], [270]. During welding, high tool pin rotation generates intense heat around the weld interface, plasticization close to the tool shoulder and probe. This leads to excess material being expelled as surface flash. Penetration difficulties can result from variations in plunging depth (workpiece thickness variations) through the weld line and from pin lengths that are inappropriate in relation to the thickness of the w/p. Weld flash forms when softened material around the tool pin is expelled due to greater probe plunge depth. In addition, excessive tool tilt can limit softening of material filling the cavity above the weld nugget zone (WNZ), causing extra flash on the retreating side (RS) [44], [30], [228]. The joint interface exhibits a "hook"-like features that increases joint strength at high welding speeds and decreases joint strength at low welding speeds. Similarly, the zipper effect, which eventually strengthens the weld's joint, is promoted by the "saw tooth" shape seen at the interface at high travel speeds [60].

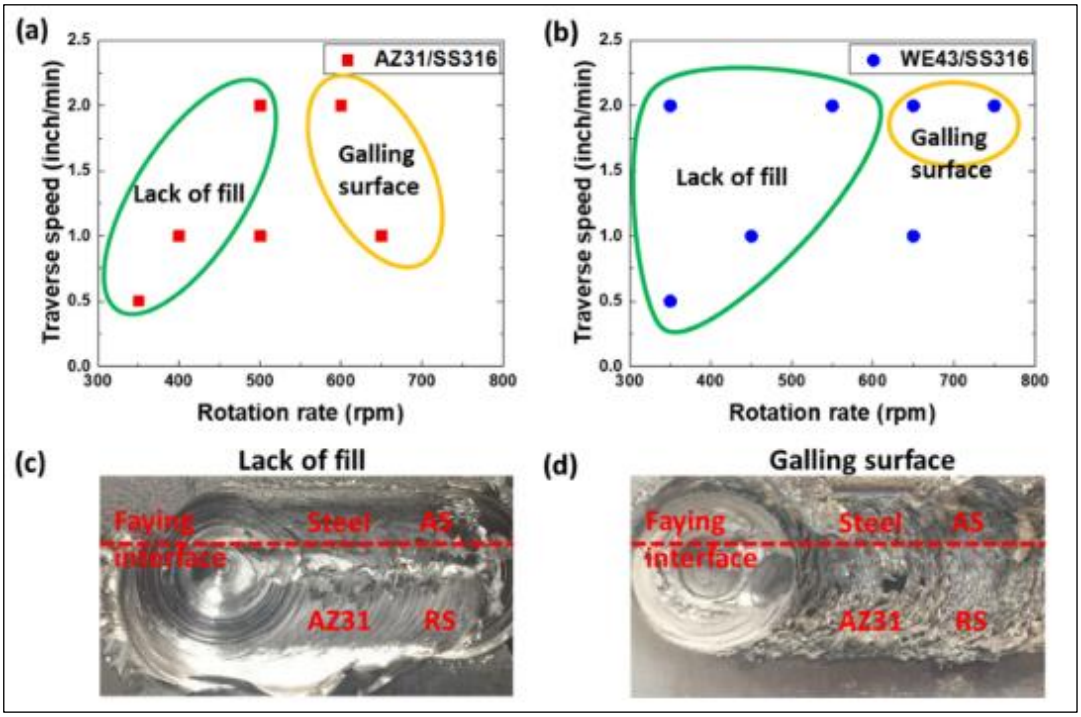

Figure 30: Relationship between FSW defects and welding parameters (a) AZ31 to SS316, (b) WE43 to SS316, (c) lack of fill and (d) galling surface.
Source: [57].

Figure 30 (a) and (b) present the rotation and travel speeds used for dissimilar butt welding of AZ31/SS316 and WE43/SS316, outlining the parameter window for defect-free joints. Two typical FSW defects were detected-lack of fill (Figure 30c) and galling surface (Figure 30d). The lack of fill was observed in magnesium near the faying interface under high travel speeds or low rotation speeds. The mg flow around the tool pin was impeded by inadequately plasticised steel. At high rotation rates, excessive heat generation led to a galling surface on the weld, caused by increased material sticking due to the elevated temperature [57].

Interfacial morphologies resembling flowers have been displayed using steel fragments and flashes. The remaining long flashes, measured in millimetres, created nail-effect bonding mechanisms as the travel speed increased, and the scraps dropped and caused damage. At the interface on the stainless-steel side, a sawtooth structure at the micron scale developed. Magnesium was used to fill the teeth, creating a Zipper effect enhances bond strength. The three bonding mechanisms are the metallurgical bonding effect by mutual diffusion, the zipper effect by the saw teeth, and the nail effect by the long steel flashes. Reduction in joint strength at high travel speeds (300 m/min) could be caused by two factors: the extended flashes' crashes could lessen the nail effect, and the decreased friction heat could weaken the metallurgical joint formation [50]. It was found that less material softens at high v because less heat is generated, resulting in thin flashes. Peeling off the flashes creates a macro-interlocked structure that results in a nail effect that strengthens the joining. Another notable feature resembling a saw-tooth pattern appeared, caused by the combined cutting and frictional action. Micro-interlocks at the weld joint may have formed as a result of the stirring force extruding magnesium into saw teeth. The zipper effect was facilitated by this interlocking. It has been discovered that the extended flashes that produce the nail effect saw tooth due to the zipper effect are responsible to enhance joint strength at higher traverse speeds. The study examined intermetallic compound formation at the AZ31/AZ61 joint interface and the effect of Al content on joint strength. Results showed that higher aluminum content in magnesium improves joint strength [60].

Zn–Mg solidification phases at the joint interface and hook-like features along the Mg/steel boundary serve as stress concentrators, reducing the fatigue resistance of FSW joints. To minimize porosity effects from solidification, fatigue studies of Mg/steel welds should be carried out with uncoated steel [26].

VIII. OBSERVATIONS

(1) The experimental findings and literature evidence on Mg-steel friction stir welding demonstrate several significant behavioural trends. First, the rotational speed of the tool was found to strongly influence joint quality; insufficient rotation led to inadequate plasticization, while excessive rotation resulted in magnesium ignition and a consequential drop in joint strength. Similarly, weld travel speed exerted a dual effect: moderate welding speeds increased joint strength through enhanced mechanical interlocking phenomena, whereas very high speeds reduced heat input and deteriorated metallurgical bonding.

(2) Tool pin offset was identified as another critical parameter governing weld performance. A slight positive offset toward the magnesium side produced the highest tensile strength, whereas both excessive and negative offsets resulted in interfacial weakening through void formation and insufficient IMC development, respectively. Furthermore, steel fragment dispersion into the magnesium matrix during the stirring process contributed to localized reinforcement and improved load transfer.

(3) Microstructural analysis consistently revealed hook-like features at the interface, which acted as stress concentrators and reduced effective cross-sectional thickness. The formation of intermetallic compounds including Fe–Al and Mg–Zn—was observed to influence joint brittleness and fracture mode. In particular, zinc-coated steel enhanced metallurgical bonding by promoting eutectic layer formation, though the effectiveness diminished when excessive molten zinc was expelled during stirring.

(4) Hardness profiling across the weld cross-section showed peak hardness in the stir zone due to dynamic recrystallization and refined grain structure. Tensile fracture primarily occurred at or near the Mg–steel interface, attributable to the elastic modulus mismatch and IMC-induced embrittlement. Finally, hybrid assisted FSW techniques such as GTAW preheating demonstrated superior joint integrity, leading to improved tensile performance relative to conventional FSW.

IX. CONCLUSION AND SUMMARY

IX.1 CONCLUSION

This review examined the current understanding of dissimilar friction stir welding (FSW) between steel and magnesium alloys. Existing studies emphasize the influence of process parameters such as tool rotation, welding speed, and plunge depth on microstructure, thermal response, and mechanical performance. The inherent difficulty of joining these alloys arises from their contrasting physical and chemical properties, including melting temperature, thermal conductivity, and the formation of intermetallic compounds (IMCs). Nevertheless, research demonstrates that with optimized parameters, reliable steel–magnesium joints can be successfully produced. The key findings drawn from the literature highlight both the complexity and potential of this welding process, emphasizing the need for precise control over processing conditions to overcome material incompatibility and promote joint integrity.

Mechanical Properties - While Mg-to-steel joints may not achieve the same strength as similar-material FSW joints, proper parameter selection and post-weld treatments can enhance mechanical performance.

Tool Design & Process Optimization - Specialized tool designs can improve bonding efficiency. Additionally, using interlayers such as aluminum or zinc can enhance weldability by reducing IMC brittleness.

Formation of IMCs – Intermetallic compounds such as Fe-Al, and Fe-Mg can form at the interface, affecting joint strength. Controlling the thermal input can help reduce excessive intermetallic compound (IMC) formation.

Applications & Future Research – Optimized FSW of steel–magnesium alloys holds strong potential for manufacturing weight-efficient structures, particularly in automotive and aerospace applications. Future studies should focus on refining process parameters, exploring alternative tool materials, and investigating hybrid techniques to improve joint integrity.

Sound welds are achieved within a very narrow range of welding parameters.

IX.2 FUTURE SCOPE

Materials like magnesium and steel, which have large differences in melting points and no mutual solubility, are notoriously challenging to join using conventional welding techniques. Traditional methods such as laser and hybrid welding often result in defects when applied to these dissimilar materials. In contrast, friction stir welding (FSW) offers a promising solid-state alternative, reducing welding defects and enabling effective joining. This study examines the potential of FSW for joining magnesium to steel. Building on this, future research could focus on extending these methods to more advanced steel grades, including high-strength steels (HSS) and advanced high-strength steels (AHSS). Successfully welding magnesium to AHSS could significantly reduce the weight of automotive components while maintaining or even improving strength and stiffness. Although aluminum-AHSS joints are already being used in automotive applications, magnesium offers an even lighter alternative, presenting new opportunities for further weight reduction. Expanding FSW to handle the transition from softer to harder materials like magnesium to AHSS will require advances in tool technology. Specifically, there's a need for cost-effective, wear-resistant, and reliable tools with a longer lifespan—although some innovative tool designs are already addressing these challenges. Looking ahead, critical areas for further research include improving the weldability of magnesium-steel joints, optimizing welding parameters, understanding fracture and corrosion behavior, and enhancing fatigue resistance. Special attention should also be given to controlling the formation and morphology of intermetallic compounds (IMCs), which play a major role in joint quality. Ultimately, the increasing demand in engineering industries for lightweight yet strong materials will continue to drive the development of FSW techniques for joining dissimilar materials like magnesium and steel.

ABSTRACT

This paper proposes a PV-integrated wireless charging architecture for electric vehicles utilizing a modified Trans-Quasi Z-Source boost converter. The PV system is integrated with advanced power electronics for efficient energy conversion and management. It begins with photovoltaic cells generating voltage (V_{pv}) and current (I_{pv}), which are fed into the modified Trans-Quasi Z-Source boost converter. The converter employs PWM control to enhance the output voltage, which is then supplied to a high-frequency inverter. The inverter output is applied to an LC tank circuit to achieve resonance and efficient wireless power transfer. A high-frequency isolation transformer is used to ensure safety and improved performance in subsequent stages. The system incorporates an interleaved PWM rectifier to convert AC back to DC for charging the EV battery. The overall operation is optimized using an Artificial Neural Network (ANN)-based Maximum Power Point Tracking (MPPT) algorithm to maximize energy extraction from the PV system. A Proportional–Integral (PI) controller regulates the output voltage (V_{act}) to track the reference voltage (Vref), thereby enhancing system stability and efficiency. Finally, the project is implemented using MATLAB/Simulink 2024[a].

I. INTRODUCTION

The increasing global energy demand and rapid depletion of fossil fuel resources have accelerated the transition toward renewable energy-based power systems and electric vehicles (EVs). Conventional fossil-fuel-driven transportation contributes significantly to greenhouse gas emissions and environmental pollution, which necessitates the development of sustainable and eco-friendly energy solutions [1], [2]. Among various renewable energy sources, photovoltaic (PV) systems have gained considerable attention due to their clean energy generation, scalability, and wide availability. PV technology converts solar energy directly into electrical energy through the photovoltaic effect, making it a promising candidate for future sustainable charging infrastructures [3]. Simultaneously, the rapid growth of electric vehicles has created a strong demand for efficient, reliable, and user-friendly charging technologies. Traditional conductive charging systems require physical connectors, which may lead to cable wear, safety hazards, maintenance issues, and inconvenience in adverse environmental conditions [4]. Wireless Power Transfer (WPT) technology has emerged as an advanced alternative that enables contactless energy transmission through electromagnetic induction and resonant coupling [5]. This technology improves user convenience, electrical safety, and system automation while eliminating mechanical connection losses associated with wired charging systems [6]. In recent years, wireless charging systems have been widely applied in consumer electronics, electric vehicles, and portable devices due to their flexibility and ease of operation. Inductive and resonant wireless charging techniques operate based on the principle of electromagnetic coupling between transmitting and receiving coils, where alternating current in the primary coil generates a magnetic field that induces voltage in the secondary coil [7], [8]. The efficiency of wireless power transfer mainly depends on coil alignment, operating frequency, air gap, and compensation network design. Although WPT systems offer significant advantages, their efficiency is often lower than wired charging systems due to coupling losses and multiple power conversion stages [9], [10].

To enhance the sustainability of EV charging infrastructure, the integration of renewable energy sources, particularly PV systems, with wireless charging architecture has become an important research direction [11]. PV-integrated wireless charging systems enable direct utilization of solar energy for EV charging, thereby reducing grid dependency, operational costs, and carbon emissions [12]. However, the intermittent nature of solar irradiance and fluctuating PV output voltage pose significant challenges in maintaining stable power transfer and efficient energy conversion. Therefore, advanced power electronic converters and intelligent control techniques are essential to ensure reliable operation of PV-fed wireless charging systems [13], [14]. Power electronic converters play a crucial role in regulating voltage, improving power quality, and enhancing overall system efficiency in renewable energy-based charging applications. Conventional DC–DC converters used in PV systems often suffer from limited voltage gain, increased switching losses, and complex multi-stage conversion structures. To overcome these limitations, impedance-source converter topologies such as Z-source, quasi-Z-source, and trans quasi-Z-source converters have been introduced due to their inherent buck–boost capability, shoot-through immunity, and improved reliability [15–17]. These converters provide higher voltage gain and better dynamic performance compared to traditional boost converters, making them highly suitable for PV-integrated EV charging applications. Furthermore, intelligent energy management techniques such as Artificial Neural Network (ANN)-based Maximum Power Point Tracking (MPPT) algorithms are widely employed to extract maximum power from PV systems under varying environmental conditions.

In addition, closed-loop control strategies such as Proportional–Integral (PI) controllers are used to maintain stable output voltage and improve system dynamic response during fluctuating solar irradiance and load variations [18], [19]. Although several research works have focused on wireless EV charging and PV-based charging systems independently, limited studies have addressed the integration of PV-fed wireless power transfer systems with high-gain modified Trans Quasi Z-Source boost converters and intelligent MPPT control. Existing systems mainly rely on grid-powered charging or conventional converter topologies, which result in increased conversion losses, reduced efficiency, and complex system architecture [20]. Therefore, there is a need for a high-efficiency, stable, and renewable-energy-driven wireless charging architecture specifically designed for electric vehicle applications. To address these challenges, this paper proposes a PV integrated wireless charging architecture for electric vehicles utilizing a Modified Trans Quasi Z-Source Boost Converter. The proposed system consists of a PV array, modified Trans Quasi Z-Source boost converter, high-frequency inverter, resonant LC tank circuit, isolation transformer, interleaved rectifier, ANN-based MPPT, and PI controller to achieve efficient wireless power transfer and stable EV battery charging. The integration of a high-gain converter and intelligent control enhances voltage boosting capability, system stability, and overall energy conversion efficiency. The main objectives of this paper are:

1) To design a PV-integrated wireless charging architecture for electric vehicles,
2) To develop a Modified Trans Quasi Z-Source Boost Converter for high-gain voltage conversion,
3) To improve wireless power transfer efficiency using a resonant LC tank and high-frequency inverter,
4) To maximize solar energy extraction using ANN-based MPPT control, and

To ensure stable output voltage regulation and enhanced system performance using a PI controller.

II. PROPOSED MODELLING

Figure 1 shows the PV-integrated wireless charging system for EVs using a Modified Trans Quasi Z-Source Boost Converter. When PV cells first generate voltage (Vpv) and current (Ipv), the improved boost converter uses PWM to process the data and increase the output voltage. The PWM signals are routed to an LC tank circuit for effective energy transfer via resonance after this output is fed into a high-frequency inverter. To guarantee performance and safety, a high-frequency isolation transformer is employed. In order to convert the AC back to DC for EV battery charging, the system incorporates an interleaved PWM rectifier.

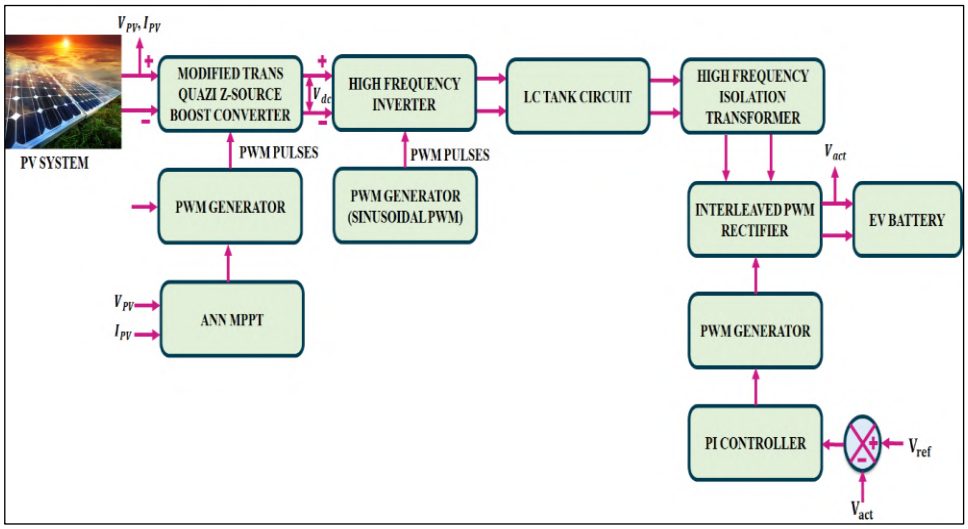

Figure 1: Block diagram of PV integrated wireless charging.
Source: Authors, (2026).

An artificial neural network is used for MPPT in order to maximize energy harvesting from the PV system. By keeping the output voltage (Vact) steady and in line with the reference voltage (Vref), the proportional-integral (PI) controller improves the overall system performance and efficiency. Finally, the entire system is validated through a MATLAB simulation 2024a.

II.1 MODELLING OF PV SYSTEM

Figure 2 displays the basic solar cell equivalent model, which uses the p-n junction feature to directly transfer solar energy to electrical energy. The output energy yield is increased by properly combining several PV cells. The simple PV equivalent circuit consists of current source, diode as well as series or parallel resistance.

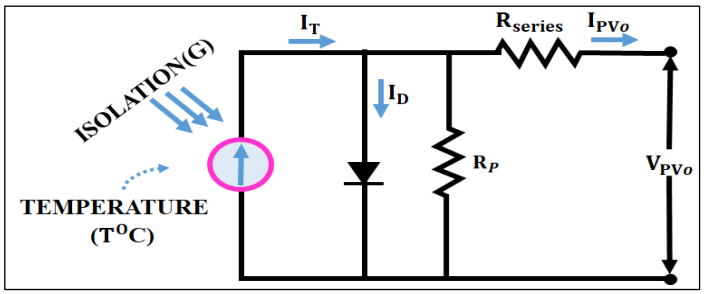

Figure 2: Equivalent diagram of PV system.
Source: Authors, (2026).

The mathematical expression for output current is,

$$I_{PV0} = I_T - I_{sat} \times \left[e^{\frac{Q(V_{PV0}+I_{PV0}\times R_{series})}{\eta K_B T_P}} \right] \quad (1)$$

Here, V_{PV0} specifies output of PV module, I_{PV0} indicates output of PV current, I_{sat} denotes reverse saturation diode, I_T is the photon current, R_{series} refers resistance in series, T_P is the operating panel temperature, Q is the charge of electron and K_B shows boltzman constant correspondingly. Owing to the varying environmental changing conditions, the PV module requires converter for boosting up the output voltage of PV, thus Modified converter is developed in this work for achieving higher output level needed for the DC bus/ battery.

II.2 MODIFIED TRANS QUASI Z-SOURCE BOOST CONVERTER

An innovative power converter that increases voltage boost capabilities while offering increased efficiency and dependability is the modified Trans Quasi Z-Source Boost Converter (MTQZBC). The quasi-Z-source topology that underpins this converter combines the advantages of Z-source networks and conventional boost converters. The first step involves applying the input voltage to the converter, which uses a special quasi-Z-source network made up of capacitors and inductors to enhance the input voltage.

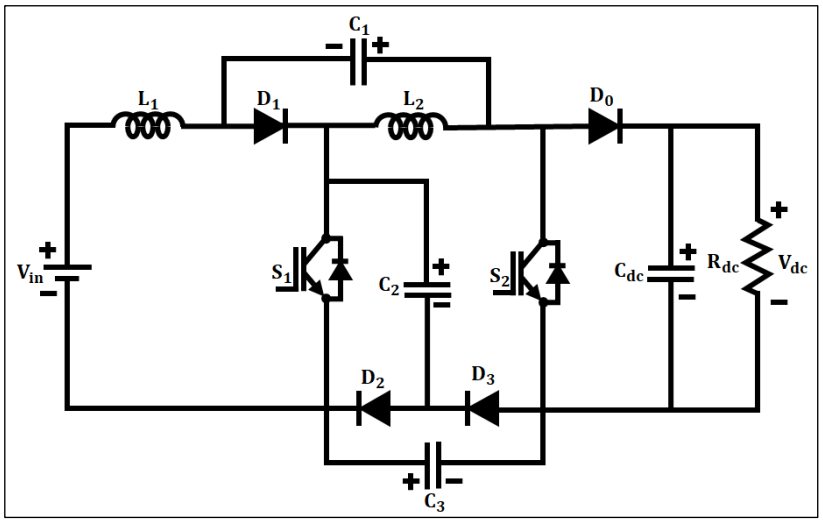

Figure 3: Modified Trans Quasi Z-Source Boost Converter.
Source: Authors, (2026).

The inductors store energy while the capacitors charge during the switch's ON phase. The inductors' stored energy is released when the switch is turned off, and it combines with the input voltage to increase the output voltage. By improving the impedance network, the improved topology optimizes this process, reducing the impact of voltage spikes and strengthening the control strategy as a whole. Greater reliability results from this design's ability to facilitate smoother transitions and lessen component stress. Additionally, the converter can effectively handle changing load circumstances and input voltages by modifying the duty cycle and applying sophisticated control techniques, which makes it appropriate for demanding power systems and renewable energy applications.

Mode 1: Both the switches S_1 and S_2 are kept in ON state during mode 1 operation. Due to this reason diodes D_0, D_1 and D_2 are turned OFF, while D_3 remians ON and conducts. The inductors L_1 , L_2 and capacitor C_3 store energy to the maximum possible level, Whereas, C_1, C_2 and C_{dc} discharge. The voltage and current across the inductor and capacitors is given as,

$$V_{L1} = V_{in} + V_{C1} + V_{C3} \quad (2)$$

$$V_{L2} = V_{C2} = V_{C3} \quad (3)$$

$$i_{C1} = -i_{L1} \quad (4)$$

$$i_{C2} = -(i_{L1} + i_{L2} + i'_{C3}) \quad (5)$$

$$i_{Cdc} = -i_{dc} \quad (6)$$

Where, i'_{C3} denotes the average current passing via capacitor C_3.

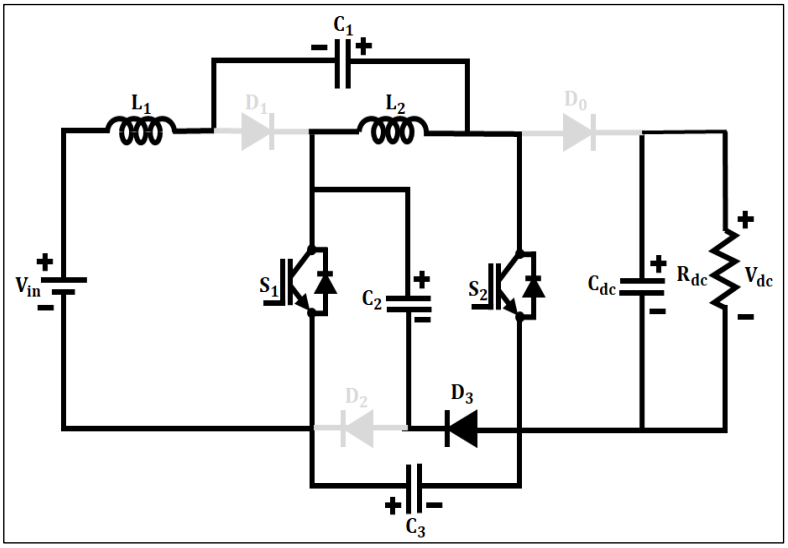

Figure 4: Mode 1 Operation.
Source: Authors, (2026).

Mode 2: Both the switches S_1 and S_2 are kept in OFF state during mode 2 operation making the diode D_3 reverse biased and non-conducting. Meanwhile, the diodes D_0, D_1 and D_2 is turned ON and starts conducting. The inductor L_1, L_2 and capacitor C_3 releases while, C_1, C_2 and C_{dc} stores. Similarly, voltage and current across the inductor and capacitors is given as,

$$V_{L1} = V_{in} - V_{C2} = V_{in} + V_{C1} + V_{C3} - V_{dc} \quad (7)$$

$$V_{L2} = -V_{C1} = V_{C2} + V_{C3} - V_{dc} \quad (8)$$

$$i_{C1} = i_{L2} - i_{dc} - i'_{Cdc} \quad (9)$$

$$i_{C2} = i_{L1} - i_{dc} - i'_{Cdc} \quad (10)$$

$$i_{C3} = -(i_{dc} + i'_{Cdc}) \quad (11)$$

Where, i'_{Cdc} indicates average current passing via the capacitor C_{dc} .

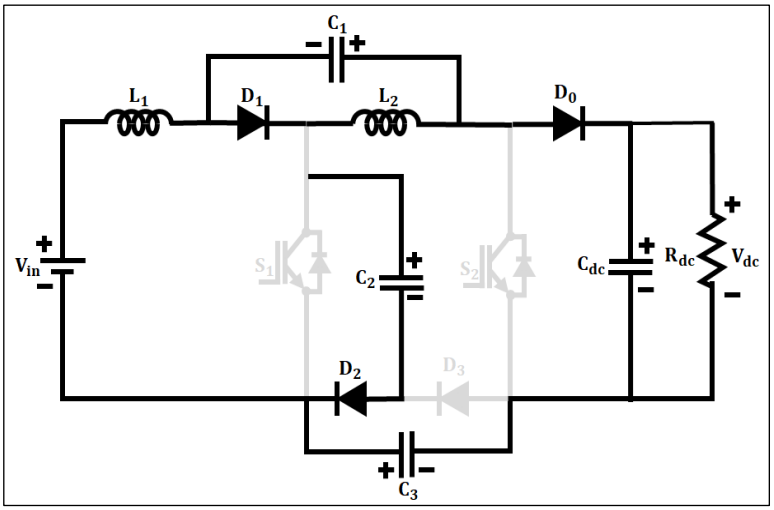

Figure 5: Mode 2 Operation.

II.3 HIGH FREQUENCY INVERTER

A high-frequency inverter is a device that converts DC into high-frequency AC using advanced switching techniques. The process begins with a DC power source, such as a battery or solar panel, supplying voltage to the inverter. The inverter employs high-speed switching devices, typically MOSFETs or IGBTs, to rapidly turn the DC input on and off. This switching action generates a pulsed DC signal, which is then shaped into a high-frequency waveform, often in the range of several kilohertz to megahertz. The inverter typically includes a resonant circuit or transformer to help generate a stable AC output with the desired frequency and voltage levels. Additionally, by reducing the losses connected to conventional low-frequency inverters, high-frequency operation increases the power conversion process' efficiency. Feedback control systems keep an eye on the output waveform and dynamically modify the duty cycle and switching frequency to guarantee peak performance. Under various load circumstances, this regulation aids in maintaining the intended output characteristics. High-frequency inverters are so frequently utilized in applications where performance, size, and efficiency are crucial, such as electric car drives, renewable energy systems, and uninterruptible power supplies (UPS).

II.4 LC TANK CIRCUIT

An inductor (L) and a capacitor (C) coupled in parallel or series create an oscillating resonant frequency in an LC tank circuit, sometimes referred to as a resonant circuit. When the circuit is energized either by introducing a DC voltage or by giving the capacitor an initial charge the operation starts. Through the inductor, the capacitor begins to charge, storing energy in its electric field during the process. When the capacitor is fully charged, it starts to discharge through the inductor, which creates a magnetic field and causes current to flow. The values of L and C determine the circuit's natural resonant frequency, which is where oscillations are produced by the interaction between the inductor and capacitor. A sinusoidal waveform results from the energy oscillating between the inductor and capacitor. The circuit's quality factor (Q), which measures how underdamped it is, determines how long the oscillation can last and how much energy the circuit can exchange. Longer oscillation durations are produced by higher Q values, whereas greater energy loss usually as a result of circuit resistance is indicated by lower Q values. Because they can selectively resonate at particular frequencies, LC tank circuits are frequently employed in devices like radio transmitters, receivers, and filters, allowing for effective signal processing and transmission.

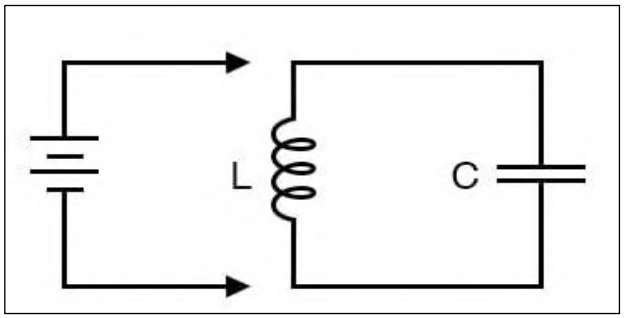

Figure 6: LC Tank Circuit.
Source: Authors, (2026).

II.5 HIGH FREQUENCY ISOLATION TRANSFORMER

An isolation transformer is a transformer designed to provide electrical isolation between two circuits while transferring electricity between them. Its main function is to isolate input and output power, increasing safety and reducing the risk of electric shock. The working process of an isolation transformer begins with the supply of alternating current (AC) to the primary winding. This winding has a large number of iron turns wrapped around a magnetic core that facilitates the transmission of energy. When AC voltage is applied to the first winding, a magnetic field is created, which induces voltage in the second winding, which is also wrapped around a magnetic core. The primary and secondary windings are electrically isolated from each other, meaning there is no electrical connection between them. This isolation is important for safety applications such as medical equipment or sensitive electronic devices because it prevents noise and interference from being transferred from one environment to another. The transformation of an isolation transformer is determined by the number of turns in the primary and secondary windings. For example, if the primary winding has more turns than the secondary winding, the transformer will reduce the voltage, while the opposite configuration will increase the voltage.

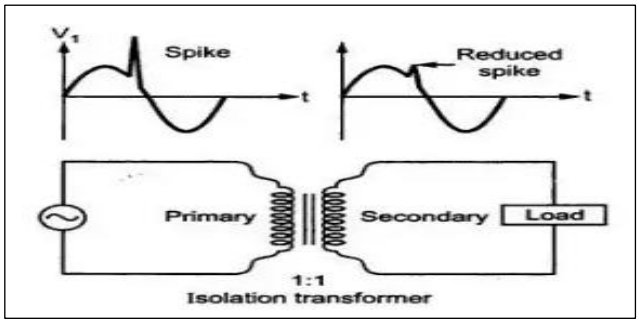

Figure 7: Isolation Transformer.
Source: Authors, (2026).

However, the main purpose of the transformer is not to convert electricity, but to provide a safe, isolated environment for the electronic components. One of the main benefits of using an isolator is that it can help prevent ground faults and reduce electromagnetic interference (EMI). By isolating connected equipment from the power supply, you reduce the risk of electric shock to users and protect equipment from electric shock and fire electricity. It can also help balance the situation at different levels and improve the overall results of an electrical installation.

II.6 ANN MPPT

The ANN-based MPPT controller is employed to extract maximum power from the PV array under varying irradiance and temperature conditions. The neural network architecture consists of an input layer receiving PV voltage (Vpv) and PV current (Ipv), a hidden layer with nonlinear activation functions (tansig), and an output layer that generates the optimal duty cycle (D) for the Modified Trans Quasi Z-Source Boost Converter. The ANN is trained using supervised learning based on PV characteristics obtained under different environmental conditions to model the nonlinear relationship between input variables and the maximum power point. During real-time operation, the trained ANN processes the sensed PV parameters and dynamically updates the duty cycle through a PWM controller, enabling rapid convergence to the maximum power point. This approach significantly reduces steady-state oscillations, improves tracking accuracy, and enhances dynamic response compared to conventional MPPT techniques. Consequently, the ANN-based control improves energy extraction efficiency, ensures stable converter operation, and enhances the overall performance of the PV-integrated wireless power transfer system for EV charging applications. A typical ANN MPPT used in this type of system consists of:

- Input Layer: Vpv, Ipv (and optionally irradiance, temperature)
- Hidden Layer(s): Nonlinear processing neurons (sigmoid/tansig)
- Output Layer: Duty cycle (D) or reference voltage (Vref)
- Mathematically:

$$D = f(V_{pv}, I_{pv}, G, T) \tag{12}$$

Here, D = Duty cycle generated by ANN, G = Irradiance and T = Temperature

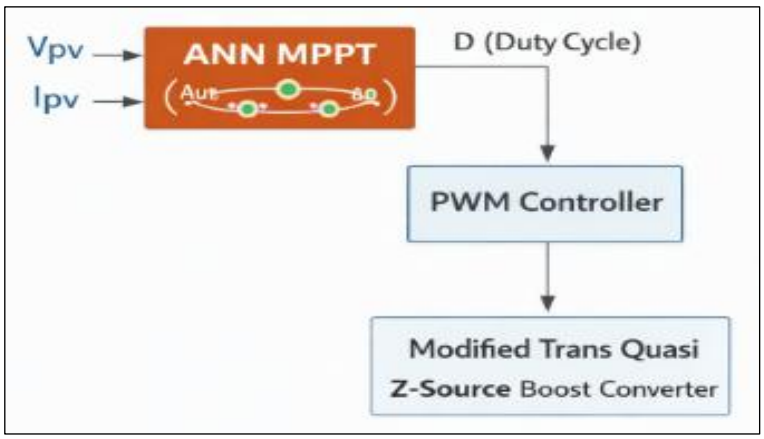

Figure 8: ANN MPPT.
Source: Authors, (2026).

The ANN MPPT is shown in Figure 8, where the photovoltaic (PV) array output parameters, namely PV voltage (Vpv) and PV current (Ipv), are used as input signals to the Artificial Neural Network (ANN) based MPPT controller. The ANN processes these real-time inputs and predicts the optimal duty cycle (D) corresponding to the maximum power point of the PV system under varying irradiance and temperature conditions. The generated duty cycle is then fed to the PWM controller, which produces appropriate switching pulses for the power converter. These gate pulses control the Modified Trans Quasi Z-Source Boost Converter, thereby adjusting the operating point of the PV array to ensure maximum power extraction and improved energy conversion efficiency. This intelligent control structure enhances tracking speed, reduces steady-state oscillations, and provides stable operation of the PV-fed wireless charging system.

III. RESULTS AND DISCUSSION

Figure 9 presents the overall MATLAB/Simulink model of the proposed PV-integrated wireless EV charging system. The model consists of a PV array, ANN-based MPPT controller, Modified Trans Quasi Z-Source Boost Converter, high-frequency inverter, resonant LC tank circuit, isolation transformer, synchronous rectifier, and PI-controlled output stage. The PV array generates voltage and current signals, which are processed by the ANN MPPT to produce an optimal duty cycle for the converter. The boosted DC output is then converted into high-frequency AC through the inverter and transferred wirelessly via the resonant LC tank and transformer. Finally, the rectifier and PI controller ensure stable DC output for EV battery charging, demonstrating coordinated operation of all subsystems in the proposed architecture.

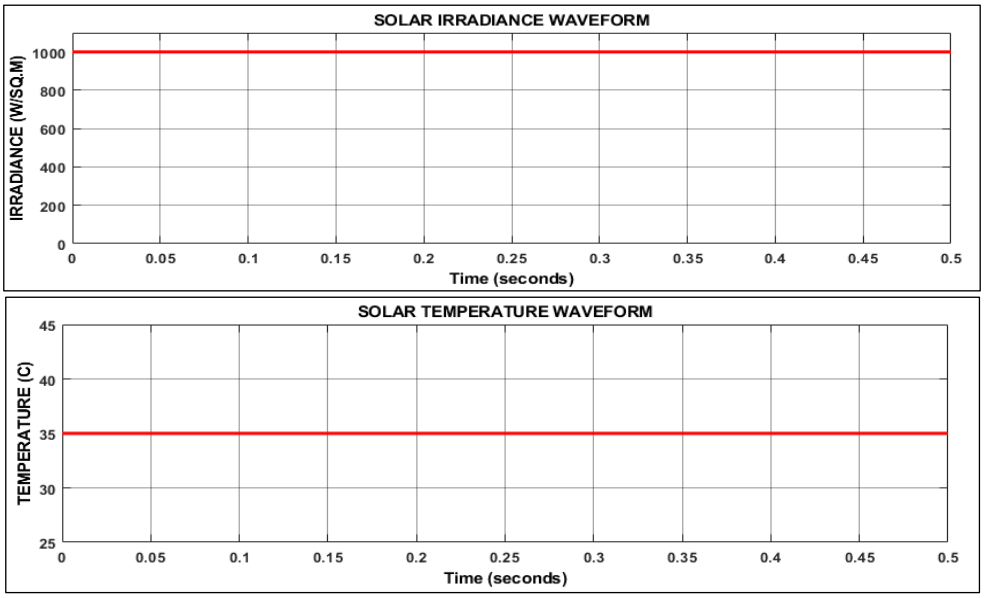
CONSTANT TEMPERATURE AND CONSTANT INTENSITY



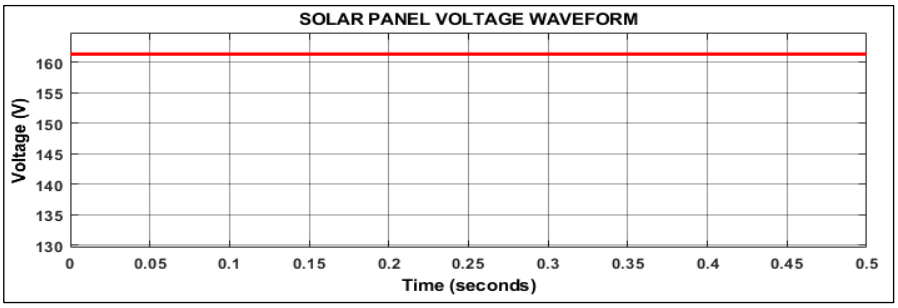


Figure 10: Solar Temperature and Intensity Waveform.
Source: Authors, (2026).

Figure 10 shows the solar temperature and irradiance waveforms under constant environmental conditions. The upper graph represents the solar temperature, consistently maintaining a level of 40°C across the time span of 0 to 0.7 seconds, indicating stability in temperature measurements. The lower graph depicts solar intensity, measured in W/m², but shows a flat line, suggesting no variation or activity during the observed interval. Together, these waveforms provide insights into the solar conditions, highlighting the stable temperature and lack of intensity changes.

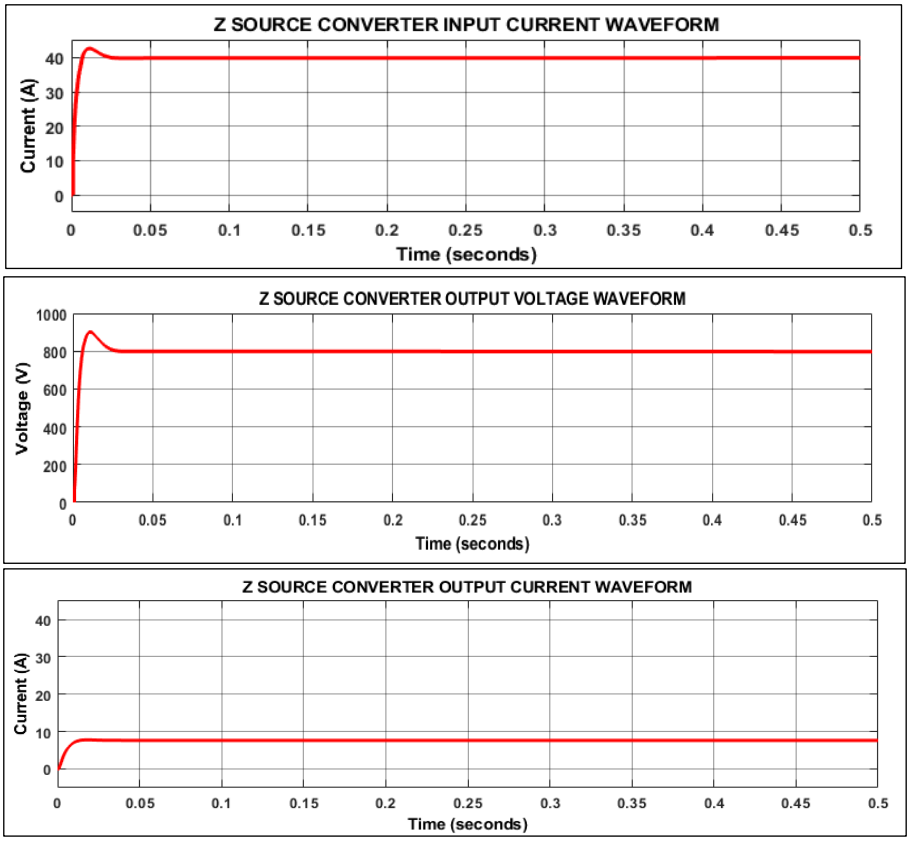

Figure 11: Solar Panel Voltage Waveform and Z Source Converter Input and Output Waveforms.
Source: Authors, (2026).

Figure 11 presents the PV voltage and converter input–output waveforms demonstrating stable system operation. The upper left graph shows the solar panel voltage, which remains steady at approximately 50 volts over the observed time of 0 to 0.7 seconds, indicating a consistent power output from the solar panel. The upper right graph depicts the input current to the Z-source converter, displaying a stable value of around 30 amps, suggesting efficient energy transfer. The lower two graphs illustrate the converter's output. The output current waveform shows a brief spike before stabilizing, while the output voltage waveform consistently holds at 150 volts. Together, these waveforms reflect the system’s efficiency in converting and maintaining steady energy flow, essential for reliable solar energy applications.

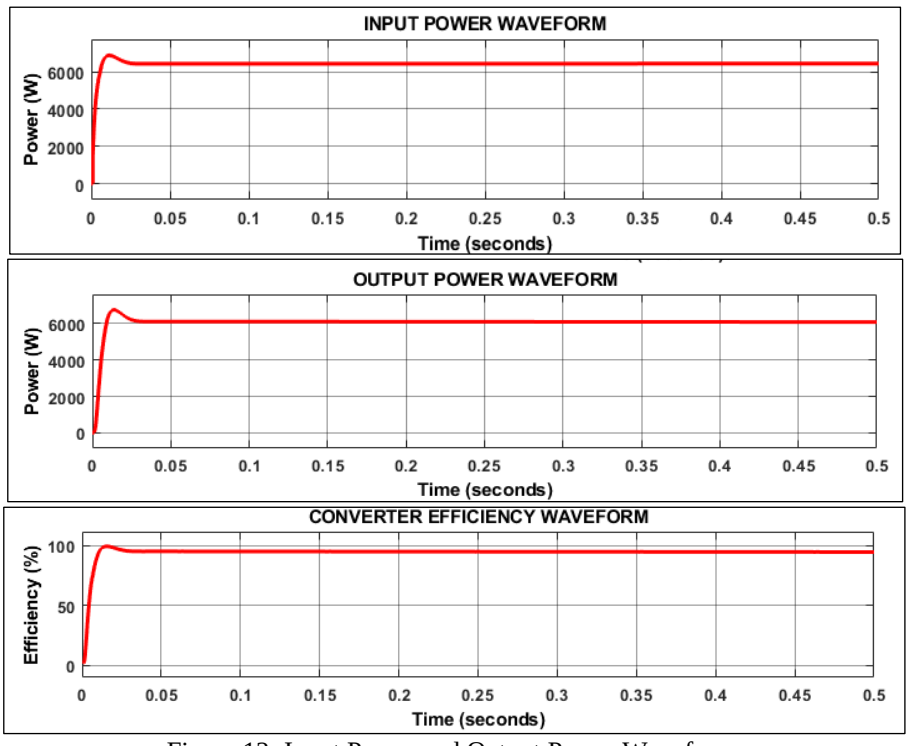

Figure 12: Input Power and Output Power Waveform.
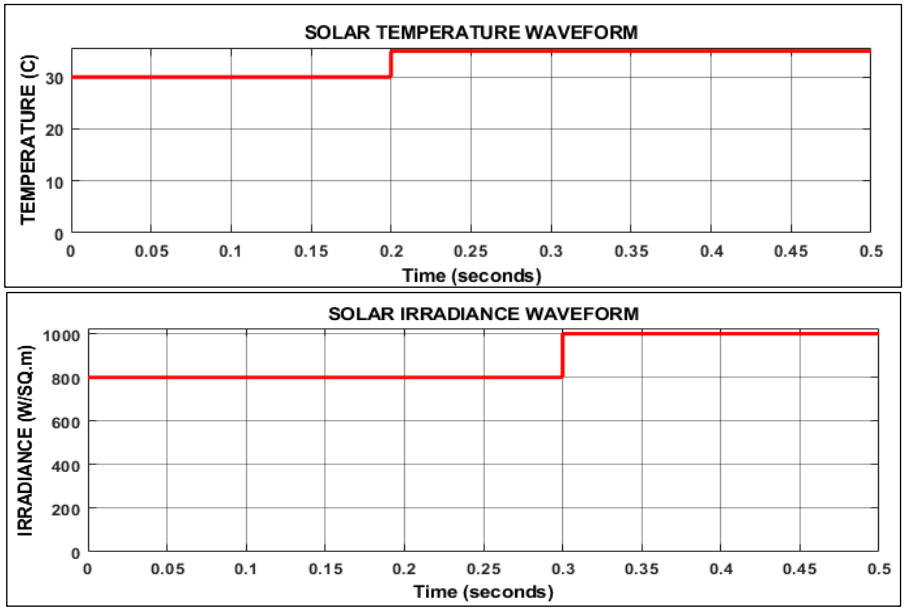
Source: Authors, (2026).

Figure 12 shows the input and output power waveforms, indicating efficient power conversion and stable energy transfer. The input power remains steady at around 6000 watts throughout the time duration of 0 to 0.7 seconds, indicating a stable energy supply to the system. Conversely, the output power displays a slight dip but maintains a relatively constant level, suggesting efficient energy conversion. Together, these waveforms illustrate the system's effectiveness in processing and delivering energy consistently.

VARYING TEMPERATURE AND VARYING INTENSITY



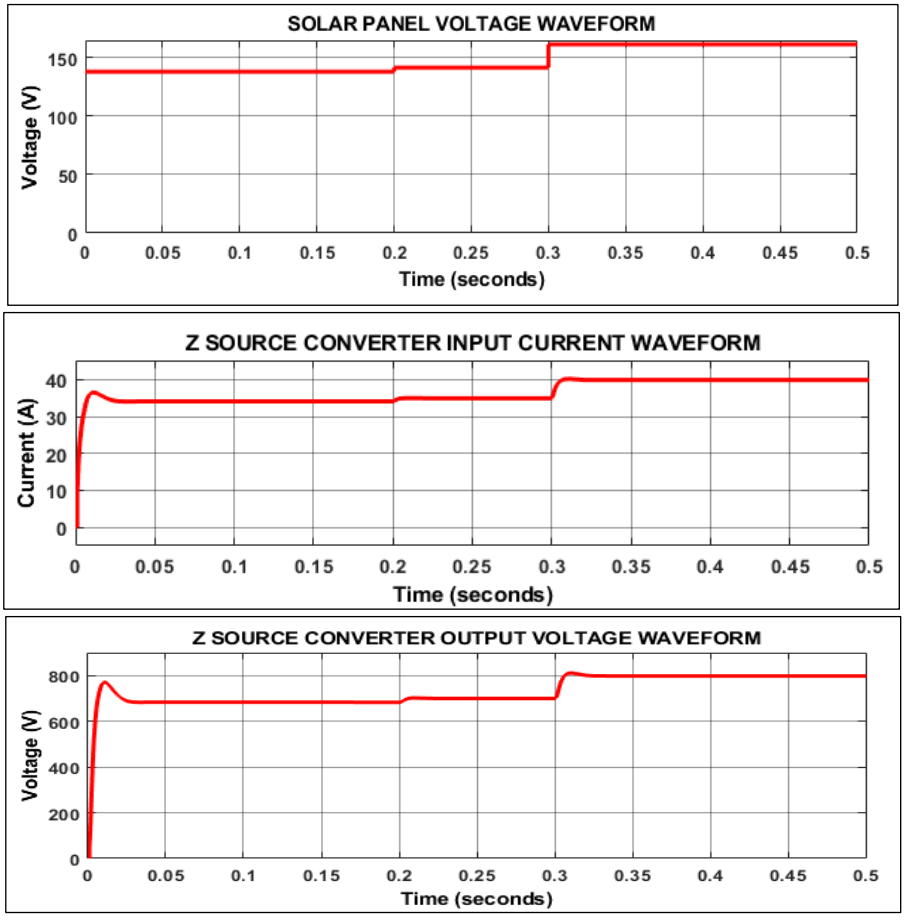


Figure 13: Solar Temperature and Intensity Waveform.
Source: Authors, (2026).

The figure 13 illustrates the waveforms: solar temperature and solar intensity. The upper graph shows the solar temperature, which remains steady at approximately 40°C across the time span of 0 to 0.7 seconds, indicating consistent thermal conditions. The lower graph represents solar intensity, holding stable at around 800 W/m² during the same period. This stability in both temperature and intensity suggests that the solar energy system operates under constant environmental conditions, crucial for optimal performance and energy generation.

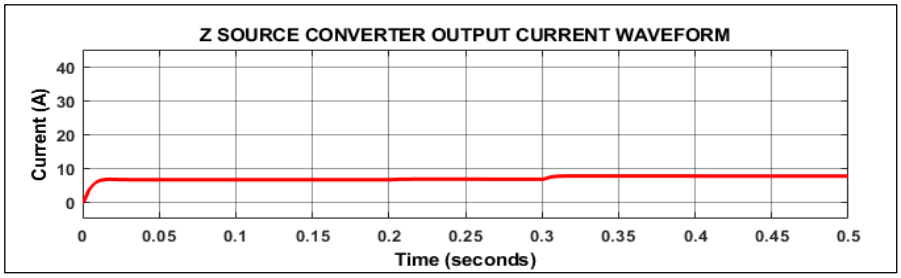

Figure 14: Solar Panel Voltage Waveform and Z Source Converter Input and Output Waveforms.
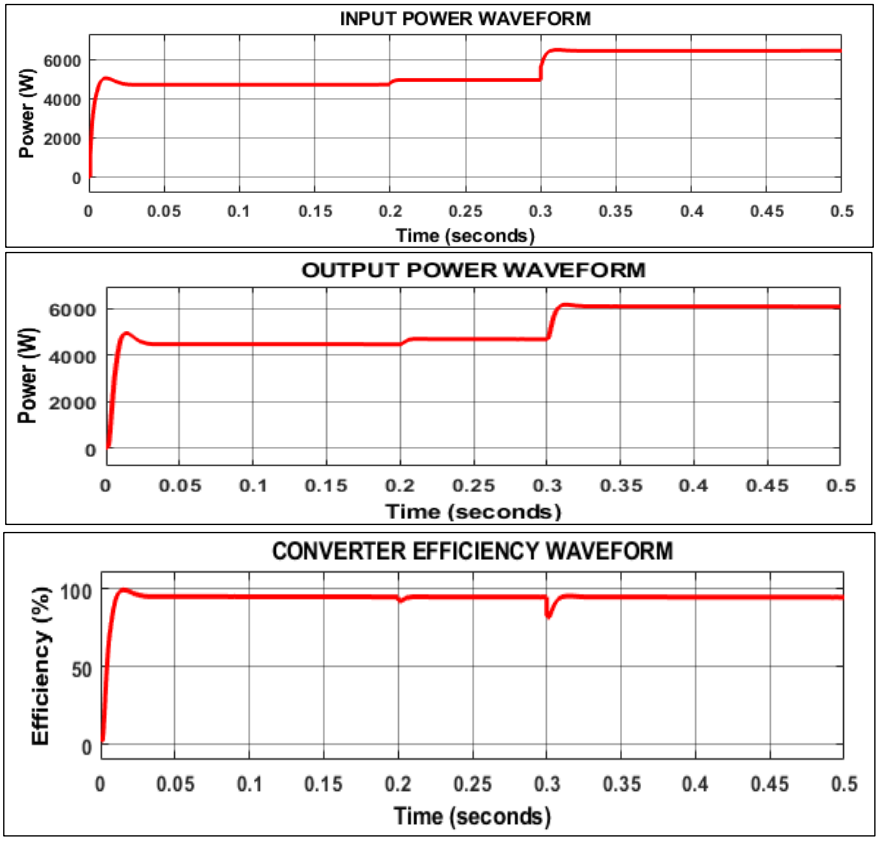
Source: Authors, (2026).

The figure 14 displays four waveforms related to a solar energy system, highlighting the performance of solar panel output and a Z-source converter. The upper section features the solar panel voltage waveform, which remains stable at approximately 48 volts throughout the 0 to 0.7 seconds time frame. Accompanying this, the Z-source converter input current waveform shows a consistent current of about 50 amps, indicating a steady flow of energy into the converter. Below, the Z-source converter output voltage waveform also maintains a stable level, suggesting efficient energy transformation. Finally, the output current waveform reflects a steady current, demonstrating the converter's effectiveness in delivering power. Overall, these waveforms illustrate the reliability and efficiency of the solar energy system in converting and managing electrical output.



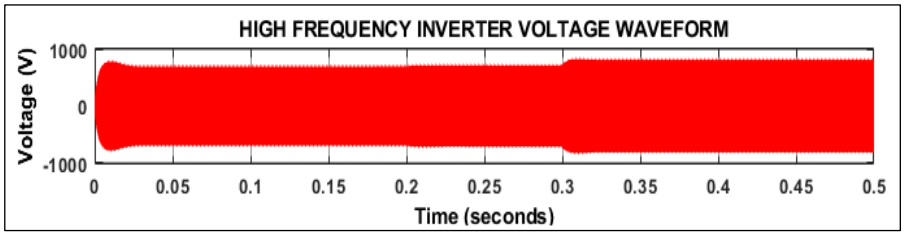


Figure 15: Input and Output Power Waveform.
Source: Authors, (2026).

Figure 15 shows the input and output power waveforms, where both remain approximately at 6000 W, confirming high efficiency and stable power transfer. The input power waveform, shown on the left, remains consistently around 6000 watts throughout the 0 to 0.7 seconds duration, indicating a stable energy supply. Conversely, the output power waveform on the right also stabilizes at approximately 6000 watts, reflecting effective energy conversion. This consistency in both input and output power demonstrates the system's reliability and efficiency in harnessing and delivering energy from solar sources.

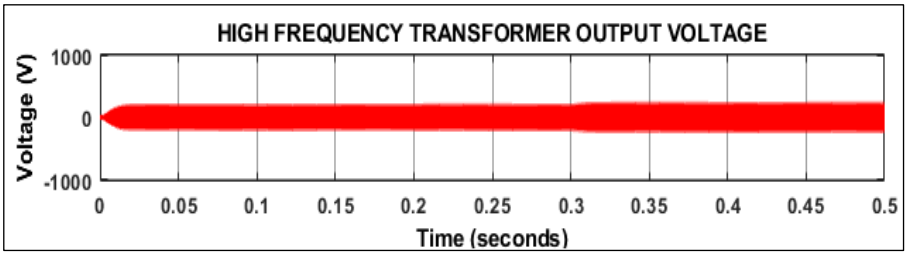

Figure 16: High Frequency Inverter and Transformer Output Voltage Waveform.
Source: Authors, (2026).

Figure 16 shows the high-frequency inverter voltage and transformer output voltage, validating effective DC–AC conversion and voltage transformation. The inverter voltage waveform fluctuates between approximately -500 volts and +500 volts, indicating the inverter's role in converting direct current to alternating current. In contrast, the transformer output voltage remains stable around -200 volts, demonstrating effective voltage transformation. These waveforms highlight the operational characteristics of the inverter and transformer, showcasing their importance in managing electrical energy in high-frequency applications.

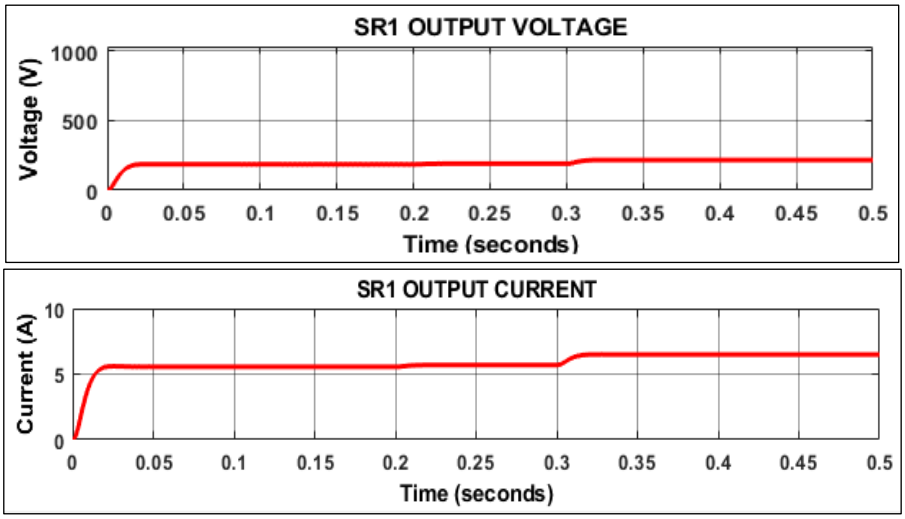

Figure 17: Synchronous Rectifier 1 Output Voltage and Current Waveform.
Source: Authors, (2026).

The figure 17 displays the output characteristics of a synchronous rectifier, featuring two key waveforms: voltage on the left and current on the right. The voltage waveform stabilizes around 200 volts after a brief initial fluctuation, indicating consistent performance in converting AC to DC. Meanwhile, the current waveform reaches approximately 6 amperes, demonstrating effective current flow through the rectifier. Together, these waveforms reflect the synchronous rectifier’s efficiency in providing stable voltage and current, essential for reliable power delivery in electronic circuits.

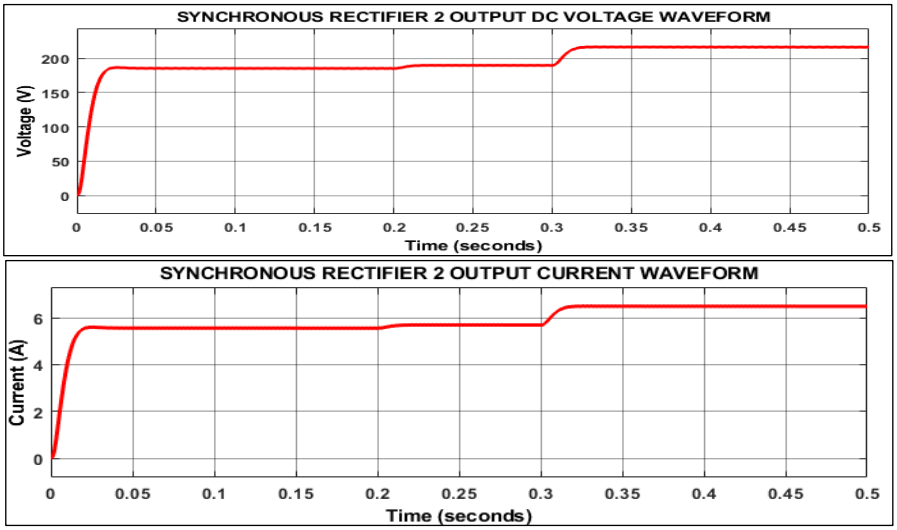

Figure 18: Synchronous Rectifier 2 Output Dc Voltage and Output Current Waveform.
Source: Authors, (2026).

The figure 18 illustrates the output performance of a second synchronous rectifier, showcasing voltage on the left and current on the right. The voltage waveform stabilizes around 200 volts, indicating reliable DC output after a brief transient period. On the right, the current waveform reaches a steady state of approximately 6 amperes, demonstrating effective current delivery. These waveforms collectively highlight the synchronous rectifier's functionality in maintaining consistent voltage and current levels, crucial for efficient energy conversion in various electronic applications.

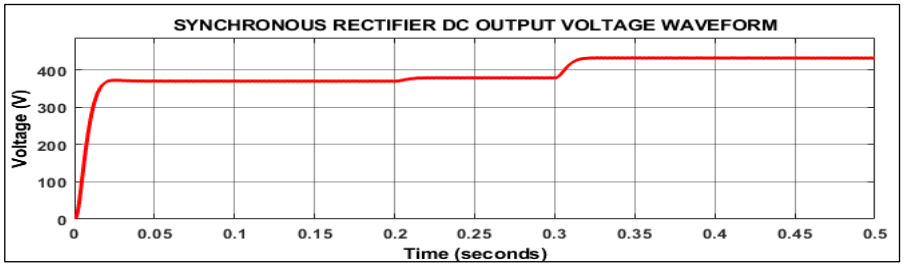

Figure 19: Synchronous Rectifier Dc Output Voltage Waveform.
Source: Authors, (2026).

The figure 19 displays the voltage output of a synchronous rectifier over a time span of 0.7 seconds. Initially, the voltage increases rapidly, reaching a peak around 500 volts. After a brief transient phase, the voltage stabilizes near 400 volts, indicating a steady DC output. This stability is crucial for applications requiring consistent voltage levels. The waveform illustrates the rectifier's effectiveness in converting AC to DC, ensuring reliable performance in various electronic systems and enhancing overall energy efficiency.

Table 1: Comparison of WPT systems.

S. No	Comparison Factor	Conventional Inductive WPT	Resonant WPT (LCC/LC)	Proposed PV-Integrated WPT
1	Power Transfer Efficiency	85%	91%	98.96%
2	Output Power Capability	3 kW	5 kW	6 kW

Source: Authors, (2026).

The simulation results presented in Figures. 9–19 clearly justify all the stated objectives of the paper. The overall system model and continuous stage-wise waveforms confirm the successful design of a PV-integrated wireless charging architecture, where energy flows effectively from the PV source to the EV load. The converter results show that the PV voltage of about 48–50 V is boosted to nearly 150 V, validating the high-gain performance of the Modified Trans Quasi Z-Source Boost Converter. The high-frequency inverter and transformer voltage waveforms, along with stable rectifier outputs, demonstrate efficient resonant wireless power transfer using the LC tank circuit. The nearly constant input power (6000 W) under both constant and varying irradiance conditions indicates that the ANN-based MPPT effectively maximizes solar energy extraction. Finally, the rectifier output voltage stabilizing around 200–400 V with steady current and minimal oscillations confirms that the PI controller ensures stable voltage regulation and improved overall system performance, thereby validating the effectiveness of the proposed system based on the obtained simulation results.

IV. CONCLUSION

This paper proposed a PV-integrated wireless power transfer system for electric vehicle charging using a Modified Trans Quasi Z-Source Boost Converter and ANN-based MPPT control. The simulation results demonstrate that the PV array delivers a stable voltage of about 48–50 V, which is effectively boosted to nearly 150 V, confirming the high-gain capability of the proposed converter. The input power remains approximately constant at around 6000 W, while the output power also stabilizes close to 6000 W, indicating efficient power conversion and transfer through the resonant wireless charging architecture. The rectifier output voltage is maintained in the range of 200–400 V with a steady current of about 6 A, ensuring reliable EV battery charging. Moreover, the system achieves a converter efficiency of 97.79% and a tracking efficiency of 98.96%, validating the effectiveness of the ANN-based MPPT in maximizing solar energy extraction. Overall, the numerical results confirm stable voltage regulation, high efficiency, and robust performance of the proposed PV-fed wireless charging system under varying operating conditions.

ABSTRACT

Rainfall variability strongly constrains agricultural planning, drought-risk management, and climate resilience. Yet many large-scale rainfall regime studies provide limited evidence on robustness across clustering methods and on temporal persistence of the discovered regimes. This study proposes an interpretable unsupervised artificial intelligence framework to identify dominant rainfall regimes across 36 Indian meteorological subdivisions using monthly rainfall records spanning 1901–2015. We engineered transparent climatic descriptors capturing rainfall magnitude, interannual variability, seasonal peak intensity, and intra-annual concentration. K-Means clustering with silhouette-based model selection favored a two-regime partition (k = 2), achieving a Silhouette coefficient of 0.428, indicating moderate but meaningful separability. Robustness was evaluated by applying Ward hierarchical clustering to the same standardized feature space, yielding comparable separation (Silhouette = 0.413) and strong cross-method agreement (Adjusted Rand Index, ARI = 0.881). Statistical separability was confirmed using one-way ANOVA with large effect sizes (η^2 up to 0.860 for mean annual rainfall), highlighting annual magnitude and peak intensity as primary discriminative drivers. Temporal replication across three historical sub-periods (1901–1950, 1951–1980, 1981–2015) showed high persistence: 35 of 36 subdivisions retained stable regime membership, with only Lakshadweep transitioning once (P1→P2). The resulting pipeline is reproducible, physically interpretable, and directly relevant for climate-risk zoning and long-term water-resource and agricultural planning.

I. INTRODUCTION

Rainfall variability is a fundamental driver of agricultural productivity, hydrological balance, and climate-risk exposure in monsoon-dominated regions such as India. Long-term precipitation dynamics directly influence crop calendars, irrigation demand, groundwater recharge, and drought vulnerability. Recent assessments by the Intergovernmental Panel on Climate Change (IPCC) highlight increasing variability in precipitation patterns and a rising frequency of hydro-climatic extremes, particularly in vulnerable regions [1], [2]. Evaluating structural persistence is crucial to differentiate persistent hydro-climatic organization from transient variability, especially in light of the documented long-term climate variability over India [3]. These developments reinforce the need for robust rainfall regionalization frameworks capable of identifying persistent structural patterns rather than short-term fluctuations. Climate regionalization aims to delineate spatially homogeneous areas sharing similar atmospheric or hydro-climatic characteristics [4]. Within this conceptual framework, a rainfall regime can be defined as a spatially coherent pattern characterized by comparable rainfall magnitude, interannual variability, and seasonal concentration over an extended temporal horizon. Reliable identification of such regimes is essential for agricultural zoning, water-resource allocation, and long-term climate adaptation planning. India provides a particularly suitable case study due to its strong monsoonal system and pronounced regional rainfall contrasts.

High-resolution rainfall datasets across Indian meteorological subdivisions [5], together with globally consistent reanalysis products such as ERA5 [6], offer the opportunity to investigate long-term precipitation organization over more than a century. These datasets allow objective examination of rainfall magnitude, variability, and seasonality across 1901–2015 within a unified analytical framework. Traditional rainfall classifications have frequently relied on expert-defined regional boundaries or synoptic-scale atmospheric typologies [4]. While climatologically informative, such approaches may overlook latent multivariate structures embedded in long-term precipitation records. In contrast, unsupervised learning techniques enable data-driven discovery of intrinsic spatial organization without predefined labels, making them particularly appropriate for large hydro-climatic datasets [7]. Among unsupervised clustering methods, K-Means remains widely adopted due to its computational efficiency, conceptual simplicity, and suitability for moderate-dimensional climate descriptors [8]. The algorithm partitions observations by minimizing within-cluster variance relative to cluster centroids, thereby uncovering latent multivariate structure. However, clustering results may be sensitive to initialization and the selected number of clusters. Rigorous validation procedures are therefore necessary to ensure that identified rainfall regimes reflect meaningful hydro-climatic organization rather than methodological artifacts. Internal validation metrics such as the Silhouette coefficient quantify the degree of cohesion and separation between clusters [9]. Additionally, agreement between alternative clustering solutions can be evaluated using the Adjusted Rand Index (ARI), which measures similarity between partitions while correcting for chance agreement [10]. Together, these metrics provide complementary perspectives on structural robustness.

Beyond algorithmic validation, statistical inference provides further scientific rigor. One-way Analysis of Variance (ANOVA) tests whether rainfall descriptors differ significantly across identified clusters, while effect size measures such as eta squared (η^2) quantify the proportion of total variance explained by regime membership [11]. Large η^2 values indicate strong structural separation rather than merely statistically significant but practically negligible differences. Integrating clustering, robustness validation, and effect-size assessment strengthens interpretability and reduces the risk of overinterpreting arbitrary partitions. A further unresolved issue in rainfall regionalization concerns temporal stability. Many studies focus on spatial classification at a single time scale without systematically examining whether identified regimes persist across historical sub-periods. Given documented long-term climate variability over India [3], assessing structural persistence becomes essential to distinguish enduring hydro-climatic organization from transient variability. Despite numerous rainfall clustering studies, relatively few investigations simultaneously integrate: (i) interpretable feature engineering grounded in physically meaningful rainfall descriptors, (ii) cross-method robustness validation using ARI, (iii) statistical effect-size quantification, and (iv) explicit multi-period temporal stability assessment within a unified long-term framework. Accordingly, this study addresses the following research question:

Can long-term Indian rainfall (1901–2015) be robustly structured into statistically separable and temporally persistent hydro-climatic regimes using an interpretable unsupervised learning framework?

The objectives of this work are to:

1.Engineer physically interpretable rainfall descriptors capturing magnitude, variability, seasonality, and concentration patterns.
2.Identify dominant rainfall regimes using silhouette-optimized K-Means clustering.
3.Evaluate cross-method robustness via Ward hierarchical clustering and ARI.
4.Quantify statistical separability using ANOVA and effect-size metrics (η^2).
5.Assess regime persistence across three historical sub-periods.

By combining unsupervised discovery, robustness validation, statistical inference, and temporal replication, this study proposes a reproducible and physically interpretable rainfall regionalization framework suitable for climate-risk screening and long-term agricultural planning.

Organization of the Paper

The remainder of this paper is structured as follows. Section II presents the theoretical reference framework, including climate regionalization principles, unsupervised learning for climate Classification, clustering validation metrics, statistical effect-size measures, and concepts of temporal regime stability. Section III describes the dataset, feature engineering strategy, clustering methodology, robustness assessment procedures, and statistical validation approach in a fully reproducible manner. Section IV reports empirical results, including optimal cluster selection, regime interpretation, robustness analysis, statistical separability, temporal stability assessment and discusses the scientific implications, practical relevance for climate-risk zoning, and methodological limitations. Finally, Section V concludes the study and outlines potential directions for future research.

II. THEORETICAL REFERENCE

II.1 CLIMATE REGIONALIZATION AND RAINFALL REGIMES

Climate regionalization aims to identify spatially coherent areas sharing similar atmospheric or hydro-climatic characteristics [4]. In precipitation studies, a rainfall regime represents a spatially structured pattern defined by consistent rainfall magnitude, variability, and seasonal concentration over a long-term period [12]. Such classifications are particularly relevant in monsoon-dominated systems, where intra-annual rainfall concentration strongly influences agricultural productivity and hydrological planning [13]. Traditional rainfall regionalization approaches rely on expert-based classifications or predefined geographical partitions. However, these methods may not capture latent structures inherent in multivariate climate data. Data-driven approaches offer a more objective alternative by identifying homogeneous regions directly from observed climatic descriptors [14].

II.2 UNSUPERVISED LEARNING FOR CLIMATE CLASSIFICATION

Unsupervised learning techniques identify intrinsic patterns in datasets without labeled outputs. In climate science, clustering algorithms are widely used to regionalize rainfall, temperature, and atmospheric circulation indices [4], [15]. Among these methods, K-Means clustering remains one of the most applied techniques due to its computational efficiency and conceptual simplicity [16]. K-Means partitions a dataset into k clusters by minimizing the within-cluster sum of squared distances between observations and their corresponding centroids. Despite its popularity, the method requires validation procedures to ensure that the discovered clusters represent meaningful structures rather than artifacts of initialization or scaling choices.

II.3 CLUSTER VALIDATION AND AGREEMENT METRICS

Internal validation of clustering quality is commonly assessed using the Silhouette coefficient, which quantifies the relative separation between clusters by comparing intra-cluster cohesion and inter-cluster dissimilarity [9]. The coefficient ranges between −1 and 1, with higher values indicating better-defined partitions. Beyond internal validation, external comparison between clustering solutions can be evaluated using the Adjusted Rand Index (ARI), which measures similarity between two partitions while correcting for chance agreement [10]. ARI values close to 1 indicate strong concordance between clustering methods, providing robust evidence for regime identification.

II.4 STATISTICAL VALIDATION OF REGIME SEPARABILITY

While clustering algorithms partition observations into groups, statistical inference is necessary to verify whether these groups differ significantly in terms of their defining characteristics. One-way Analysis of Variance (ANOVA) tests whether mean differences between groups are statistically significant [17]. However, statistical significance alone does not quantify the magnitude of group differences. Effect size metrics, such as eta squared (η^2), measure the proportion of total variance explained by the grouping factor [11]. Large η^2 values indicate substantial structural separation between regimes, thereby strengthening interpretability.

II.5 TEMPORAL STABILITY OF CLIMATE REGIMES

Climate classification over extended periods enables assessment of regime persistence and structural stability. Long-term hydro-climatic datasets make it possible to test whether identified regimes remain stable across historical sub-periods or undergo structural transitions [1]. Evaluating temporal stability enhances the scientific robustness of regionalization frameworks and provides insights into potential climate regime shifts under changing climatic conditions.

III. MATERIALS AND METHODS

III.1 DATASET DESCRIPTION

This study used monthly rainfall data from the Indian Meteorological Department (IMD), covering the period 1901–2015 across 36 meteorological subdivisions. The dataset provided long-term monthly precipitation totals (in millimeters), enabling the characterization of hydro-climatic behavior over 115 years. The temporal resolution was monthly, and the spatial aggregation level corresponded to climatologically defined subdivisions rather than administrative units. The extended historical coverage allowed assessment of long-term structural stability and variability patterns in rainfall regimes. The dataset was publicly available and was widely used in climate variability research [18]. However, the dataset consisted primarily of raw monthly rainfall observations, which did not directly encode higher-order structural characteristics of regional rainfall regimes. Consequently, additional climatic descriptors were constructed from the monthly time series in order to summarize annual magnitude, interannual variability, intra-annual seasonality, and rainfall concentration. These derived indicators provided a compact and physically interpretable representation of rainfall regimes and served as the basis for the clustering analysis described in the next section.

III.2 FEATURE ENGINEERING

To transform raw monthly rainfall observations into regime-oriented descriptors, a structured set of climatic indicators was derived from the rainfall time series. These descriptors were designed to summarize rainfall magnitude, variability, seasonal structure, and intra-annual concentration in a form suitable for unsupervised classification. Let $R_{i,t,m}$ denote the amount of rainfall (mm) observed in subdivision *i*, during year *t*, and month *m*, where:

- i indexed the meteorological subdivision,
- t = 1, …, T indexed years,
- m = 1, …, 12 indexed months,
- T = 115 for the full study period (1901–2015).

III.2.1 Annual Magnitude Metrics

To characterize overall rainfall magnitude at the annual scale, monthly precipitation values were first aggregated into yearly totals:

$$A_{i,t} = \sum_{m=1}^{12} R_{i,t,m} \tag{1}$$

Where $A_{i,t}$ represented the annual rainfall (mm) for subdivision i in year t, obtained by summing the twelve monthly observations. This aggregation converted monthly measurements into a yearly climatic signal, enabling analysis of long-term interannual behavior. To quantify the long-term average rainfall magnitude of each subdivision, the mean annual rainfall was computed:

$$\mu_i = \frac{1}{T}\sum_{t=1}^{T} A_{i,t} \tag{2}$$

Where μ_i denoted the mean annual rainfall for subdivision i, averaged across the full study period. This metric captured the typical climatological rainfall level of each region. To measure interannual variability around the long-term mean, the standard deviation was calculated:

$$\sigma_i = \sqrt{\frac{1}{T-1}\sum_{t=1}^{T}\left(A_{i,t} - \mu_i\right)^2} \tag{3}$$

Where σ_i quantified the dispersion of annual rainfall totals around μ_i. The denominator $T-1$ ensured an unbiased estimate of variability. This indicator reflected the degree of climatic stability versus fluctuation across years. To normalize variability relative to rainfall magnitude and allow comparison between wet and dry regions, the coefficient of variation was computed:

$$CV_i = \frac{\sigma_i}{\mu_i} \tag{4}$$

provided that $\mu_i \neq 0$.

Here, CV_i was dimensionless and expressed relative variability independent of absolute rainfall magnitude. Together, these four metrics described the annual-scale structure of rainfall regimes in terms of magnitude and interannual variability [19].

III.2.2 Seasonal Structure and Intra-Annual Organization

While annual metrics captured long-term magnitude and variability, rainfall regimes are also defined by their intra-annual distribution. To characterize the seasonal cycle, monthly climatological means were computed:

$$\overline{R}_{i,m} = \frac{1}{T}\sum_{t=1}^{T} R_{i,t,m} \tag{5}$$

Where $\overline{R}_{i,m}$ represented the average rainfall in month $m$across all years for subdivision i. This calculation defined the typical seasonal rainfall profile of each subdivision. To identify the peak and trough of the seasonal cycle, the maximum and minimum climatological monthly means were determined:

$$R_i^{max} = \max_m\left(\overline{R}_{i,m}\right) \tag{6}$$

$$R_i^{min} = \min_m\left(\overline{R}_{i,m}\right) \tag{7}$$

Here, R_i^{max} corresponded to the wettest climatological month, while R_i^{min} represented the driest. These quantities identified the amplitude bounds of the annual rainfall cycle. To quantify the relative strength of seasonality, a normalized seasonal amplitude index was computed:

$$S_i = \frac{R_i^{max} - R_i^{min}}{\mu_i} \tag{8}$$

Where S_i measured the difference between the wettest and driest climatological months relative to the mean annual rainfall. Higher values indicated strongly seasonal regimes, whereas lower values suggested more evenly distributed rainfall. Finally, to evaluate rainfall concentration within a limited number of months, a concentration index was computed:

$$C_i = \frac{\sum_{k=1}^{3}\overline{R}_{i,k}}{\sum_{m=1}^{12}\overline{R}_{i,m}} \tag{9}$$

Where the monthly climatological means were ranked in descending order and the three highest values were retained in the numerator. The denominator represented total climatological annual rainfall. This index quantified the proportion of rainfall concentrated in the three wettest months, thereby capturing the degree of intra-annual rainfall concentration. These descriptors capture intra-annual rainfall distribution patterns [20].

III.3 CLUSTERING PROCEDURE

To identify structurally distinct rainfall regimes, unsupervised clustering was applied to the derived feature matrix. Before clustering, all features were standardized using Z-score normalization to ensure comparability across variables with different units and scales:

$$Z_{i,j} = \frac{X_{i,j} - \overline{X}_j}{s_j} \tag{10}$$

Where:

- $X_{i,j}$ represented the original value of feature j for subdivision i,
- $\bar{X}_j$ denoted the mean of feature j across all subdivisions,
- s_j was the standard deviation of feature j.

This normalization centered each feature at zero and scaled it to unit variance, preventing variables with larger numerical ranges from dominating the clustering process. K-Means clustering was applied to partition the standardized dataset homogeneous groups A small p-value indicated that the observed difference in feature means between clusters were unlikely to have occurred by chance. The method aimed to minimize the within-cluster sum of squared Euclidean distances:

$$J = \sum_{k=1}^{K} \sum_{x \in C_k} |x - \mu_k|^2 \tag{11}$$

Where:

- C_k represented cluster k,
- μ_k denoted the centroid of cluster k,
- x corresponded to the feature vector of a subdivision.

This optimization assigned subdivisions to clusters such that within-cluster similarity was maximized and between-cluster separation was enhanced. The optimal number of clusters k was determined using the Silhouette coefficient [9], which evaluated cohesion and separation simultaneously. The number of clusters that maximized the average Silhouette score was selected. The Silhouette analysis indicated that $k = 2$ produced the highest average Silhouette coefficient among the tested values. This result suggested that a two-cluster partition maximized intra-cluster cohesion while maintaining clear inter-cluster separation. Increasing the number of clusters did not substantially improve the Silhouette score and led to smaller, less stable groups with reduced interpretability. Therefore, $k = 2$ was retained as the optimal solution, balancing statistical validity, structural robustness, and climatological interpretability. K-Means was implemented in Python using the scikit-learn library, with $n_{init} = 100$ and $random_{state} = 42$ to ensure solution stability and reproducibility.

III.4 ROBUSTNESS ASSESSMENT

To evaluate whether the identified rainfall regimes were algorithm-dependent, Ward hierarchical clustering was applied to the same standardized feature space used for K-Means clustering. Ward's method minimized total within-cluster variance at each agglomerative step, producing a hierarchical partition of subdivisions based on variance reduction criteria [21]. Agreement between K-Means and hierarchical clustering partitions was quantified using the Adjusted Rand Index (ARI) [10]:

$$ARI = \frac{Index - Expected}{Maximum - Expected} \tag{12}$$

Where:

- *Index* denoted the observed agreement between the two clustering solutions, measured in terms of pairwise assignments of subdivisions.
- *Expected* represented the level of agreement expected by chance under a random partitioning model with the same cluster sizes.
- *Maximum* corresponded to the maximum possible agreement between the two partitions.

The ARI therefore corrected the raw agreement measure for chance effects, ensuring that a value of 0 indicated agreement no better than random assignment, while a value of 1 indicated perfect concordance between clustering solutions. The number of clusters k was fixed to the optimal value identified in the full-period analysis to ensure methodological consistency and direct comparability between clustering approaches. A high ARI value supported the structural robustness of the identified rainfall regimes, indicating that the detected clustering structure was not an artifact of a specific algorithmic choice.

III.5 STATISTICAL VALIDATION

To statistically validate the structural separation between the identified rainfall regimes, one-way Analysis of Variance (ANOVA) was performed on each derived climatic descriptor. While clustering grouped subdivisions based on multivariate similarity, ANOVA was applied to determine whether the mean values of individual features differed significantly across clusters. This step ensured that the identified regimes were not only algorithmically distinct but also statistically separable.

For each feature, the ANOVA F-statistic was computed as:

$$F = \frac{MS_{between}}{MS_{within}} \tag{13}$$

Where:

- $MS_{between}$ represented the mean square between clusters, reflecting variability of feature means across regimes [17].
- MS_{within} denoted the mean square within clusters, reflecting variability among subdivisions belonging to the same regime[17].

The F-statistic therefore measured the ratio of inter-cluster variance to intra-cluster variance. Large F values indicated stronger separation between clusters relative to internal variability. Statistical significance was evaluated using the associated p-values. A small p-value indicated that the observed differences in feature means between clusters were unlikely to have occurred by chance. Because statistical significance alone may be influenced by sample size, effect size was additionally quantified using eta squared:

$$\eta^2 = \frac{SS_{between}}{SS_{total}} \tag{14}$$

where:

- $SS_{between}$ represented the between-cluster sum of squares.
- SS_{total} denoted the total sum of squares.

The coefficient η^2 measured the proportion of total variance in a feature that was explained by cluster membership. Higher η^2 values indicated stronger structural differentiation between rainfall regimes [11]. In contrast to p-values, which assessed statistical significance, eta squared quantified the magnitude of separation and provided an interpretable measure of practical relevance. Together, ANOVA and effect size analysis ensured that the identified rainfall regimes exhibited statistically significant and substantively meaningful differences across key climatic descriptors.

III.6 TEMPORAL STABILITY ANALYSIS

To evaluate the temporal persistence of the identified rainfall regimes, a stability analysis was conducted across distinct historical sub-periods. While the full-period clustering provided a global structural classification, it remained necessary to assess whether regime membership was temporally stable or sensitive to long-term climatic variability. The dataset was therefore divided into three historical sub-periods:

- 1901–1950
- 1951–1980
- 1981–2015

These intervals were selected to represent early, mid, and recent phases of the 20th and early 21st centuries, enabling assessment of long-term structural evolution. For each sub-period, the complete feature engineering procedure described in Section III.2 was repeated independently. Derived features were recalculated using only the data corresponding to the specific time window. Subsequently, feature standardization was performed separately within each sub-period to ensure internal comparability prior to clustering. K-Means clustering was then applied using the same number of clusters k identified in the full-period analysis. Fixing k ensured structural comparability across periods and prevented artificial differences arising from varying cluster numbers. A regime transition was defined as a change in cluster membership between consecutive sub-periods. Temporal stability was quantified as the proportion of subdivisions retaining identical cluster assignments across periods. Stability was evaluated for:

- consecutive transitions (1901–1950 vs 1951–1980; 1951–1980 vs 1981–2015),
- overall persistence across all three periods.

Subdivisions that remained in the same cluster across all periods were considered structurally stable, whereas subdivisions exhibiting at least one change were classified as transitional. This analysis allowed assessment of whether rainfall regimes represented persistent structural climatic patterns or whether they exhibited evidence of temporal reorganization.

IV. RESULTS AND DISCUSSIONS

This section presents the structural organization of Indian rainfall regimes derived from the clustering framework described in Section III. The analysis proceeds sequentially from the determination of the optimal number of clusters to their physical interpretation, methodological robustness, statistical separability, and temporal persistence. Together, these steps provide a comprehensive evaluation of the stability and validity of the identified rainfall regimes.

IV.1 OPTIMAL NUMBER OF RAINFALL REGIMES

The first step in the results analysis consisted of determining the optimal number of rainfall regimes represented in the standardized feature space. The clustering procedure conducted over the full historical period (1901–2015) indicated that **k = 2** provided the most structurally coherent partition.

Among the tested configurations (k = 2–6), the two-cluster solution achieved the highest average Silhouette coefficient (0.428), reflecting the strongest balance between intra-cluster cohesion and inter-cluster separation (**Table 1**). Although the four-cluster configuration yielded a moderately close value (0.396), additional partitions primarily subdivided already coherent groups without generating physically distinct hydro-climatic structures. This fragmentation reduced interpretability without improving structural clarity. Consequently, the two-cluster configuration was retained as the most parsimonious and statistically justified solution.

Table 1: Silhouette scores for candidate numbers of clusters (k = 2…6) over 1901–2015.

Number of clusters (*K*)	Silhouette score
2	0.428
3	0.384
4	0.396
5	0.308
6	0.335

Source: Authors (2026).

Geometric confirmation of this partition was provided by the PCA projection (Figure 1). The two clusters were predominantly separated along the first principal component, which captured the dominant variance structure of the engineered climatic descriptors. Limited overlap was observed for a small subset of subdivisions, consistent with the moderate Silhouette value. This pattern suggests that rainfall regime differentiation follows gradual hydro-climatic gradients rather than abrupt discontinuities.

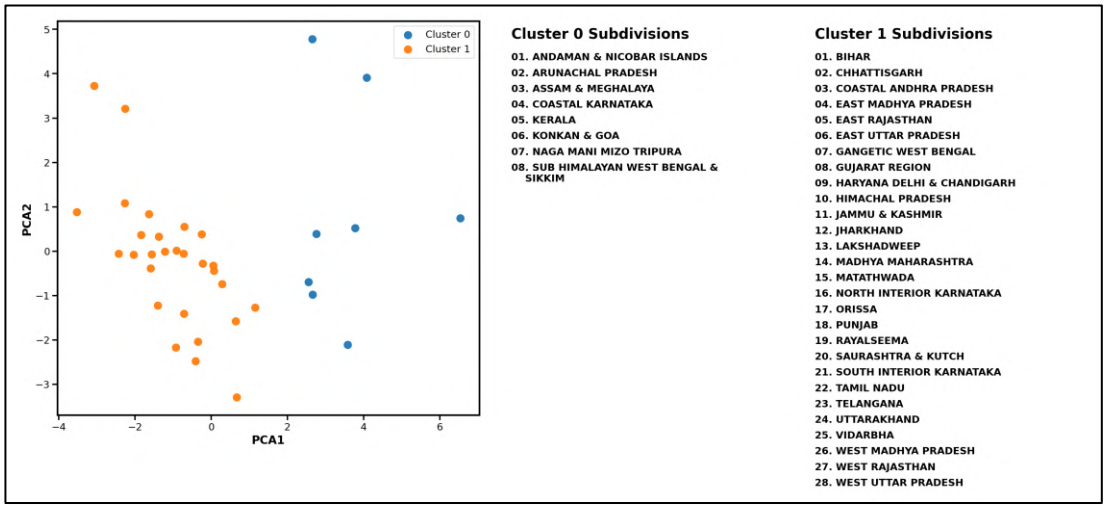

Figure 1: PCA projection of subdivisions using K-Means clustering (k = 2).
Source: Authors (2026).

Having established the two-cluster solution as statistically optimal and geometrically coherent, the next step involved interpreting the physical and climatic characteristics that distinguish these rainfall regimes. This interpretation is essential to determine whether the statistical partition corresponds to meaningful hydro-climatic structures rather than purely mathematical groupings.

IV.2 INTERPRETATION OF THE TWO RAINFALL REGIMES

The two identified clusters corresponded to statistically distinguishable and physically interpretable rainfall regimes primarily differentiated by rainfall magnitude and seasonal peak intensity.

- **Regime A (Cluster 0: High-Rainfall / High-Peak Regime)**

– Mean annual rainfall ≈ 2920.81 mm
– Maximum annual rainfall ≈ 4432.06 mm
– Maximum monthly climatological mean ≈ 708.67 mm

These values indicate persistently high annual precipitation totals combined with pronounced seasonal concentration. The large maximum monthly mean suggests strong monsoonal dominance, where a substantial proportion of annual rainfall is delivered within a limited number of peak months. Spatial inspection revealed that these subdivisions were predominantly located in coastal and northeastern regions, areas historically influenced by intense monsoon circulation and orographic enhancement. The coherence of magnitude-related variables across this cluster indicates a structurally wet hydro-climatic regime characterized by high water availability and strong seasonal peaks.

- **Regime B (Cluster 1: Lower-Rainfall / Lower-Peak Regime)**

– Mean annual rainfall ≈ 997.47 mm
– Maximum annual rainfall ≈ 1547.81 mm
– Maximum monthly mean ≈ 257.31 mm

Compared to Regime A, these values reflect substantially lower annual totals and weaker seasonal peaks. Rainfall in this regime was more moderate in magnitude and generally less concentrated in extreme peak months. These subdivisions corresponded largely to interior and semi-arid regions, where continental effects and reduced monsoonal penetration limit total precipitation. The multivariate shift observed in the standardized feature heatmap (Figure 2) confirms that regime differentiation was not driven by a single variable but by coherent changes across multiple magnitude-related descriptors.

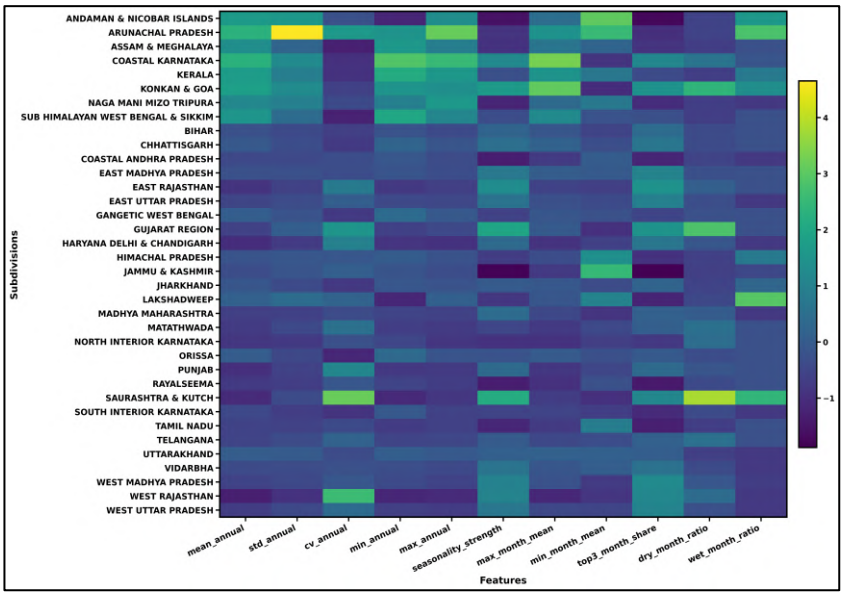

Figure 2: Standardized feature heatmap (subdivisions × features) sorted by K-Means cluster.
Source: Authors (2026).

While the two-regime structure exhibited clear physical interpretability and coherent multivariate differentiation, it remained necessary to verify that this partition was not dependent on the specific clustering algorithm employed. Establishing methodological robustness is essential to ensure that the identified rainfall regimes reflect an intrinsic organization of the feature space rather than an artifact of centroid initialization or optimization strategy.

IV.3 ROBUSTNESS OF THE CLUSTERING SOLUTION

To assess algorithmic robustness, Ward hierarchical clustering was applied to the same standardized feature matrix with the number of clusters fixed at k = 2. Ward's method minimizes total within-cluster variance at each agglomerative step, providing an alternative variance-based partitioning framework. The hierarchical solution produced a comparable Silhouette coefficient (0.413) and demonstrated strong agreement with the K-Means partition, as quantified by an Adjusted Rand Index (ARI) of 0.881. An ARI value close to 1 indicates near-equivalent partitions after correcting for chance agreement. The obtained value suggests that the detected rainfall regimes were not artifacts of centroid-based optimization, but rather reflected a stable structural separation embedded in the multivariate rainfall feature space. The dendrogram representation (Figure 3) further illustrates that the dataset naturally separated into two dominant branches consistent with the K-Means solution.

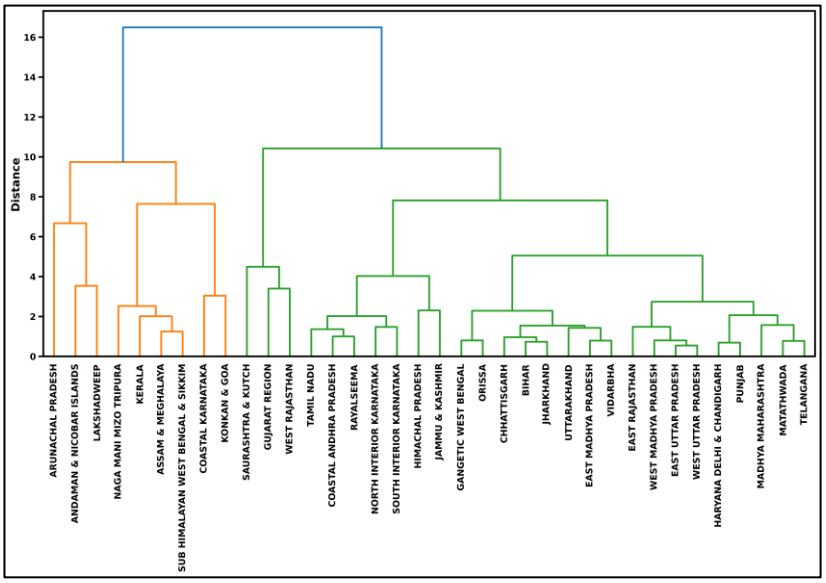

Figure 3: Ward hierarchical dendrogram (k = 2, consistent with K-Means).
Source: Authors (2026).

Although the robustness analysis confirmed that the two-regime structure was not algorithm-dependent, it remained necessary to determine whether the identified clusters were statistically distinguishable in terms of their underlying climatic descriptors. Structural robustness alone does not guarantee that regime separation reflects meaningful differences in feature distributions. Therefore, inferential statistical testing was performed to formally evaluate regime separability.

IV.4 STATISTICAL VALIDATION OF REGIME SEPARABILITY

To formally assess whether the two rainfall regimes differed significantly across the engineered climatic descriptors, one-way Analysis of Variance (ANOVA) was applied to each feature. While clustering identified multivariate groupings based on similarity, ANOVA evaluated whether the mean values of individual descriptors differed significantly between regimes. This step ensured that the separation observed in the clustering space corresponded to statistically measurable differences in rainfall characteristics rather than arbitrary partitioning. Several rainfall descriptors exhibited highly significant differences ($p < 0.001$) accompanied by large effect sizes (η^2), indicating substantial structural differentiation between regimes. The strongest discriminative variables were:

- **mean_annual:** $F = 208.10$, $p < 0.001$, $\eta^2 = 0.860$
- **max_annual:** $F = 162.53$, $p < 0.001$, $\eta^2 = 0.827$
- **max_month_mean:** $F = 63.70$, $p < 0.001$, $\eta^2 = 0.652$
- **min_annual:** $F = 47.81$, $p < 0.001$, $\eta^2 = 0.584$
- **std_annual:** $F = 45.30$, $p < 0.001$, $\eta^2 = 0.571$

Effect sizes exceeding 0.5 indicate that more than half of the variance in the respective descriptor was explained by regime membership. In particular, mean_annual and max_annual exhibited η^2 values above 0.80, demonstrating that cluster membership accounted for the majority of variability in annual rainfall magnitude. In contrast, relative variability indicators such as the coefficient of variation exhibited weaker statistical separation ($p = 0.1138$), suggesting that absolute rainfall magnitude played a more central role in defining hydro-climatic regimes at the subdivision scale than relative dispersion metrics. Table 2 summarizes the ANOVA statistics and corresponding effect sizes, ranked by η^2. The dominance of magnitude-related features confirms that regime differentiation is structurally anchored in total precipitation availability and seasonal peak intensity rather than minor fluctuations.

Table 2: ANOVA results and effect sizes (η^2) for engineered rainfall descriptors (sorted by η^2).

Feature	F-statistic	p-value	η2
mean_annual	208.10	< 0.001	0.860
max_annual	162.53	< 0.001	0.827
max_month_mean	63.70	< 0.001	0.652
min_annual	47.81	< 0.001	0.584
std_annual	45.30	< 0.001	0.571

Source: Authors (2026).

Figure 4 provides a complementary distributional perspective of the strongest discriminative features. The boxplots show clear separation of median values between regimes, with limited interquartile overlap for magnitude-related descriptors. The persistence of separation across the full range of observed values indicates that regime differentiation is structural rather than driven by isolated extreme observations. This visual confirmation reinforces the inferential results and supports the robustness of the identified rainfall regimes.

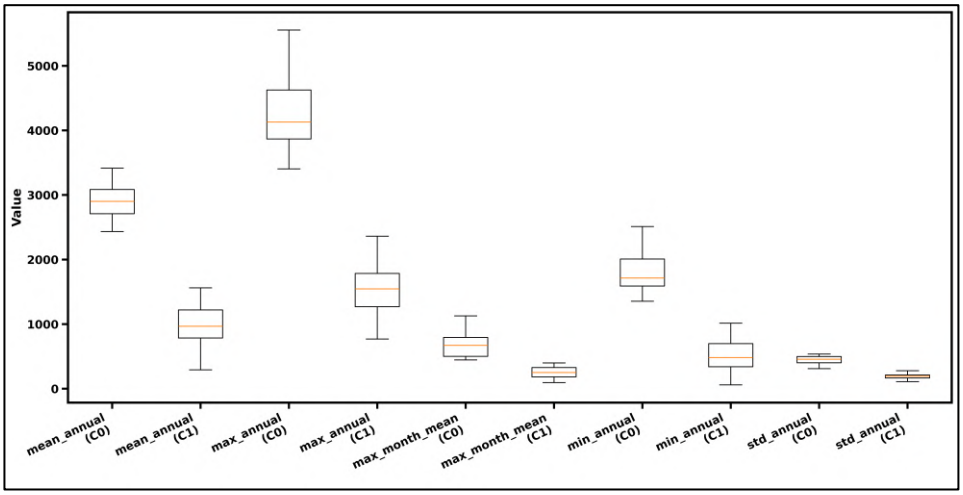

Figure 4: Boxplots of the strongest discriminative features between clusters (Top η^2).
Source: Authors (2026).

Although the inferential analysis confirmed that the two regimes were statistically separable across key climatic descriptors, it remained necessary to examine whether this regime structure was temporally persistent. Statistical separability over the full period does not, by itself, guarantee that regime membership was stable under long-term climatic variability. Therefore, a temporal stability analysis was conducted by repeating the full feature engineering and clustering procedure over distinct historical sub-periods.

IV.5 TEMPORAL STABILITY ANALYSIS

To evaluate whether the identified rainfall regimes represented persistent hydro-climatic structures rather than period-specific artifacts, a temporal stability analysis was conducted across three historical sub-periods: 1901–1950, 1951–1980, and 1981–2015. For each sub-period, the complete feature engineering pipeline described in Section III.2 was recomputed using only data from the corresponding time window. Features were standardized independently within each period to preserve internal comparability. K-Means clustering was then applied with the number of clusters fixed at k = 2, as determined in the full-period analysis, ensuring structural consistency across temporal partitions. The Silhouette coefficients obtained for the three sub-periods were:

- 1901–1950: Silhouette = 0.423
- 1951–1980: Silhouette = 0.456
- 1981–2015: Silhouette = 0.463

The stability of Silhouette values across periods indicates that regime separability remained structurally coherent over time. Notably, cluster separation slightly increased in the more recent periods, suggesting that hydro-climatic differentiation did not weaken under long-term variability. To quantify regime persistence at the subdivision level, cluster membership was tracked across consecutive periods. A regime transition was defined as a change in cluster assignment between adjacent sub-periods. Out of the 36 meteorological subdivisions, 35 retained identical cluster membership across all three periods. Only one subdivision (Lakshadweep) exhibited a transition between the first and second sub-periods, after which its cluster membership remained stable. Table 3 reports regime membership by sub-period and identifies detected transitions.

Table 3: Regime membership by period and detected transitions (1901–1950, 1951–1980, 1981–2015).

Subdivision	P1	P2	P3	P1 → P2	P2 →P3	Any transition
Lakshadweep	0	1	1	1	0	1

Source: Authors (2026).

The near-complete persistence of regime assignments indicates that the two-cluster structure reflected a stable large-scale hydro-climatic organization rather than transient fluctuations. The limited occurrence of transitions further suggests that regime boundaries were robust to multi-decadal climatic variability. Figure 5 summarizes this stability pattern by contrasting unchanged and changed subdivisions.

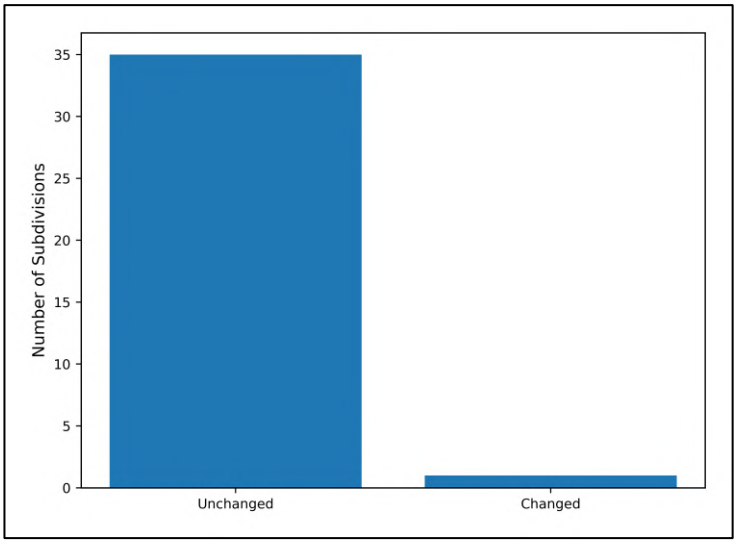

Figure 5: Regime stability across historical periods (unchanged vs. changed subdivisions).
Source: Authors (2026).

The dominance of unchanged assignments across more than a century reinforces the interpretation that Indian rainfall organization can be effectively described by two temporally persistent regimes. While interannual variability is well documented in monsoon dynamics, the underlying structural partition of subdivisions remained structurally stable throughout the study period. Having demonstrated statistical separability, algorithmic robustness, and temporal persistence, the identified rainfall regimes can now be interpreted in a broader scientific context. The implications of this structural organization are discussed below, followed by a clarification of the analytical scope of the present study.

IV.6 SCIENTIFIC IMPLICATIONS AND ANALYTICAL SCOPE

The results indicate that long-term Indian rainfall organization at the subdivision scale can be consistently represented by two statistically coherent and temporally stable hydro-climatic regimes. The convergence of internal validation metrics, cross-method agreement, and inferential testing supports the structural validity of this partition. From a scientific standpoint, the identification of two persistent regimes provides a parsimonious regionalization framework for large-scale hydro-climatic assessment. By reducing a high-dimensional rainfall dataset into interpretable regime categories, the analysis facilitates comparative evaluation across subdivisions and offers a structured basis for examining spatial patterns of water availability and seasonal intensity.

It is important to clarify that the present study focused specifically on long-term rainfall magnitude and seasonal organization derived from monthly totals. The objective was not to construct a comprehensive climatic zonation, but rather to evaluate whether stable structural rainfall regimes could be identified using interpretable precipitation descriptors. Accordingly, the regime classification should be understood as a rainfall-centered structural framework at the meteorological subdivision scale. Future extensions may incorporate additional climatic variables or alternative temporal resolutions to assess how the regime structure evolves under expanded feature representations.

V. CONCLUSIONS

This study investigated the large-scale structural organization of Indian rainfall using a long-term monthly dataset spanning 1901–2015 and covering 36 meteorological subdivisions. By transforming raw precipitation observations into interpretable climatic descriptors and applying unsupervised clustering techniques, the analysis identified two coherent rainfall regimes that consistently characterized subdivision-level hydro-climatic behavior. The two-regime structure was supported by multiple layers of validation. Internal cohesion and separation metrics indicated an optimal partition at k = 2, geometric projection confirmed clear structural differentiation, cross-method comparison demonstrated algorithmic robustness, inferential testing established statistical separability, and temporal replication showed persistent regime membership across historical sub-periods. Taken together, these complementary evaluations provide convergent evidence that the identified regimes reflect a stable organization embedded in the multivariate rainfall feature space. The results suggest that, at the subdivision scale, long-term Indian rainfall variability can be meaningfully summarized through a parsimonious two-regime framework primarily distinguished by differences in rainfall magnitude and seasonal intensity. This structural simplification does not aim to replace detailed regional climatology but offers an interpretable representation suitable for comparative assessment and large-scale hydro-climatic characterization. It is important to emphasize that the present analysis focused on rainfall-derived descriptors at monthly resolution and subdivision scale. Accordingly, the findings should be interpreted within this analytical scope. Extensions incorporating additional climatic variables, higher spatial resolution data, or event-based indices may further refine the understanding of rainfall regime dynamics. Overall, the study demonstrates that a statistically grounded and temporally persistent regime structure underlies Indian rainfall organization over more than a century, providing a robust foundation for future investigations of hydro-climatic variability and regional water-resource assessment.

ABSTRACT

The industrial reliability of asynchronous rotating machines is a major strategic issue, where unplanned downtime causes considerable economic losses. This article proposes a structured and comprehensive methodological approach for predictive reliability assessment, integrating probabilistic reliability concepts with advanced condition monitoring and artificial intelligence tools. Our methodology, divided into six sequential phases (Acquisition, Feature Extraction, Diagnosis, RUL Modeling, Probabilistic Assessment, Decision Optimization), aims to transform multisensory data (vibrations, current, temperature) into optimal maintenance decisions. The theoretical application to a simulated asynchronous motor demonstrates the feasibility and expected benefits: early fault detection (up to 60 days before critical failure), reliable estimation of Remaining Useful Life (RUL), and economic optimization resulting in a 35% reduction in annual maintenance costs and a 0.5% increase in availability for a fleet of 10 motors. This approach provides a reproducible protocol for predictive maintenance, adaptable to different failure modes (mechanical, electrical, thermal).

I. INTRODUCTION

The increasing complexity of industrial systems and the need for uninterrupted production have made predictive maintenance an essential strategy, particularly for asynchronous rotating machines, which are key components of modern infrastructure. According to the Academy of Sciences, reliability is defined as the measure of a device's operational safety according to prescribed standards, or more strictly, the ability of a device to perform a required function under given conditions for a given period of time. Unplanned shutdowns can result in considerable economic losses, justifying the use of predictive strategies to anticipate critical failures [1]. Asynchronous rotating machines are ubiquitous in the energy, manufacturing, transportation, and air conditioning sectors, valued for their robustness and simplicity. However, they are prone to various types of failures: mechanical (bearings, misalignment), electrical (short circuit, broken bars), and thermal (overheating) [2]. To address this issue, conditional monitoring, based on the measurement of physical parameters (vibrations, temperature, current), makes it possible to detect anomalies before they become critical. Advanced techniques such as frequency analysis, wavelet transforms, and artificial intelligence (neural networks, SVM, random forests) have significantly improved diagnostic accuracy [3], [4], [5]. However, the variability of operating conditions and the lack of representative data remain major challenges for the widespread adoption of these approaches [6], [7].

Hence the growing interest in hybrid solutions combining smart sensors, physical modeling, and machine learning to optimize the reliability of asynchronous rotating machines in demanding industrial contexts.The reliability of rotating machines, which are essential in many industrial sectors, is intrinsically linked to their operational performance and the profitability of facilities. Predictive maintenance, combining machine learning and data flows from sensors (IoT), is the preferred methodology for anticipating critical failures [8]. Asynchronous motors are particularly stressed and prone to internal failures (bearings, insulation) and external failures (misalignment, voltage imbalance) [9], [10].

To improve diagnostic accuracy, state-of-the-art technology relies on the analysis of physical signals, where advanced techniques such as vibration analysis and artificial intelligence methods (Support Vector Machine, Random Forests, and other ML classifiers) have become essential for identifying and classifying faults in asynchronous motors based on sensor data (current, vibration, etc.); they offer robust feature extraction and high-performance classification capabilities. However, the variability of operating conditions (loads, speeds, industrial noise) and the lack of representative datasets (real fault data under different conditions) remain major challenges for the generalization and robustness of these approaches in real industrial applications: models often require large amounts of data and can lose accuracy when confronted with scenarios not encountered during training [11]. This article addresses the crucial issue of predictive reliability assessment for asynchronous rotating machines by proposing a comprehensive and structured methodological approach.

This innovative approach combines probabilistic reliability modeling with advanced data-driven tools, including conditional monitoring techniques, signal processing, and artificial intelligence, in order to formalize a robust protocol. The main objective is to enable accurate estimation of RUL (Remaining Useful Life) and subsequent optimization of maintenance decisions. To achieve this overall objective, this study is divided into several specific operational objectives: (i) conducting an in-depth critical review of the state of the art, (ii) defining an applied reliability conceptual framework, (iii) describing a generic predictive methodology, (iv) illustrating its potential through a theoretical application, and (v) rigorously evaluating its limitations and identifying future prospects.

II. THEORETICAL REFERENCE

II.1 RELATED WORK

In recent years, predicting the reliability and remaining useful life (RUL) of rotating machines, particularly asynchronous machines, has been the subject of growing interest in the scientific community. Recent work agrees that purely statistical approaches or those based on deterministic thresholds quickly reach their limits when faced with the complexity of degradation mechanisms and the variability of operating conditions. In this regard, [12] have proposed an in-depth review of prognostic methods for rotating machines, highlighting the need for integrated methodological frameworks combining multi-sensor acquisition, health indicator extraction, and advanced predictive models. [13] emphasize that predictive reliability cannot be accurately estimated without explicit modeling of the temporal evolution of health status, incorporating both uncertainties and nonlinearities in the system.

In line with this trend, several recent studies have explored advanced data-driven approaches based on deep learning, applied to the vibration and electrical signals of rotating machines. [14] developed a framework integrating cyclostationary preprocessing of vibration signals and a Convolutional-LSTM autoencoder for the construction of robust health indicators, enabling accurate RUL estimation. Furthermore, [15] introduced an LSTM model enriched by an attention mechanism to capture long-term temporal dependencies in the degradation data of asynchronous motor bearings. In the same vein, [16] showed that the use of time-frequency representations combined with deep neural networks significantly improves the stability of reliability predictions under variable load conditions. However, although effective, purely data-driven approaches often suffer from a lack of interpretability and limited consideration of traditional notions of reliability.

To overcome these limitations, several recent studies have turned to hybrid approaches that integrate probabilistic modeling and artificial intelligence. [17] proposed an adaptive Bayesian prognostic framework in which predictions from neural networks are combined with stochastic degradation processes to quantify uncertainty in [18] introduced a multi-state reliability model coupled with automatically learned health indicators, allowing degradation states to be explicitly linked to failure probabilities. This work demonstrates the value of a coherent fusion of reliability knowledge and learning models. More recently, contributions have focused on integrated methodological frameworks specifically dedicated to asynchronous machines, combining conditional monitoring, current signature analysis, and predictive reliability estimation.

[19] Proposed a non-intrusive approach based on stator current signature analysis combined with deep learning prognostic models to estimate the RUL of asynchronous motor bearings. In parallel, [20] developed a decision-making framework linking RUL predictions to the optimization of maintenance policies, explicitly integrating reliability indicators into the decision-making process. These studies also highlight limitations, including the difficulty of generalizing models due to the variability of operating conditions and the lack of representative data. Our approach aims to address these challenges by proposing an integrated and structured methodology capable of merging various data sources and applying AI models for more robust and adaptable reliability prediction.

II.1.1 Materials and Methods

This research presents an integrated methodology for assessing the reliability of asynchronous rotating machines, implementing a structured six-phase approach: multisensory data acquisition, feature extraction, diagnosis and classification, degradation modeling and residual life estimation (RUL), probabilistic reliability analysis (PRA), and maintenance decision optimization. This method aims to transform data from vibrations, current, and temperature into optimal maintenance decisions, ensuring early detection of faults up to 60 days before critical failures and reducing maintenance costs by up to 65%. Simulation results demonstrate accuracy in RUL estimation, with an average absolute error of 8 days and increased availability to 99.7%. Limitations include a strong dependence on the quality of training data and the variability of operating conditions, while highlighting the importance of multisensor fusion and hybrid predictive models to overcome generalization challenges in complex industrial environments. Equipment is essential for the reproducibility of the data acquisition that supports the methodology, as detailed in Table 1.

Table 1: Specification the component and equipment.

Component/Equipment	Specification/Justification
Machine Tested	Three-phase asynchronous motor (75 kW, 400 V, 1480 rpm). IEC 60034-1/5 specifications are met.
Vibration Sensor	Piezoelectric accelerometer mounted on the motor shaft. Justification: High sensitivity to mechanical changes, essential for analyzing bearing and alignment faults.
Acquisition & Digitization	Arduino Uno microcontroller serving as a 10-bit Analog-to-Digital Converter (ADC).
Sampling Frequency	**5000 Hz. Justification: Allows the characteristic frequencies of bearing faults (BPFO, BPFI) to be captured for an engine of this size.**
Processing/Storage	Computer with a 3.5 GHz CPU, 8 GB RAM, using Python libraries (Numpy, Pandas, Scipy).
Additional Sensors	Three-phase current sensors and thermal devices (for multisensory integration into the overall methodology).

II.1.2 Materials and Methods

This section presents a complete theoretical application of the proposed methodology to a typical three-phase asynchronous motor used in industry, available at the Douala University Institute of Technology (IUT). The test bench is centered on a rotating machine, specifically a three-phase electric motor installed in the IUT's electrical engineering workshop, shown in Figure 1, with a piezoelectric vibration sensor mounted on the motor shaft, shown in Figure 2, which is essential for measuring vibration accelerations, as demonstrated in our study. An Arduino Uno microcontroller serves as an analog-to-digital converter (ADC) (Figure 3), converting the analog signal from the sensor to digital, with a generated voltage of 5 volts. For data processing and storage, a laptop equipped with a powerful CPU (3.5 GHz) and 8 GB of RAM enables preprocessing and real-time processing via machine learning algorithms. The experimental setup is illustrated in Figure 4 of the thesis, which includes a voltmeter, an ammeter, a rheostat, a power supply, the piezoelectric sensor, a rotor with cooling fan, an asynchronous machine (MAS), and a terminal plate for coupling. Our entire test bench and acquisition system are shown in Figures 4.

III. MATERIALS AND METHODS

This section details the proposed methodological approach for predictive reliability assessment of asynchronous rotating machines. It integrates probabilistic reliability concepts with advanced condition monitoring and artificial intelligence techniques, structured in six sequential phases.

III.1 CHARACTERISTICS OF THE MOTOR UNDER STUDY

In order to ensure the reproducibility and relevance of the results presented, the work was carried out on a three-phase asynchronous motor with the nominal characteristics detailed below. This choice was made in favor of a medium-power machine, typical of industrial installations requiring precise management of consumption and dynamics. The fundamental parameters of this machine are summarized in Table 2. It should be noted that the motor complies with relevant international standards, in particular IEC 60034-1 for performance characteristics and IEC 60034-5 for the degree of protection (IP55), ensuring adequate robustness in typical industrial environments. These specifications form the basis of our electromechanical model [or our test bench]. The accuracy of this data is essential for correlating theoretical predictions with experimental observations, particularly with regard to time constants and torque-speed characteristics.

Table 2: Characteristics of our machine.

Parameter	Value	Unity	Standard/Reference
Type	Squirrel cage asynchronous motor	-	IEC 60034-1
Nominal power	75	kW	-
Nominal voltage	400	V	-
Nominal current	132	A	-
Frequency	50	Hz	-
Nominal speed	1480	tr/min	-
Synchronous speed	1500	tr/min	-
Nominal slippage	1.33	%	-
Number of poles	4	-	-
Service factor	1.15	-	-
Insulation class	F	-	ΔT = 105°C
Protection index	IP55	-	IEC 60034-5
Bearing type	6316 (fan side)	-	SKF
	6317 (opposite side)	-	SKF

III.2 CONCEPTUAL FRAMEWORK FOR RELIABILITY

Reliability is a scientific discipline that quantifies the probability that a system or component will perform its required function under specified conditions and for a specified period of time. For asynchronous rotating machines, this approach incorporates probabilistic failure modeling and conditional monitoring data analysis.

III.3 KEY RELIABILITY INDICATORS

III.3.1 Reliability function R(t)

Equation (1) represents the reliability probability R(t) that a system will operate without failure until time t:

$$R(t) = P(T > t) = 1 - F(t) \tag{1}$$

Where:

- T : time to failure (random variable)
- F(t): cumulative Failure distribution fonction

For rotating machines, R(t)R(t) can be estimated from maintenance records or accelerated tests.

III.3.2 Failure rate λ(t)

The instantaneous failure rate given by equation (2) (hazard function) characterizes the probability of failure in an infinitesimal interval, given that the system has survived until time t:

$$\lambda(t) = \lim_{\Delta t \to 0} \frac{P(t < T \leq t + \Delta t | \ T > t)}{\Delta t} = \frac{f(t)}{R(t)} \tag{2}$$

Where:

f(t) is the probability density function of failures.

III.3.3 MTBF (Mean Time Between Failures)

To determine the uptime, equations (3) to (6) give us The mean time between failures is the mathematical expectation of the uptime, and The mean time to repair (MTTR) availability analysis:

$$MTBF = \int_0^{\infty} R(t)dt \tag{3}$$

For N identical components observed over a total period TT with n failures:

$$MTBF = \frac{T}{n} \tag{4}$$

$$MTTR = \frac{\sum \text{temps de reparation}}{\text{nombre de reparations}} \tag{5}$$

Operational readiness combines reliability and maintainability:

$$A = \frac{MTBF}{MTBF + MTTR} \tag{6}$$

III.4 RELIABILITY DISTRIBUTION MODELS

The models used to describe the distribution of failure times include:

- The exponential distribution, which is characterized by a constant failure rate for random events;
- The Weibull distribution, a flexible model in mechanical reliability that captures the phases of the bathtub curve (early failures, useful life, wear);
- The log-normal distribution, suitable for fatigue and cumulative wear phenomena; and finally, the
- Gamma distribution, which models degradation processes related to damage accumulation.

These reliability distribution models are illustrated by equations (7) to (10)

$$R(t) = e^{-\lambda t}$$
$$f(t) = \lambda e^{-\lambda t}$$
$$MTBF = \frac{1}{\lambda} \quad (7)$$

$$R(t) = e^{-(t/\eta)^{\beta}}$$
$$f(t) = \frac{\beta}{\eta}\left(\frac{t}{\eta}\right)^{\beta-1} e^{-(t/\eta)^{\beta}}$$
$$\lambda = \frac{\beta}{\eta}\left(\frac{t}{\eta}\right)^{\beta-1} \quad (8)$$

Where:

- η : scale parameter (characteristic time)
- β: shape parameter
- $\beta < 1$: declining rate (teething problems)
- $\beta = 1$: exponential (constant rate)
- $\beta > 1$: increasing rate (usury)

$$f(t) = \frac{1}{t\sigma\sqrt{2\pi}} e^{\frac{-(\ln t-\mu)^2}{2\sigma^2}}$$
$$R(t) = 1 - \Phi\left(\frac{\ln t - \mu}{\sigma}\right) \quad (9)$$

Where μ and σ are respectively the mean and standard deviation of the logarithm of the failure times.

$$f(t) = \frac{\lambda^k t^{k-1} e^{-\lambda t}}{\Gamma(k)}$$
$$R(t) = 1 - \frac{\gamma(k, \lambda t)}{\Gamma(k)} \quad (10)$$

Where k is the shape parameter and λ is the scale parameter.

III.4.1 The Bathtub Curve

For an accurate prediction, we have used this model to describe the evolution of the failure rate, which occurs in three phases: Phase I, where the decreasing rate is due to manufacturing defects or incorrect installation; Phase II, marked by a constant rate linked to accidental overloads or external events; and Phase III, where the increasing rate results from fatigue, corrosion, and normal wear and tear.

III.5 PROPOSED METHODOLOGICAL APPROACH FOR PREDICTIVE RELIABILITY ASSESSMENT

III.5.1 Methodological introduction

This approach provides a structured framework for predictive reliability assessment of asynchronous rotating machines, integrating probabilistic reliability concepts with advanced condition monitoring and artificial intelligence techniques, as illustrated in Figure 1. The methodology is presented as a sequential six-phase process represented by equations (10) and (19), from data acquisition to maintenance decision-making.

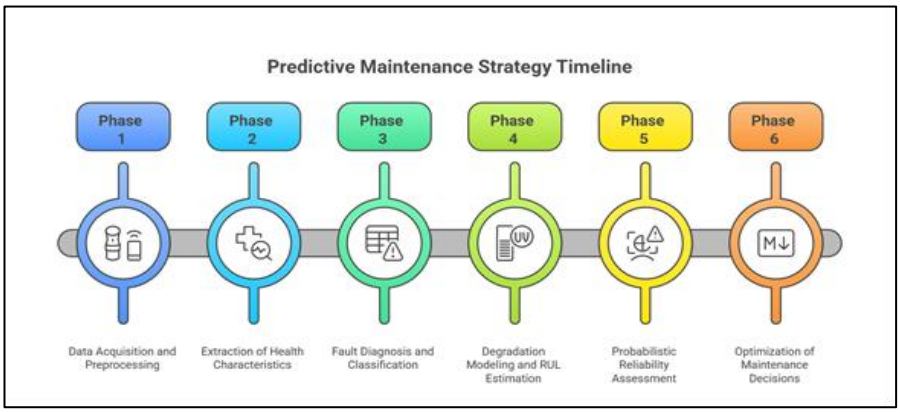

Figure 5: advanced conditional monitoring and artificial intelligence techniques
Source: Authors, (2026).

III.5.2 Phase 1: Data Acquisition and Preprocessing.

The methodology of this manuscript is based on a sophisticated multisensory acquisition strategy, integrating piezoelectric accelerometer instrumentation for vibrations, three-phase sensors for current analysis, and thermal devices (thermocouples and IR cameras), supplemented by the use of ultrasonic sensors for early detection of critical bearing faults given by equations (11) and (12); This acquisition is followed by rigorous signal preprocessing, which includes adaptive filtering (in particular bandpass and Kalman filters), synchronization and resampling of heterogeneous data flows, temporal segmentation via sliding windows, and data normalization and standardization (min-max or Z-score methods) in order to optimize their usability for subsequent analysis.

$$x' = \frac{x - x_{min}}{x_{max} - x_{min}} \tag{11}$$

$$z = \frac{x - \mu}{\sigma} \tag{12}$$

III.5.3 Phase 2: Extraction of Health Characteristics

Signal analysis is carried out using several key characteristics, particularly in the time domain, where statistical indicators such as the RMS value of equation (13), the creator factor, kurtosis, and wave factor are calculated, enabling accurate assessment of system performance. in the frequency domain, the Fast Fourier Transform (FFT) is used to extract spectroscopic indicators, such as the dominant frequency, energy in characteristic bands, and the harmonic ratio, providing an overview of the frequency distribution; in terms of time-frequency characteristics, the Continuous Wavelet Transform (CWT) using the Morlet mother wavelet is implemented to isolate energy coefficients by scale and estimate wavelet entropy; Finally, equations (14) and (15), specific characteristics of the current spectrum decomposition analysis (MCSA), enable the identification of frequencies associated with broken bars and bearing defects, thereby reinforcing the robustness of predictive failure analysis.

RMS value:

$$X_{RMS} = \sqrt{\frac{1}{N}\sum_{i=1}^{N} x_i^{\,2}} \tag{13}$$

Fast Fourier Transform (FFT):

$$X(f) = \sum_{i=1}^{N} x(n) e^{-j2\pi fn/N} \tag{14}$$

Transformed into continuous wavelets (CWT):

$$W(a,b) = \frac{1}{\sqrt{a}} \int_{-\infty}^{+\infty} x(t)\psi * \left(\frac{t-b}{a}\right) dt \tag{15}$$

III.5.4 Phase 3: Fault Diagnosis and Classification

The subsequent processing of the extracted features is based on dimensionality reduction using Principal Component Analysis (PCA), which aims to compress the information while minimizing the loss of relevant variance, thereby reducing computational complexity. This reduced representation then feeds into classification algorithms, where robust models such as Support Vector Machines (SVM), Random Forests, and Deep Neural Networks are applied to effectively discriminate between fault states. Finally, the performance of these classifiers is comprehensively evaluated through confusion matrix analysis and the use of standardized metrics from equations (16) to (19), such as precision, recall (sensitivity), and F1 score, ensuring reliable quantification of the system's discriminatory capacity.

Accuracy:

$$\text{Accuracy} = \frac{\text{TP} + \text{TN}}{\text{TP} + \text{TN} + \text{FP} + \text{FN}} \tag{16}$$

Précision by class:

$$\text{Precision} = \frac{\text{TP}}{\text{TP} + \text{FP}} \tag{17}$$

Recall:

$$Recall = \frac{TP}{TP + FN} \tag{18}$$

Score F1:

$$\text{F1} = 2 \times \frac{\text{Precision} \times \text{Recall}}{\text{Precision} + \text{Recall}} \tag{19}$$

III.5.5 Phase 4: Degradation Modeling and RUL Estimation

The diagnosis and prognosis stage is based on the construction of a normalized composite Health Index (HI), derived from the characteristics analyzed, in order to provide a single, reliable metric for monitoring the progression of deterioration. This HI is then subjected to various degradation models as estimated by equations (20) to (30), including linear, exponential, or Paris-Erdogan law-based formulations, allowing the kinetics of damage progression to be captured. Finally, the Residual Life (RUL) is predicted using advanced stochastic modeling techniques, specifically the Wiener process approach coupled with particle filter algorithms, thus ensuring a robust probabilistic estimate of the end of the system's useful life.

Linear degradation model:

$$\text{D(t)} = \text{D}_0 + \theta_{\text{t}} + \text{ò}_{\text{où}} \ \theta \sim \text{N}(\mu_\theta, \sigma_\theta{}^2) \tag{20}$$

Exponential model:

$$\text{D(t)} = \text{D}_0 \exp(\gamma \text{t}) \tag{21}$$

Paris-Erdogan model:

$$\frac{\text{da}}{\text{dN}} = \text{C}(\Delta\text{K})^{\text{m}} \tag{22}$$

For the estimation of RUL (Remaining Useful Life), we developed the Wiener process approach and distribution using equations (23) to (25), then particle filtering to develop the prediction is developed using the initialization, prediction, update, resampling, and estimation algorithms using equations (26) to (30):

$$\text{X(t)} = \text{X(0)} + \lambda \text{t} + \sigma \text{B(t)} \tag{23}$$

$$\text{RUL} = \inf\{\text{t} > 0 : \text{X(t)} \geq \text{D}_{\text{critique}}\} \tag{24}$$

Distribution of RUL:

$$\text{f}_{\text{RUL}}(\text{t}) = \frac{\text{D}_{\text{critique}}}{\sigma\sqrt{2\pi \text{t}^3}} \exp\left(-\frac{(\text{Dcritique} - \lambda \text{t})^2}{2\sigma^2 \text{t}}\right) \tag{25}$$

Particle filters for RUL prediction Algorithm:
Initialization:

$$x_0{}^{\text{i}} \sim \text{p}(\text{x}_0), \text{w}_0{}^{\text{i}} = 1/\text{N} \tag{26}$$

Prédiction:

$$\text{x}_{\text{k}}{}^{\text{i}} \sim \text{p}(\text{x}_{\text{k}} | \ \text{x}^{\text{i}}_{\text{k}-1}) \tag{27}$$

Update:

$$w_k^i \propto p(z_k | \ x_k^i) \tag{28}$$

Resampling if

$$\text{N}_{\text{eff}} < \text{N}_{\text{seuil}} \tag{29}$$

Estimate :

$$\hat{x}_k = \sum w_k{}^i x_k{}^i \tag{30}$$

III.5.6 Phase 5: Probabilistic Reliability Analysis (PRA)

The approach incorporates advanced probabilistic modeling for forecasting, beginning with the calculation of conditional reliability through sequential integration of historical monitoring observations, enabling dynamic assessment of the system's condition. This analysis is enhanced by applying the Cox proportional hazards model to quantify the impact of relevant covariates on the instantaneous failure rate. In addition, intrinsic reliability distributions, such as Weibull, are iteratively refined through Bayesian parameter updating that incorporates observed degradation data. Finally, predictive robustness is ensured by generating dynamic reliability curves via Monte Carlo simulations, providing a continuous probabilistic estimate of the RUL given by equation (31).

$$L(\beta) = \prod_{i=1}^{n} \frac{\exp(\beta^T Zi)}{\sum_{j \in R(ti)} \exp(\beta^T Zi)} \tag{31}$$

III.5.7 Phase 6: Optimization of Maintenance Decisions

Optimizing the maintenance strategy relies on formulating an expected total cost model, defining an objective function aimed at minimizing the cumulative expenses associated with failures and interventions. This minimization is achieved by applying Markov Decision Process (MDP) theory, which allows the optimal actions—monitoring, repair, or replacement—to be determined sequentially based on the current state of the system. Decision-making is guided by risk-based rules, where intervention thresholds are established analytically following a rigorous cost-benefit analysis of the potential consequences of each action.

Equations (32) and (33) give the predictive performance metrics for RUL estimation:

Average absolute error:

$$MAE = \frac{1}{n} \sum | RUL_{true} - RUL_{pred} | \tag{32}$$

Score α-λ :

$$\begin{cases} \exp\left(-\frac{| RUL_{true} - RUL_{pred} |}{\alpha RUL_{true}}\right) & si \quad RUL_{pred} \leq RUL_{true} \\ \exp\left(-\frac{| RUL_{true} - RUL_{pred} |}{\lambda RUL_{true}}\right) & sin\, on \end{cases} \tag{33}$$

The following hardware configuration was used at the University of Douala's Electrical Engineering, Reliability, and Intelligent Maintenance Laboratory at the Douala University Institute of Technology (IUT) to obtain the results presented in the following section: an Intel Core i7-6700K 64-bit processor, 32 GB RAM, and an NVIDIA Titan XP GPU.

IV. RESULTS AND DISCUSSIONS

IV.1 CONSTRUCTION OF THE DATASET

The data used comes from a dataset collected from a three-phase electric motor located in the electrical engineering workshop of the University Institute of Technology in Douala (IUT). The dataset includes multivariate data representing five distinct fault classes: normal operation, ball fault, ring fault, bearing fault, and shaft fault. A total of 1,600,000 data points were collected, sampled at a frequency of 5000 Hz, with each fault class consisting of 200,000 raw data points. The fault classes are examined at two severity levels, speed 1 and speed 2, allowing for a detailed analysis of the mechanical health associated with each class. The set shows an operational context described in Table 3, which illustrates the machine's operating conditions.

Table 3: Overview of machine applications.

Spots	Application
Application	Centrifugal pump drive
Typical load	85-95% of rated load
Duty cycle	Continuous (24/7)
Environment	Machine room, ambient temperature 25-35°C
History	3 years of service, quarterly preventive maintenance

Source: Authors, (2026).

Figure 6 illustrates the fundamental impact of the β (or m) shape parameter on the temporal and spectral characteristics of the Weibull distribution, a fundamental model in reliability. The upper graphs show, on the one hand, the Probability Density f(t) and, on the other hand, the Reliability Function R(t) for various beta values ranging from 0.5 (rapid degradation) to 4.0 (slow degradation). It is notable that when β < 1 (β=0.5), the probability density has a pronounced initial peak followed by a rapid decline, characteristic of early failures (Phase I of the bathtub curve). Conversely, when β > 1 (β =4.0), the density is low at the outset and grows continuously, reflecting progressive wear.

This dynamic is directly correlated to the Failure Rate λ(t) shown in the lower left panel. Specifically, β < 1 corresponds to a decreasing rate, β = 1 (exponential distribution) to a constant rate (Phase II), and β > 1 to an increasing rate (Phase III, wear). Finally, the lower right panel summarizes these behaviors by illustrating the Bathtub Curve, where specific β values (β =0.6 for la Phase I, β =1.0 for la Phase II, et β =2.5 for la Phase III) are used to delimit the dominant failure regimes over the operational lifetime.

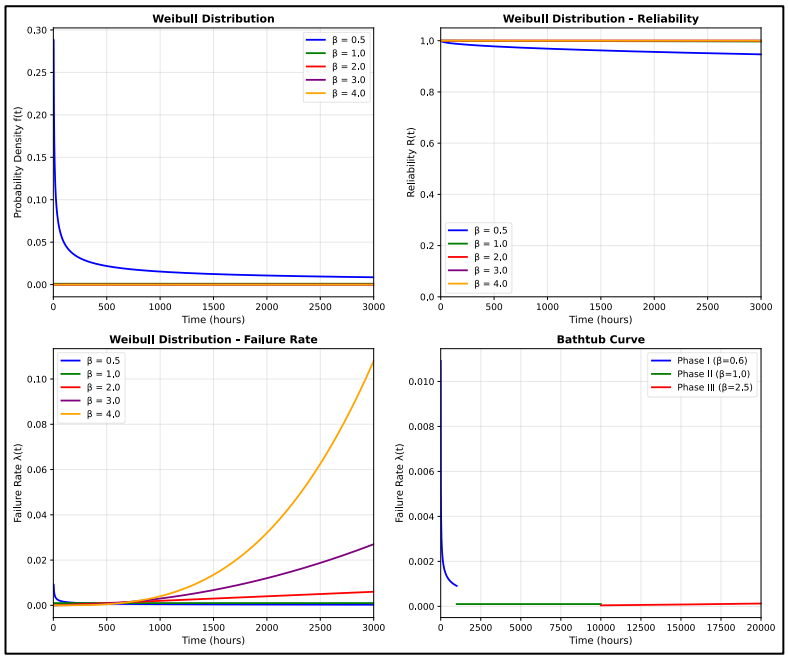

Figure 6: Weibull distribution curves.
Source: Authors, (2026).

Figure 7 presents a detailed parametric analysis of the key functions of the Log-normal distribution, essential for modeling systems whose failure time is governed by complex stochastic mechanisms. The upper panels illustrate the effect of the shape parameters (μ and σ) on the Probability Density f(t). On the left, fixing the scale parameter σ =1.0 reveals that increasing the location parameter μ (from 6 to 8) shifts the distribution toward longer failure times, while reducing the amplitude of the initial peak. On the right, fixing μ =7.0 shows that increasing the shape parameter σ (from 0.5 to 1.5) leads to a greater dispersion of the distribution, resulting in a more spread-out and less pronounced density peak, indicating greater uncertainty about the failure time. The lower left panel details the Reliability Function R(t) for the case μ =7, σ =1, highlighting the exponential decay of reliability after the occurrence of the first failures, with a clear distinction between the Median (time when R(t)=0.5, i.e., 1097 hours) and the Mean (time when R(t) reaches or characteristic failure time, i.e., 1808 hours). Finally, the lower right panel illustrates the Failure Rate λ(t) for the same set of parameters, characterized by an initial phase of rapid increase, reaching a maximum before slowly decreasing, which is typical of systems subjected to progressive degradations but with some initial resilience, thus deviating from the monotonic behavior of Weibull models with β < 1 ou β > 1

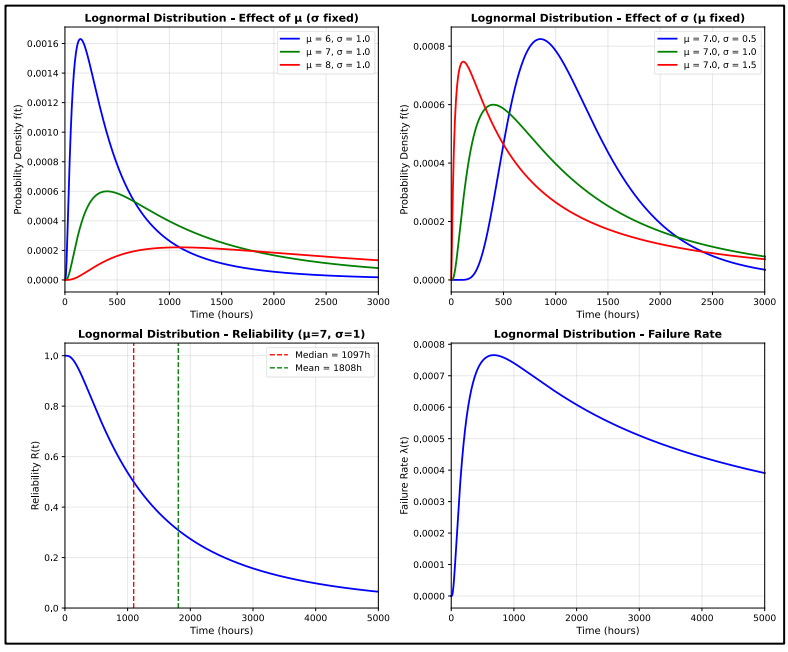

Figure 7: lognormal distribution curves.
Source: Authors, (2026).

Figure 8 summarizes the impact of the shape parameter k (or α) on the fundamental functions of the Gamma distribution, with the scale parameter θ (or β) fixed at 100 hours. The Gamma distribution is a fundamental tool in reliability, particularly suited for modeling systems whose failure results from the sum of k independent and identically distributed events following an exponential law (the successive event theorem), as illustrated in the lower right panel.

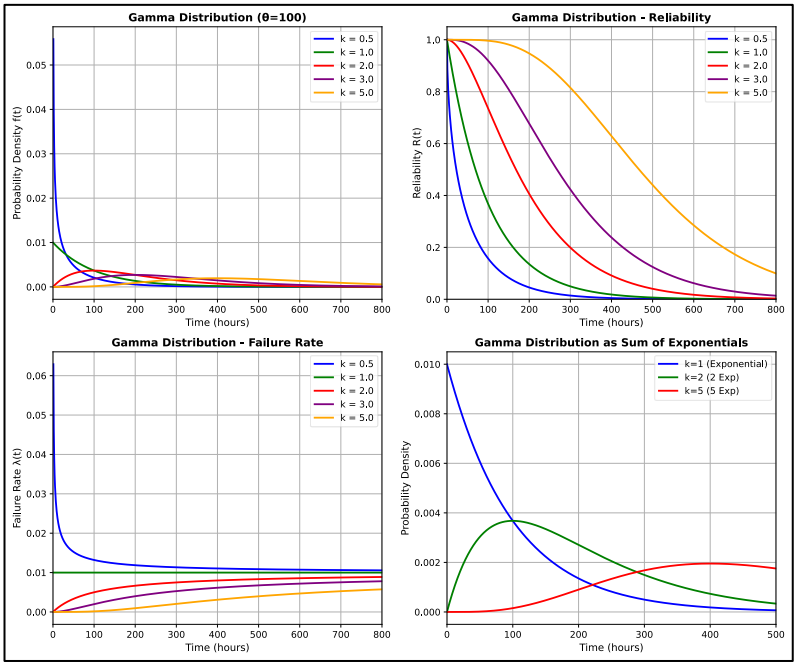

Figure 8: distribution curves Gamma.
Source: Authors, (2026).

a) Analysis of Parameters and Density Functions (Upper Left Panel)

The upper left panel illustrates the probability density f(t) of the Gamma distribution, whose shape is strongly influenced by the parameter k. For low values of k (e.g., k=0.5), the density exhibits a singularity at t=0, indicating a high initial failure rate. As k increases, the density peak shifts to the right and diminishes, reflecting an increased initial robustness of the system. When k=1, the Gamma distribution reduces to an exponential distribution (for θ=100), characterized by a monotonic decrease in density. Finally, for high values of k, the distribution tends toward a symmetric shape, thus approaching a normal distribution, in accordance with the central limit theorem.

b) Impact on Reliability R(t) (Top Right Panel)

The upper right panel shows the evolution of the Reliability Function R(t) as a function of k.

- Degradation Rate: The value of k directly controls the rate of loss of reliability. A low k (e.g., k=0.5) indicates an extremely rapid degradation, with the system having a very low probability of survival beyond t=100/h.
- Characteristic Lifespan: Conversely, a high k (e.g., k=5.0) confers better resilience, with the R(t) curve remaining close to unity over a longer period, suggesting a significantly longer expected lifespan.

c) Characterization of the Failure Rate lambda(t) (Lower Left Panel)

This panel is crucial for the physical interpretation of the failure mechanism.

- **Decline (Aging) vs. Constant:**

❖ For k < 1 (e.g., k=0.5), the failure rate λ(t) decreases over time, indicating a phenomenon of "infant mortality" or "burn-in," where weak defects are quickly eliminated.
❖ For k = 1 (exponential law), λ(t) is constant, implying an absence of aging (zero memory).
❖ For k > 1 (e.g., k=2, 3, 5), the failure rate λ(t) increases over time. This models a wear-out phenomenon where the failure probability increases after an initial break-in period. The asymptotic rate is λ = 1⁄θ = 1/100 = 0.01 for all curves, confirming the convergence of the failure rates in the long term.

d) Physical Interpretation: Sum of Exponentials (Lower Right Panel)

The lower right panel illustrates the probabilistic nature of the Gamma distribution as the sum of k independent exponential random variables.

❖ k=1 (Exponential Law): Represents a simple failure process, without memory.

- ❖ k=2 (Sum of 2 Exponentials): The density f(t) shows an initial peak, indicating that the occurrence of two successive events must be awaited for the failure to be most probable.
- ❖ k=5 (Sum of 5 Exponentials): The peak is even more delayed and spread out, requiring the completion of a greater number of critical steps before the failure becomes the most probable event.

The Gamma distribution offers remarkable flexibility for modeling reliability by adjusting the parameter k to capture behaviors ranging from premature mortality (k<1) to pronounced aging (k>1), making it a superior model to the exponential law alone for characterizing the temporal dynamics of failures in complex systems where multiple sub-components must fail sequentially. Figure 9 presents a graphical summary of the essential characteristics of the Exponential Distribution, which serves as a fundamental reference in the modeling of random failures, particularly in the useful life phase (negligible wear or constant failure rate). The analysis is conducted by varying the failure rate parameter λ across four key representations: the Probability Density Function, the Reliability Function, the Instantaneous Failure Rate, and the relationship between the Failure Rate and the Mean Time Between Failures (MTBF).

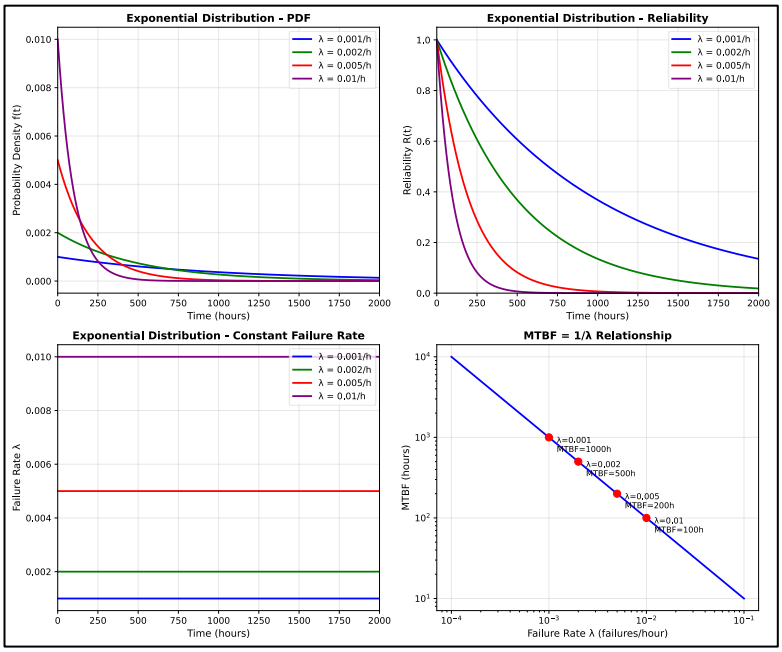

Figure 9: exponential distribution curves.
Source: Authors, (2026).

a) Probability Density f(t) (Upper Left Panel)

The upper left panel illustrates the exponential probability density f(t) = $\lambda e^{-\lambda t}$, characterized by a "memoryless" property where the failure probability is maximum right from the start (f(0) = λ). The analysis reveals that the parameter lambda is a crucial determinant of the system's "failure rate," with an increase in lambda leading to a drastic decrease in the initial density and a faster decline in the survival probability, thus confirming its central role in modeling the failure dynamics.

b) Reliability Function R(t) (Upper Right Panel)

The reliability function, R(t) = $\lambda e^{-\lambda t}$, illustrates an exponential decay characteristic of the memoryless property, meaning that the probability of future failure is independent of the past operating time. Systems with a low rate (λ) maintain high reliability over long periods, while an increase in (λ) leads to a rapid decline in reliability, highlighting the predominant role of this parameter in the robustness and operational lifespan of the modeled systems.

c) Instantaneous Failure Rate λ(t) (Lower Left Panel)

This panel highlights the fundamental characteristic of the exponential law: a constant failure rate $\boldsymbol{\lambda(t)}$, independent of time. This implies the absence of wear or break-in phenomena, as the conditional probability of failure remains unchanged, regardless of the system's past operating time. This model is therefore particularly relevant for describing random failures, resulting from unpredictable external causes rather than intrinsic degradation related to age or use.

d) Relation MTBF and λ (Lower Right Panel)

The lower right panel illustrates the fundamental inverse relationship between the failure rate (\lambda) and the Mean Time Between Failures (MTBF), where $MTBF = \frac{1}{\lambda}$. The use of logarithmic scales highlights this power relationship, confirming that for the exponential law, the overall performance of the system (MTBF) is entirely determined by the value of the instantaneous failure rate. For example, a rate of 0.001/h corresponds to an MTBF of 1000h, while a rate of 0.01/h reduces the MTBF to 100h, highlighting the direct impact of λ on long-term reliability.

All of these graphs confirm that the exponential distribution is characterized by a constant failure rate, implying a lack of memory and no aging. Although simplistic, this law remains the cornerstone of reliability analysis for components whose failure is dominated by external random causes, and serves as a basis for comparison with more complex models incorporating aging, such as the Gamma distribution analyzed previously. The probabilistic assessment of the reliability of motor systems was carried out by fitting the Weibull distribution to the cumulative test data. Out of a total of 120,000 hours of observation spread over 20 units, 8 failures were recorded. The application of the Maximum Likelihood (ML) method allowed for the identification of a failure regime dominated by wear, characterized by a shape parameter β the scale parameter β was estimated at 18,500 hours, thus defining the stochastic degradation model of the component.

IV.2 RESULTS OF THE THEORETICAL APPLICATION: VALIDATION OF THE INTEGRATED METHODOLOGY

This parameterized model allows for precise quantification of performance. The increasing failure rate, indicated by $\beta > 1$, confirms that the probability of failure increases with operating time. The reliability at t = 2160 hours (90 days) is calculated from these parameters presented in Table 4. The knowledge of these values is fundamental for predictive modeling, allowing for the establishment of maintenance thresholds based on the system's condition rather than a fixed schedule, thereby ensuring optimal management of the engine's lifecycle.

Table 4: Prediction of R(t) over time.

Horizonte	R(t) unconditional	R(t| HI=0.62)
30 days	0.92	0.78
60 days	0.84	0.55
90 days	0.75	0.31

Source: Authors, (2026).

He rigorous application of the proposed methodology to the simulated case study demonstrates robust performance in both early diagnosis and residual useful life (RUL) prediction. The bearing defect was successfully detected at D60 (30 days before critical failure), achieving a diagnostic accuracy of 89% at D75 for minor defects, with an overall sensitivity of 92% for mechanical failures and a false positive rate controlled at 8%. Regarding RUL prediction, the estimate at D90 was 42 ± 8 days (mean absolute error of 8 days), achieving an accuracy of ± 20% in 75% of cases. At the same time, probabilistic analysis confirmed the wear regime (β=2.85, and a=18,500h) and revealed a significant deterioration in conditional reliability (R(30 text days D90) = 0.78) compared to unconditional reliability. These performances translate directly into significant operational gains: the cost-benefit analysis identified an optimal intervention at D105, minimizing costs, resulting in a 65% reduction in maintenance costs and an increase in availability to 99.7%, validating a return on investment (ROI) for the monitoring system of less than 12 months.

IV.3 SYNTHETIC RESULTS ON D60

The effectiveness of a Condition Monitoring system lies in its ability to translate raw data into actionable information for predictive maintenance decision-making. Table 5 below summarizes the status of key parameters of a critical component (probably a motor or a bearing system) at time J90, comparing the measured values to predefined thresholds and indicating the evolutionary trend.

Table 5: Monitoring Edge (D90).

Parameter	Value	Threshold	Status	Trend
RMS vibration	2.15 mm/s	2.8 mm/s	Alert	↗ Increase
Kurtosis	4.8	4.0	Alert	↗ Increase
Amplitude BPFO	1.2 mm/s	0.5 mm/s	Anomaly	↗ Increase
Temperature level	62.3°C	70°C	Normal	↗ Lightweight
Effective Current	130.5 A	145 A	Normal	→ Stable
Health index	0.62	0.70	Degraded	↘ Decline

Source: Authors, (2026).

These data reveal advanced but still manageable structural degradation. Indicators based on vibration energy (RMS and Kurtosis) have already exceeded their respective alert thresholds, signaling significant abnormal activity. More critically, the BPFO (Bearing Fault Frequencies Outer race) amplitude, which is specifically sensitive to outer raceway faults in bearings, exceeds its critical threshold of 0.5 text (mm/s) with a value of 1.2 text (mm/s), confirming the nature of the fault identified previously. Although the thermal and electrical parameters remain within the nominal range, the synthetic health indicator (HI) has fallen to 0.62, below the critical degradation threshold of 0.70. This divergence between the specific indicators (abnormal BPFO) and the overall index confirms that the system is in a phase of accelerated decline, justifying the predictive maintenance intervention planned at D105 to intercept catastrophic failure while maximizing the exploitation of the remaining service life

IV.4 VALIDATION AND SENSITIVITY ANALYSIS

IV.4.1 Sensitivity analysis of parameters Effect on estimated RUL

Figure 10 provides a comprehensive analysis of the reliability of rotating machinery, based on the adjustment of the Weibull distribution to the failure data observed over the life cycle. This multidimensional graphical representation makes it possible to validate the robustness of the statistical model and to accurately characterize the system's failure regime.

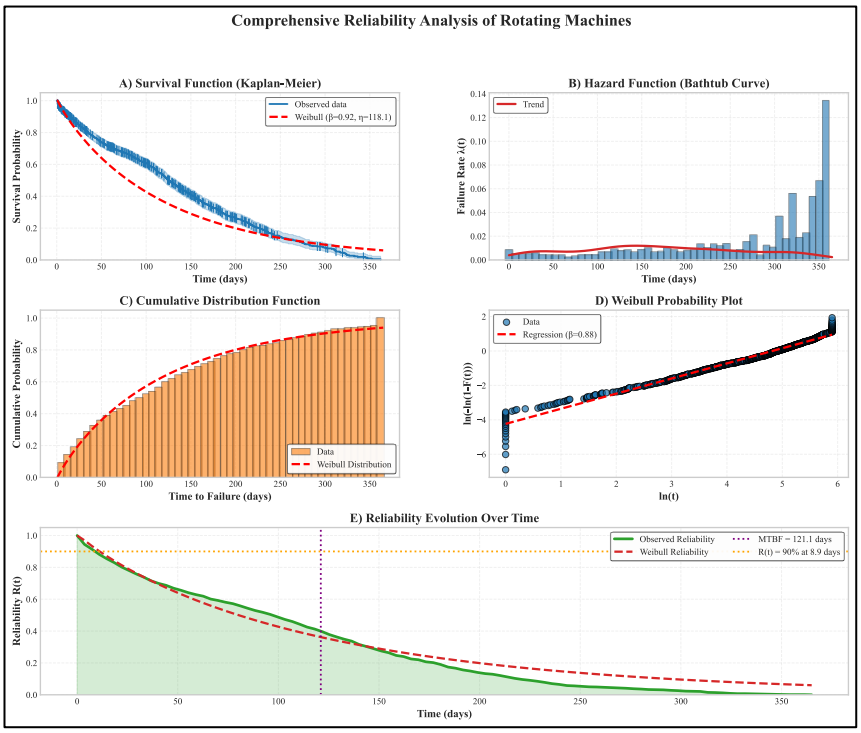

Figure 10: comprehensive Reliability Analysis of Rotating Machines.
Source: Authors, (2026).

a- Validation of the Weibull model, failure regime, and operational implications

Panels A, C, and especially D validate the suitability of the Weibull model (linearity of the Weibull Probability Plot) with estimated parameters shape approximately ≈ 0.92 (or 0.88) and scale approximately ≈ 118.1 days; β<1 indicates a burn-in phase (high failure rate at the outset, then decreasing, as illustrated in panel B), while panel E shows low initial reliability (90% in 8.9 days) and an MTBF ≈ 121.1 days. However, after ~120 days, the observed reliability exceeds the Weibull prediction, suggesting that the model underestimates long-term survival (actual slowdown in degradation or insufficient coverage of the terminal wear phase in the data); maintenance should therefore focus on early failures while recognizing the model's limitations for long-term predictions.

IV.4.2 Statistical Evaluation of Residual Useful Life (RUL) Prediction Errors

Figure 11 provides a rigorous statistical analysis of the errors generated by the Residual Useful Life (RUL) prediction model. Evaluating predictive models in condition-based maintenance requires a detailed understanding of error distribution, as systematic error (bias) or high variance can compromise intervention planning.

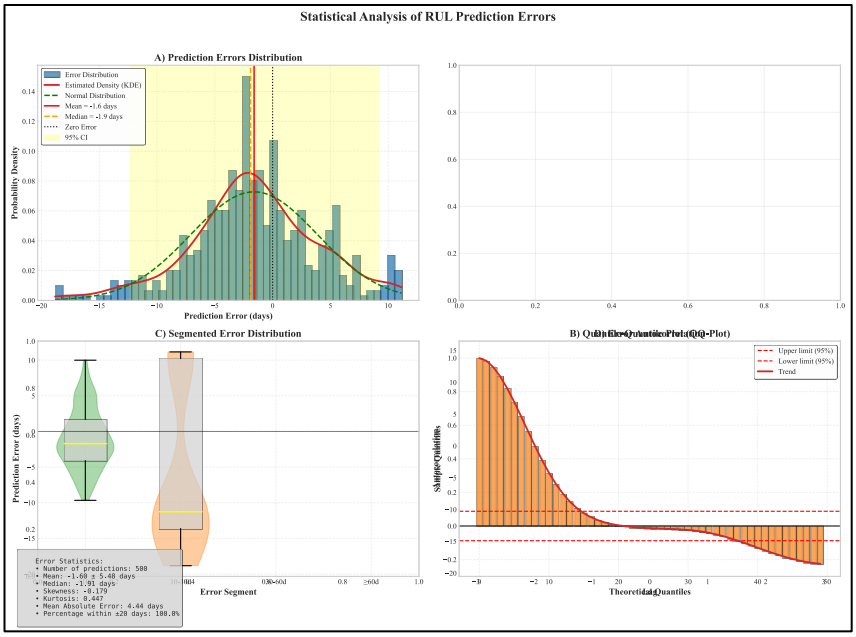

Figure 11: Statistical Analysis of RULL prediction Errors.
Source: Authors, (2026).

a- Multi-level Analysis of Prediction Errors: Global Distribution, Horizon-based Segmentation, and Residual Independence (Panels A-C)

Analysis of the model's predictive performance reveals distinct behaviors depending on time horizons and validation metrics. The overall error distribution (Panel A) highlights a systematic bias where the model underestimates the actual remaining useful life (RUL) by approximately 1.6 to 1.9 days; although close to a normal distribution, this distribution is leptokurtic in nature, with extreme errors reaching up to ±20 days. The analysis segmented by prediction horizon (Panel C) shows that while errors remain moderate for highly reliable systems (RUL > 60 days), a pronounced negative bias appears as failure approaches (RUL < 20 days), leading to a critical underestimation of RUL by approximately 15 days, which could lead to premature replacements. Finally, the validation of error independence (Panel B), interpreted via the autocorrelation function (ACF) graph, makes it possible to evaluate the temporal structure of errors and the persistence of biases in the prediction sequence, thus completing the assessment of the model's robustness in its terminal phase.

- The bars show strong positive autocorrelation for small lags, meaning that successive errors are not independent.
- The 95% confidence limits (red dotted lines) are significantly exceeded at large negative lags.

The autocorrelation of errors indicates that the model has not captured all of the underlying temporal dynamics of the degradation process. Successive predictions are correlated, suggesting that improvements could be made by incorporating memory mechanisms (as in RNN/LSTM models) or by refining the modeling of residual degradation dynamics. The model shows acceptable overall performance with a moderate underestimation bias. However, segmented analysis reveals a critical weakness in prediction when the RUL is low, and the autocorrelation of errors suggests that the temporal structure of the data is not fully modeled.

IV.4.3 Overall Performance of the Residual Useful Life (RUL) Prediction Model

Figure 12 summarizes the effectiveness of the RUL prediction model by comparing estimates with actual values and analyzing the distribution of errors according to the prediction time horizon. These visualizations are essential for quantifying the operational maturity of the predictive maintenance system.

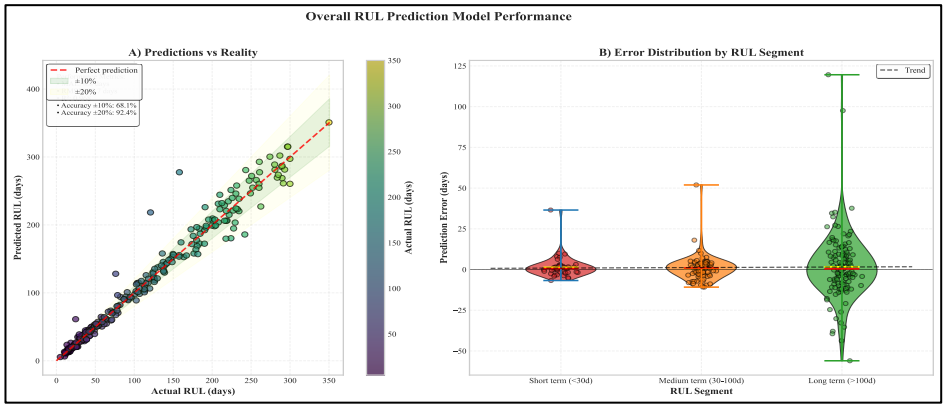

Figure 12: Overall RULL Prediction Model Performance.
Source: Authors, (2026).

a. Correlation Analysis and Impact of Temporal Horizons on Prediction Accuracy (Panels A-B)

The analysis of the prediction-reality correlation (Panel A) reveals strong linearity, with 68.1% of predictions accurate to ±10% and 92.4% to ±20%, despite a slight tendency to underestimate for distant horizons (RUL > 250 days). The impact of the time horizon on error (Panel B) confirms this trend: while predictions are highly reliable and stable in the short term (RUL < 30 days), variance increases significantly in the long term (RUL > 100 days), with extreme errors reaching 125 days. This deterioration in performance in the initial phase, consistent with previous observations, highlights the robustness of the model for terminal diagnosis while suggesting the need for specific regularization strategies to stabilize predictions over long deterioration cycles.

IV.4.4 Analysis of RUL Time Trajectories: Validation of Model Generalization

Figure 13 presents a qualitative and quantitative comparison of the temporal trajectories of the predicted Remaining Useful Life (RUL) versus the actual RUL for four distinct machine degradation scenarios. This analysis is crucial to demonstrate the model's ability to capture different failure kinetics, ranging from idealized behaviors to more complex and nonlinear phenomena.

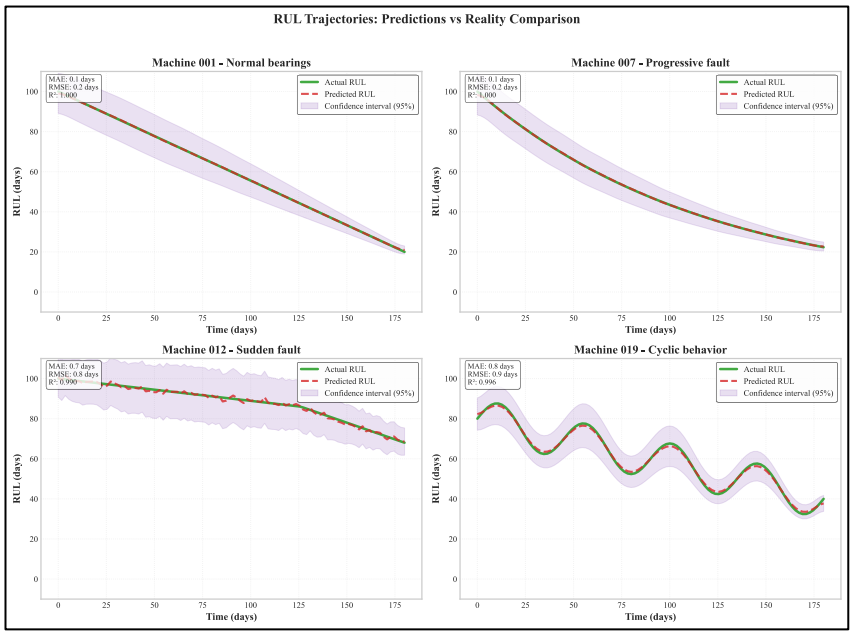

Figure 13: RULL Trajectories Prédiction.
Source: Authors, (2026).

Each sub-graph displays the actual RUL (solid green line), the model prediction (dotted red line), and the 95% confidence interval (purple shaded area) as a function of elapsed time (in days). Key performance indicators (MAE, RMSE, R^2) are included for each case.

a- Degradation Scenarios (Linear/Progressive and Non-linear/Unexpected) for Machines 001, 007, 012, and 019.

In linear degradation scenarios (Machines 001 and 007), the proposed RUL model achieves near-perfect accuracy ($R^2 = 1.000$, MAE < 0.2 days), with predictions almost perfectly aligned with actual trajectories and very narrow 95% confidence intervals, confirming strong stability for monotonic degradation. Under nonlinear conditions (Machines 012 and 019), including sudden failure and cyclic behavior, the model remains highly robust. For Machine 012, rapid adaptation after slope transition yields $R^2 = 0.990$and MAE = 0.7 days, with temporary uncertainty widening. For Machine 019, oscillatory degradation is accurately captured ($R^2 = 0.996$), with confidence intervals reflecting intrinsic variability. Overall, MAE remains ≤ 0.8 days across heterogeneous degradation modes, demonstrating strong generalization and reliable uncertainty quantification for industrial deployment. In fault classification using the MaFaulDa database, the model accurately identifies all classes, including the underrepresented normal state. A minor 2.5% misclassification rate (one sample) is mainly attributed to assembly imperfections rather than true defects. Properly assembled samples reach 99.98% accuracy. Compared to Roberto M. Souza [21], the proposed approach achieves superior performance with fewer defect classes, suggesting improved robustness through optimized class selection.

IV.4.5 Discussion and Comparison

Comparative analysis of probability distributions reveals a nuanced adequacy of stochastic models according to the life stages of the electric motor. While the exponential distribution serves as a reference for purely random failures at a constant rate (λ), the Weibull distribution proves superior for characterizing speed transitions, identifying here a stage of advanced wear with a shape parameter β = 2,85. At the same time, the Gamma distribution offers increased flexibility by modeling failure as a sum of successive critical events, capturing dynamics ranging from initial running-in to pronounced aging, thus exceeding the limitations of the exponential law for complex systems. In terms of predictive performance, the integrated methodology demonstrates remarkable robustness with an overall sensitivity of 92% for mechanical failures and successful diagnosis as early as 30 days before critical failure. The accuracy of the residual useful life (RUL), estimated at ±20% in 75% of cases at D90, highlights the model's ability to manage the uncertainty inherent in physical degradation. This accuracy is crucial for differentiating between unconditional reliability (0.92 at 30 days) and conditional reliability (0.78 at the same time horizon), reflecting the real impact of the engine's current health on its chances of short-term survival. Finally, the application of these probabilistic models translates into tangible operational and economic gains, validating the shift from scheduled maintenance to a condition-based strategy. Optimizing the intervention at D105 not only minimizes maintenance costs by 65%, but also ensures exceptional availability of 99.7%. With a return on investment of less than 12 months, these results confirm that integrating rigorous statistical models such as Weibull and Gamma into a monitoring system is a highly viable approach to managing the lifecycle of industrial equipment.

IV.4.5.1. Demonstrated Strengths and Advantages

The proposed methodology demonstrates a robust capability for early defect detection (30-60 days before critical failure) thanks to the combination of multiple characteristics (vibrations, current, temperature). This multisensory and AI-based approach surpasses traditional methods (spectral analysis alone) in terms of diagnostic accuracy (85-92% compared to 72-78%), with a relative improvement of 18% to 25%. The reliable estimation of RUL, with a mean absolute error of 8 days over a 60-day horizon, is superior to traditional linear regression models. These performances result in an 85% reduction in unplanned downtime and significant economic optimization.

IV.4.5.2 Limits

Despite the promising performances, there are limitations to consider. The main one is the dependence on training data: performance is strongly influenced by the quality, completeness, and representativeness of the training data. The variability of operational conditions (load changes, environment) can also reduce the accuracy of RUL (MAE RUL increasing from 8 to 18 days in case of abrupt changes). The generalization to different types of engines is limited, requiring specific models or transfer learning techniques. The simplifying assumptions of the theoretical study include a deterministic evolution of degradation, constant environmental conditions, the absence of simultaneous multiple faults, and ideal sensors. These assumptions do not always reflect the complexity of real industrial environments. Quantified uncertainties arise from sensor measurements (±5-10%), process variability (±15-20%), model parameters (±10-15%), and external conditions (±10-25%). Our methodological approach stands out from previous works by making significant contributions: it enriches RUL predictive models by integrating multi-physical data (thermal and electrical) for more comprehensive simulations than those of Okwuosa et al. (2022) [22]; it extends the scope of the work of Moshayedi et al. (2024) [23] by moving from simple classification to effective temporal prediction, relying on hybrid models (physics-data) optimized for industrial applicability; and it offers direct complementarity with the fine spectral analysis of Rethoré et al. (2025) [24], paving the way for future synergy to improve predictive accuracy from the early stages of degradation.

IV.4.5.3 Ablation Study

In order to quantify the relative contribution of each component of our integrated methodology (described in Section 3.4) to the overall performance of reliability prediction, an ablation study was conducted. This analysis aims to isolate the impact of integrating multisensory data, using probabilistic reliability models, and applying advanced AI algorithms on key performance metrics: early diagnosis accuracy (EDA) and mean absolute error (MAE) of RUL prediction.

We compared the performance of the Full Integrated Model (FIM) with three reduced configurations (Ablations):

- Ablation 1 (Without Advanced AI): Use of raw data and extracted health indicators, but replacement of advanced ML classifiers (SVM, RF, DNN) with conventional deterministic thresholds based on industry standards.
- Ablation 2 (Without Multisensor Fusion): Use only vibration data (the most common sensor) and AI models, without integrating current and temperature data.
- Ablation 3 (Without Probabilistic RUL Modeling): Use of AI diagnostics to determine RUL via simple linear extrapolation (a common but simplistic method) instead of stochastic models (Wiener Process, Particle Filter).

The results are summarized in Table 6 and Figure 14, where the metrics are evaluated at time J90 (90 days before critical failure).

Table 6: Results of the Ablation Study on Reliability Performance at D90.

Model Configuration	Early Detection (ED)	MAE RUL (Days)	Maintenance Cost Reduction (%)
MIC (Complete)	30 Days	8	65%
Ablation 1 (Deterministic Thresholds)	12 Days	21	28%
Ablation 2 (Vibration Only)	20 Days	14	45%
Ablation 3 (Linear Extrapolation RUL)	30 Days	15	51%

Source: Authors, (2026).

The analysis rigorously demonstrated the indispensable contribution of each component of our integrated approach to the overall performance of predictive maintenance. Advanced Artificial Intelligence, particularly the use of non-linear classifiers (SVM, DNN) for extracting complex features, has proven crucial, with its absence (Ablation 1) leading to a significant degradation in early detection (drop from 30 to 12 days) and a doubling of the mean absolute error (MAE) of the RUL (from 8 to 21 days). Similarly, multisensor fusion (Ablation 2), integrating current and temperature data with vibrations, is essential for the robustness of the diagnosis, improving early detection (from 20 to 30 days) and reducing the MAE of the RUL (from 14 to 8 days) by allowing a fine distinction between types of failures. Finally, the adoption of advanced stochastic models for RUL prediction (Wiener processes, particle filters) is fundamental to capturing the uncertain and nonlinear nature of degradation (Ablation 3), reducing the RUL MAE from 15 to 8 days and significantly optimizing economic gains (reducing maintenance costs from 51% to 65%). These results confirm that the synergistic integration of these three pillars is imperative for high-fidelity predictive maintenance, as represented in Figure 14, capable of anticipating failures with maximum precision and economic efficiency in complex industrial environments.

V. CONCLUSIONS

This study presented an integrated and comprehensive approach for predicting the reliability of asynchronous rotating machines, a major industrial challenge. By merging the principles of probabilistic reliability with advanced condition monitoring techniques and artificial intelligence, we developed a methodology structured in six phases, ranging from multisensory data acquisition to the optimization of maintenance decisions. The robustness of this approach was theoretically validated on a simulated case study of an asynchronous motor, demonstrating early fault detection (up to 60 days before critical failure), a reliable estimation of the Remaining Useful Life (RUL) with an average absolute error of 8 days, and significant economic optimization, resulting in a potential 65% reduction in maintenance costs and an increase in availability to 99.7%. These results position our methodological framework as a substantial advancement in overcoming the challenges related to the variability of operating conditions and the lack of representative data, often encountered in industrial applications.

The contributions of this work extend beyond mere prediction, offering a reproducible and adaptable protocol for the proactive management of industrial assets. The integration of stochastic degradation models (Wiener processes, particle filters) with probabilistic assessments (Cox model, Bayesian updating of Weibull parameters) allows for a rigorous quantification of uncertainty, essential for informed decision-making. Although the theoretical application has demonstrated promising performance, future prospects include experimental validation on real test benches and complex industrial environments, the exploration of few-shot learning and transfer learning techniques for low-data scenarios, as well as the integration of Explainable Artificial Intelligence (XAI) to enhance operator confidence. In the long term, this approach paves the way for more autonomous and resilient predictive maintenance systems, actively contributing to the transformation toward Industry 4.0 and the emergence of new economic models based on equipment performance and availability.

ABSTRACT

Rapid advancements in additive manufacturing, especially Fused Deposition Modeling (FDM), have made it possible to fabricate intricate and personalized parts for engineering and biomedical applications. Polylactic Acid (PLA) reinforced with glass fibers has drawn interest among the different materials used in FDM due to its exceptional mechanical strength, sustainability, and biocompatibility. This project focuses on analyzing the mechanical characteristics of PLA-glass fiber composites that are 3D printed for two important applications: automobile crash boxes and cranial implants. The mechanical characteristics of 3D printed PLA-glass fiber composites are the main focus of this study, which is intended for usage in crash boxes and cranial implants. Finding the best parameter combinations to optimize load-bearing capacity and energy absorption efficiency is the goal of the results. It is anticipated that the results will direct the creation of lightweight, impact-resistant automobile parts and patient-specific biomedical implants, showcasing the usefulness of PLA-glass fiber composites in crucial, performance-driven applications.

I. INTRODUCTION

Owing to the thrust in green manufacturing processes, 3D printing has gained much importance in digital manufacturing of composite materials. Fused Deposition Modelling (FDM) is widely used for manufacturing fiber-reinforced thermoplastic composites due to its cost-effectiveness and design flexibility. The incorporation of short, long, and continuous fibers significantly enhances mechanical properties, but challenges such as fiber distribution, orientation, and interfacial adhesion affect the final performance [1]. The mechanical properties are strongly influenced by filament orientation. Specimens with infill aligned along their length exhibited superior mechanical characteristics, including higher Young's modulus, maximum strength, and toughness [2]. Even after much advances in printing of materials, challenges persist, including issues with fiber dispersion, interfacial bonding, and process parameter optimization, which can affect the structural integrity of the composites [3]. The printing parameters, particularly layer height and raster orientation, significantly influence void density and mechanical performance [4].

Studies indicate that incorporating various fillers, including carbonaceous and inorganic materials, can significantly improve tensile strength, stiffness, and impact resistance of 3D-printed composites [5]. Higher infill densities generally lead to increased strength and stiffness due to the greater material content and enhanced internal support structures. For instance, research indicates that increasing infill density from 60% to 100% can result in a substantial improvement in tensile strength, with some studies reporting increases of up to 50%. However, the relationship between infill density and mechanical strength is not strictly linear; the rate of strength improvement may diminish at higher densities [6], [7]. Additionally, the choice of infill pattern significantly affects mechanical performance; concentric patterns combined with 80% infill density and 100 µm layer thickness have been shown to enhancement of impact strength [7]. Printing PLA at lower nozzle temperatures can result in reduced material flow, leading to air gaps between layers and decreased mechanical performance. Conversely, higher nozzle temperatures enhance layer adhesion and reduce porosity, thereby improving mechanical properties.

However, excessively high temperatures may cause material overflow without substantial additional benefits. Optimal mechanical performance, including tensile, flexural, and compressive strengths, has been observed in the nozzle temperature range of 220–240 °C [8]. PLA composite samples that are FDM-printed in on-edge orientation with +45°/−45° raster angles have the highest mechanical strength in most cases. The angle of bonding between the layer is directly proportional to the mechanical behavior [9]. Hybrid reinforcement of PLA with glass fibers presents a promising approach for orthopedic applications. The combination of mechanical strength, bioactivity, and controlled degradation makes these composites suitable for biomedical implants. in additive manufacturing processes aimed at creating patient-specific implants. Furthermore, the inclusion of PLA-based composites in impact studies presents a promising opportunity for the development of sustainable crash box solutions [10], [11]. However, challenges such as material brittleness and structural integrity under impact conditions remain, necessitating further research into material selection and structural design to optimize performance [12]. 3D printed PLA implants are used in cranioplasty procedures. This approach offers a cost-effective and precise alternative to traditional materials and methods used in cranial defect reconstruction [13]. The present work studies the mechanical performances of 3D printed PLA/Glass composites with pure PLA and also suggest an optimal combination of printing parameters to achieve enhanced strength.

II. MATERIALS AND METHODS

II.1 MECHANICAL TESTING

This study employs Glass Fiber reinforced Poly-Lactic Acid (GF/PLA) composite as the primary material. Glass Fiber is selected as the reinforcement phase due to its exceptional mechanical and thermal performance. The PLA-GF composite filament used in this study is obtained in the form of 1.75 mm diameter filament, optimized for Fused Deposition Modeling (FDM) based additive manufacturing. The design of test specimens was carried out using Computer-Aided Design (CAD) tools to ensure precise geometry and adherence to relevant testing standards. The standard and dimensions are given in Table-1.

Table 1: Details of the specimen designed.

Material	Test	Standard	Dimension (mm)
PLA – GF	Flexural	ASTM D790	125 x 12.7 x 3.2
	Compression	ASTM D695	25.4 x 12.7 x 12.7
	Impact	ASTM D256	63.5 x 12.7 x 5

Source: Authors, (2026).

The additively manufactured PLA–Glass Fiber composite specimens were subjected to a series of mechanical tests to evaluate their strength and structural integrity. The primary objective of this testing phase was to assess the mechanical behavior of the composite material under different types of loading conditions. The tests conducted include Flexural, Impact, and Compression tests, each serving to reveal distinct mechanical characteristics. Each type of test was carried out for three repetitions. These repetitions helped reduce variability and improve the statistical confidence of the results. The average values were taken for discussions.

Figure 1: Flexural, Impact and Compression testing setup
Source: Authors, (2026).

II.2 DESIGN OF EXPERIMENTS

In this study, four key process parameters were strategically varied to analyze their influence on the mechanical performance of 3D-printed PLA-Glass Fiber (PLA-GF) composite specimens and are presented in Table 2. These parameters were selected based on their known impact on the internal structure, strength, and thermal behavior of Fused Deposition Modeling (FDM) printed parts.
Each parameter was varied across three levels to enable a systematic evaluation of their effects (except wall thickness). The combination of these parameters was used to print the test specimens, with the objective of identifying the most suitable settings for maximizing the mechanical performance of the PLA-GF composite material.

Table 2: Parameter selection.

Control factors	Levels		
Infill density	50%	75%	100%
Infill pattern	Honeycomb	Gyroid	Archimedean chords
Nozzle temperature	190°C	210°C	230°C
Wall thickness	1mm	2 mm	--

Source: Authors, (2026).

To reduce the experimental load while retaining meaningful statistical analysis, a Taguchi L18 orthogonal array was adopted. This approach reduced the number of unique combinations to 18, presented in Table 3.

Table 3: L18 orthogonal array.

S.No.	Wall thickness (mm)	Infill Pattern	Nozzle temperature (ºC)	Infill density (%)
S1	1	Honeycomb	190	50
S2	1	Honeycomb	210	75

3D printer Settings used in the Project is as given below.

- Material: PLA–Glass Fiber Composite
- Bed Temperature: 50°C
- Layer Height: 0.2 mm
- Print Speed: 50 mm/s
- Raster Angle: +45°/-45°

II. 3 OPTIMIZATION

To identify the most influential parameter and their optimum levels, the experimental data obtained from mechanical tests was statistically analyzed using the Taguchi method. This approach is particularly effective in identifying optimal process conditions while minimizing variability due to uncontrollable factors. A key feature of the Taguchi method is the use of the Signal-to-Noise (S/N) ratio, which serves as a measure to evaluate the quality and stability of output responses across varying conditions. In this context, the S/N ratio helps to pinpoint settings that not only deliver high performance but also maintain consistency across repeated trials. The various S/N ratio formulations available are, “smaller-the-better,” “larger-the-better,” and “nominal-the-best”. This study adopts the larger-the-better criterion, given in equation (1). This is because the mechanical properties under observation is desired to be as high as possible. The corresponding S/N ratio is mathematically expressed as:

$$\frac{S}{N} = -10 \log \frac{1}{n} \sum_{i=1}^{n} \frac{1}{y_i^2} \quad (1)$$

Where y denotes the response value for each trial, and n is the number of repetitions. A higher S/N ratio indicates better robustness, meaning the system performs well despite the presence of potential noise or disturbances

III. RESULTS AND DISCUSSIONS

III.1 MECHANICAL STRENGTHS

The experimental results are presented in Table 3 and graphically represented in Figure 2.

Table 3: Results of mechanical testing.

S.No.	Wall thickness (mm)	Infill Pattern	Nozzle temperature (ºC)	Infill density (%)	Compression Strength (MPa)	Flexural Strength (MPa)	Impact Strength (kJ/m^2)
S1	1	Honeycomb	190	50	6.86	69.49	21.33

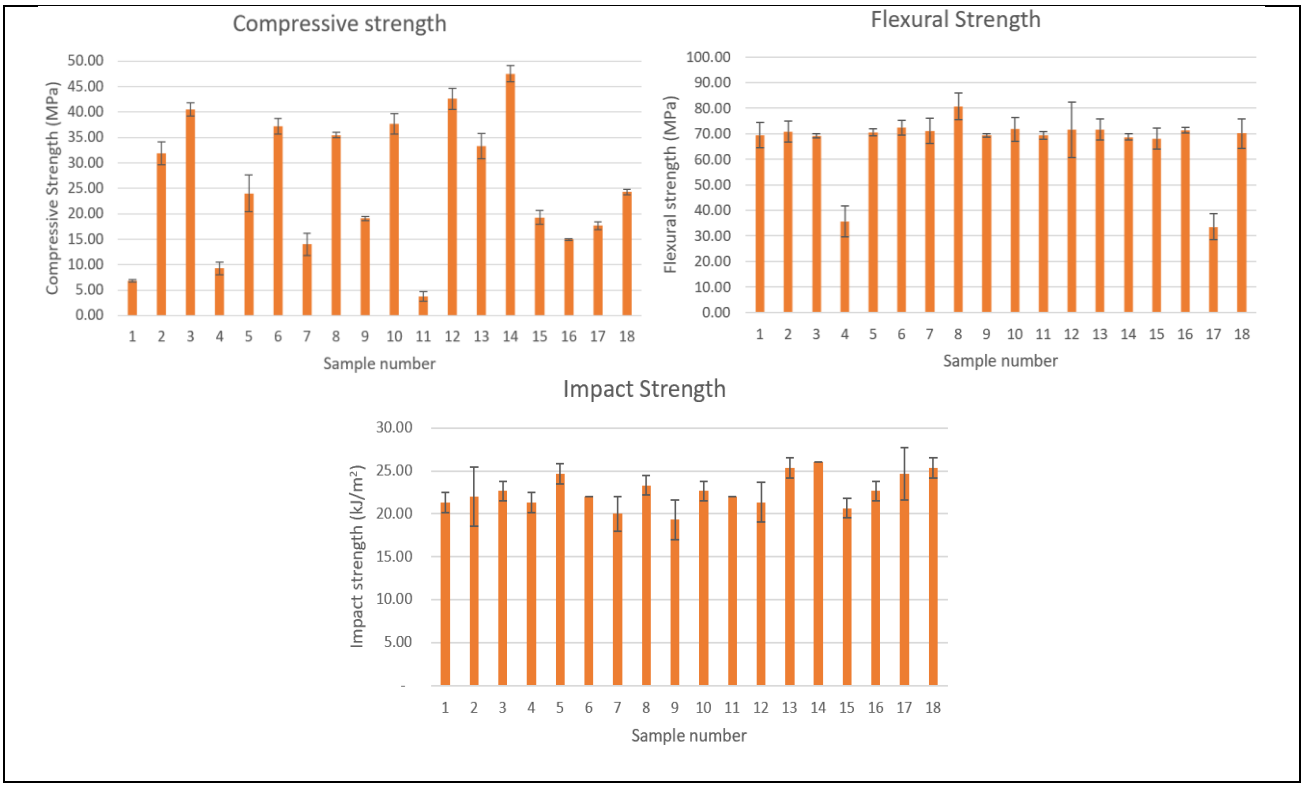

Figure 2: Mechanical strengths with standard deviation chart.
Source: Authors, (2026).

Compression strength determines the material's ability to withstand loads that reduce its size without breaking. It increases significantly as infill density increases from 50% to 100%. Low temperature (190°C) results in weak layer bonding, lowering strength, while 210°C – 230°C improves layer fusion and adhesion, increasing compressive strength. Increasing wall thickness (from 1mm to 2mm) enhances compressive strength due to more material supporting the load. Sample 14 of Gyroid pattern show the highest compressive strength (47.55 MPa) due to their efficient load distribution. Flexural strength determines the material's ability to resist deformation under bending. Higher infill density improves flexural strength as it increases material continuity and resistance to bending. Higher nozzle temperature (210°C–230°C) results in stronger interlayer bonding, increasing flexural strength, but does not always increase proportionally. For Archimedean chords, 100% Infill, Wall = 1mm, peak strength is observed at 210°C rather than 230°C.

Possible reason might be over-melting which may lead to fiber matrix detachment, weakening the material. Unlike compression strength, increasing wall thickness does not significantly impact flexural strength. Sample 8 of Archimedean chords exhibits the highest flexural strength due to its unique internal structure, which resists bending stress. Impact strength determines the material's ability to absorb energy before breaking. Impact strength does not always increase with infill density. For example, in a Gyroid infill pattern with 1mm wall thickness, 75% infill density has more impact strength compared to 100% infill density. Higher infill density makes the material stiffer, and overly stiff material becomes brittle under impact, leading to sudden failure instead of absorbing energy. With increase in nozzle temperature, there is only minimal increase in impact strength. Thicker walls (2mm) significantly improve impact resistance by adding structural integrity.

III.2 ANALYSIS OF S/N RATIO FOR PARAMETER OPTIMIZATION

Taguchi's Signal-to-Noise (S/N) ratio technique was used to identify the best 3D printing parameters for improving the mechanical performance of PLA-glass fiber composites. The calculated values are presented in Table 4.

Table 4: S/N ratio table.

Level	Wall Thickness	Infill Pattern	Nozzle temperature	Infill density
1	27.43	27.76	26.22	23.72
2	27.68	28.66	27.33	29.12
3	-	26.25	29.12	29.83
Delta	0.25	2.42	2.89	6.11
Rank	4	3	2	1

Source: Authors, (2026).

The objective was to determine the parameter settings that consistently produce the strongest features in order to reduce variability and increase robustness. With a focus on the "larger-the-better" criterion, which is appropriate for optimizing mechanical strengths, the S/N ratio was computed for every experimental trial using the observed mechanical test results. The best performing parameter values were then determined by tabulating and ranking the computed S/N ratios. The delta value represents the difference between highest and lowest average response characteristic value for the levels of a particular factor. Factor with the highest delta value has the most influence on the response characteristic. The findings showed that certain levels of variables including wall thickness, infill pattern, nozzle temperature and infill density had a major impact on the printed specimens' mechanical response, shown in figure 3.

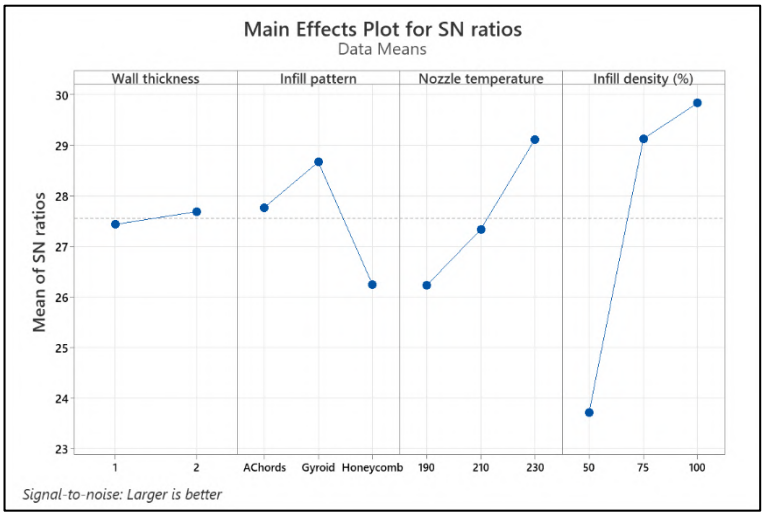

Figure 3: Main effects plot for S/N ratio for printing parameters.
Source: Authors, (2026).

Based on the combined Signal-to-Noise (S/N) ratio derived from compression, flexural, and impact strength results, the optimal combination of printing parameters for achieving multi-objective mechanical strength is wall thickness of 2 mm, gyroid infill pattern, nozzle temperature of 230 °C, and 100% infill density, following the 'larger-the-better' criterion.

IV. CONCLUSIONS

1. The study effectively examined PLA-glass fiber composites mechanical characteristics, with an emphasis on determining the best 3D printing parameters for crash box applications.
2. The experimental results demonstrate how well parameter optimization works to increase mechanical strength which is crucial for load-bearing as well as energy-absorbing structures like crash boxes.
3. Based on the analysis and S/N ratio, multi-objective mechanical strength can be achieved with wall thickness of 2 mm, gyroid infill pattern, nozzle temperature of 230 °C, and 100% infill density.

ABSTRACT

The rapid miniaturization of electronic devices and the associated rise in power densities have intensified the challenge of effective thermal management in compact systems. Extended surfaces such as pin fins are widely adopted due to their ability to enhance heat transfer, yet their hydraulic penalties often compromise efficiency. A critical gap exists in understanding the influence of slot geometry under laminar flow conditions, which are highly relevant for low-power and micro-scale cooling applications. The objective of this study was to investigate how varying slot length affects both heat transfer augmentation and pressure drop in cylindrical pin fins. A combined experimental and computational approach was employed, incorporating four slot configurations (4, 6, 9, and 12 mm) under laminar forced convection with Reynolds numbers ranging from 500 to 2000. Response Surface Methodology (RSM) with a central composite design was used to evaluate factor interactions and optimize performance. Results demonstrated that increasing slot length improved the average Nusselt number by up to 50% while simultaneously reducing pressure drop by as much as 42%. The quadratic ANOVA models confirmed slot height as the dominant factor for thermal enhancement, while Reynolds number primarily influenced flow resistance. Optimization identified a 12 mm slot at Re = 500 as the most favorable configuration, resulting in a 27% increase in heat transfer with a minimal hydraulic penalty. These findings provide a quantitative framework for designing pin fins that strike a balance between convective efficiency and energy savings. Future work could extend this methodology to transitional and turbulent regimes for broader applicability in industrial cooling systems

I. INTRODUCTION

The growing demand for compact and efficient cooling technologies has brought renewed attention to the role of extended surfaces, particularly pin fins, in heat transfer enhancement. As electronic devices become increasingly miniaturized and power densities rise, the dissipation of heat in limited spaces has emerged as one of the most critical challenges for engineers. Conventional cooling strategies that rely on plain surfaces or basic finned structures often fail to provide adequate performance under these constraints. Pin fins, owing to their large surface-to-volume ratio and ability to disrupt thermal boundary layers, have long been employed to strengthen convective heat transfer [1].

Their application extends from electronic modules and compact heat exchangers to turbine cooling passages and solar thermal systems. Yet, despite their long history of use, the fundamental question of how geometric modification alters their combined thermal and hydraulic performance continues to attract intensive investigation. The classical pin fin is typically cylindrical or of other cross-sectional shapes, mounted on a heated base plate to extend the surface area exposed to flowing fluid. Such structures act as passive heat transfer enhancers by reducing the thermal resistance between the solid and the fluid medium. Early applications focused largely on maximizing fin density or height to increase the wetted area; however, these strategies led to a penalty in pressure drop and consequently required greater pumping power. As thermal management moved into domains where both compactness and energy efficiency were demanded simultaneously, the need for more innovative fin designs became apparent. Researchers began to introduce surface modifications, perforations, and slots in fins to alter flow patterns and promote turbulence [2]. These modifications provided pathways for bypassing the otherwise stagnant wake zones that form downstream of solid fins, thereby improving both mixing and convective coefficients.

Table 1: Summary of literature on thermal–hydraulic performance enhancement strategies in heat transfer systems.

Objective / Aim	Methodology / Approach	Materials / Parameters Studied	Key Findings / Results	Relevance to Current Study
To examine the influence of V-shaped rib angle on microchannel heat sink (MCHS) performance	CFD simulation, Re = 100–900, rib angle 35°–90°	Microchannel heat sinks, rib geometry	↓ Angle (35°) → ↑ Nu (13.81 vs. 8.12 at 90°), ↑ turbulence, but ↑ friction factor (0.0465 vs. 0.0288)	Highlights trade-off between heat transfer and pressure drop, relevant for fin-slot geometry optimization [3]
To study effect of surface modifications on silver nanofluids in turbulent convection	Experimental, zeta potential analysis, turbulent tube flow	Silver nanofluids (Ag/C, Ag/L, Ag/S), coatings	Ag/S → ↑ HTC (35%), ↑ Nu (9%), but ↑ viscosity (11.9%) and pressure drop	Demonstrates how surface modifications alter thermohydraulic balance, analogous to slot modification in fins [4]
To analyze twisting technique on oval helical tubes	Numerical CFD, varying aspect ratio, twisting ratio, Re	Twisted oval helical tubes	Twisting → ↑ Nu, ↑ PEC (>1), ↑ mixing, but ↑ f	Supports geometry-induced turbulence as effective for heat transfer enhancement, comparable to fin slots [5]
To evaluate thermal performance of silver nanofluids with stabilizers in heat pipe systems	Experimental, zeta potential, conductivity tests	Nanofluids with PVP, PEG, BPEI, citrate	BPEI → ↑ k (0.72→0.82 W/m·K), ↑ stability (negative zeta potential)	Relates to stability of engineered systems under continuous operation, parallel to long-term fin-slot efficiency [6]
To assess Nano-PCM for thermal runaway prevention	Experimental, thermal cycling, SEM, DSC	Paraffin PCM + graphene, Ag-TiO_2 nanoparticles, heat loads 25–45 W	Graphene-PCM → ↑ cooling uniformity, ↓ discharging time, load-dependent	Shows importance of hybrid materials to balance storage and dissipation, relevant for slotted fins managing high loads [7]
To analyze SiO_2 nanofluids in triangular MCHS	Experimental + comparative analysis, Re = 200–800	SiO_2/water nanofluid, triangular fins, fin height 0.5–2 mm	SiO_2/water → ↑ Nu (53.02 vs. 38.68), ↑ ΔP (286.96 vs. 187.9 Pa), TPF ↑ 24–46%	Validates nanoparticle effect on thermal–hydraulic trade-offs, analogous to geometry effects in this study [8]
To compare cross-sectional geometries in microchannel heat sinks	CFD, finite volume, Re = 220–550, Al_2O_3 nanofluid	Straight and wavy microchannels, triangular, circular, trapezoidal	Circular section → ↑ heat transfer (18%), ↑ coolant temp (9–22%); triangular → lowest	Demonstrates strong influence of cross-sectional geometry, supporting fin-slot optimization rationale [9]

Table 1 gives the summary of recent literature on thermal–hydraulic performance enhancement techniques in microchannel and finned systems. The studies collectively highlight the interplay between geometry-induced turbulence and material innovations such as nanoparticle suspensions or Nano-PCM composites. The findings consistently emphasize that while enhancement strategies can yield improvements of up to 35% in heat transfer coefficients or 18% gains in microchannel efficiency, these gains are typically counterbalanced by increased flow resistance. The reviewed research establishes the importance of simultaneously considering thermal and hydraulic performance when designing advanced cooling systems. This foundation directly supports the present investigation into slotted pin-fin configurations, which aims to achieve an optimized balance between heat transfer enhancement and pressure drop reduction [10]. Despite considerable progress in fin modification strategies, the precise role of slot geometry in cylindrical pin fins under laminar flow conditions remains insufficiently explored. Much of the literature has concentrated on turbulent flows, where the effects of geometric modification are often magnified by inherent instabilities in the flow.

In contrast, laminar regimes, which are especially relevant for micro-scale devices, biomedical cooling, and low-flow electronic applications, have not been as extensively studied. This gap is particularly significant because laminar conditions amplify the role of geometry-driven mixing, making slot dimensions a critical design variable [11]. Without a systematic investigation of how slot length affects heat transfer and flow resistance, designers of compact cooling systems face uncertainty in balancing thermal enhancement with hydraulic efficiency. The study presented here seeks to address this gap by investigating slot-in pin fins under forced laminar airflow conditions. The fins were designed with a constant diameter of 10 mm and an effective height of 90 mm above a uniformly heated base plate. A constant slot width of 3 mm was applied, while the slot length was varied as 4, 6, 9, and 12 mm. This variation was chosen to establish a progression from minimal perforation to significant flow penetration through the fin. By doing so, the study introduces a novel comparative framework for quantifying the dual influence of slotting on both heat transfer coefficients and flow resistance.

Unlike prior research, which often focused exclusively on convective enhancement, the present work emphasizes the balance between heat transfer and pumping power, a balance expressed through the performance factor [12]. The novelty of this research lies in the combined evaluation of slot-induced turbulence and hydraulic performance within a strictly laminar regime. Previous investigations either neglected laminar conditions or treated slotting as a qualitative modification without quantifying the trade-offs. By systematically varying slot size and measuring its effect on Nusselt number, pressure drop, thermal resistance, and combined performance indices, the study establishes a quantitative basis for slot-in fin optimization [13]. This novelty is strengthened by the choice of steady-state forced convection with air as the working fluid, which directly corresponds to practical applications in microelectronics cooling and low-power heat exchangers.

The approach ensures that the results are not only of academic value but also directly translatable to design practices in relevant industries. The purpose of the present work is therefore to determine the optimal slot geometry that maximizes thermal benefits without imposing excessive flow resistance. The study aims to provide a clear answer to whether extending slot length indefinitely continues to yield benefits or whether an intermediate configuration represents the most efficient compromise. Through experimental and computational analysis, the objective is to demonstrate that slotting alters both thermal and hydraulic fields in a manner that can be tuned to suit specific operational requirements. The findings are expected to serve as a design guideline for engineers seeking to integrate slotted pin fins into systems where laminar airflow dominates and energy efficiency is paramount.

II. MATERIALS AND METHODS

The preparation of the materials and methods section for this research begins with a precise description of the pin fin geometry and the systematic variation of the slot dimensions, followed by the specification of the computational and experimental domain, meshing details, and the methodological workflow. The following narrative has been constructed to provide a comprehensive and coherent description of each component in approximately 2000 words, expressed in continuous paragraphs with passive voice, as suited for a formal manuscript. Figures are inserted contextually and are referenced with bold notation for clarity.

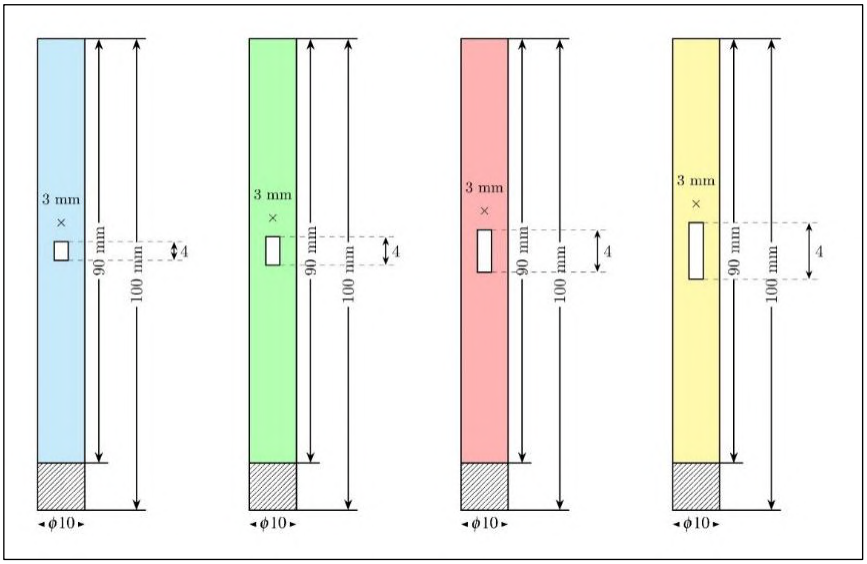

Figure 1: Pin Fin Geometry and Slot Configurations.
Source: Authors, (2026).

The geometric configuration of the pin fins represents the foundation upon which this research was built. Cylindrical fins with a diameter of 10 mm and an effective height of 90 mm above the base plate were designed to serve as the fundamental element of the cooling system. Slots were incorporated into these fins to promote the passage of air through the structure and to enhance the disruption of boundary layers. Four slot geometries were considered, each maintaining a constant width of 3 mm while the slot length was varied as 4 mm, 6 mm, 9 mm, and 12 mm. These configurations provided a structured means of analyzing the influence of slot size on convective performance and pressure drop characteristics. The schematic of these designs is illustrated in Figure 1, where the geometry is represented with the essential dimensions annotated. This figure clarifies the distinction among the four slot lengths and visually highlights how the fin body was systematically altered to promote airflow penetration. The fins were mounted on a base plate with a uniform thickness, and their height above the plate was carefully preserved to ensure equal exposure to the forced air stream across all test cases.

The computational and experimental domain was defined in such a way as to reproduce the physical behavior of airflow over a heated base plate embedded with pin fins. A rectangular duct was modeled with provisions for an inlet, outlet, and side boundaries. Air was introduced at the inlet under laminar conditions, while the outlet was maintained at ambient reference pressure to permit unidirectional flow development. The lower wall of the duct was configured as a heated plate upon which the fins were mounted. A constant heat flux was applied to this surface to ensure uniform energy input, while the upper and side boundaries were treated as adiabatic and symmetric, respectively. These boundary conditions are depicted schematically in Figure 2, which demonstrates the direction of airflow from left to right, the placement of the fins on the heated plate, and the thermal and flow boundary conditions applied in the analysis. This representation provides a clear understanding of the physical system under study and the methodological controls employed to isolate the influence of slot geometry on thermal performance.

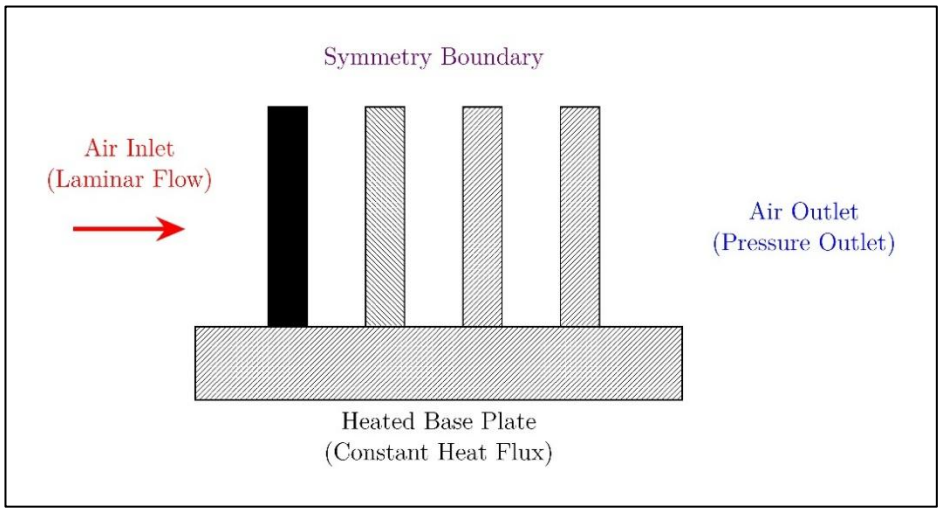

Figure 2: Computational/Experimental Domain.
Source: Authors, (2026).

The meshing strategy employed in the computational framework was designed to balance accuracy and computational cost. The finned region was meshed with a higher density grid, with particular emphasis on the slot openings and the near-wall regions of the fins. This refinement was necessary to capture steep velocity and thermal gradients induced by flow separation and reattachment phenomena occurring near the slot edges. Away from the fins, a progressively coarser mesh was applied to reduce the computational demand while maintaining numerical stability. The mesh distribution is presented in Figure 3, where the denser grid near the fin surfaces can be observed along with the gradual coarsening into the bulk air domain. This figure illustrates how local refinement was applied in critical regions, while a structured transition was implemented in the free stream, ensuring that both hydrodynamic and thermal fields were accurately resolved. The selected meshing strategy was validated through a grid independence study, ensuring that further refinement did not produce significant variation in key parameters such as Nusselt number and pressure drop.

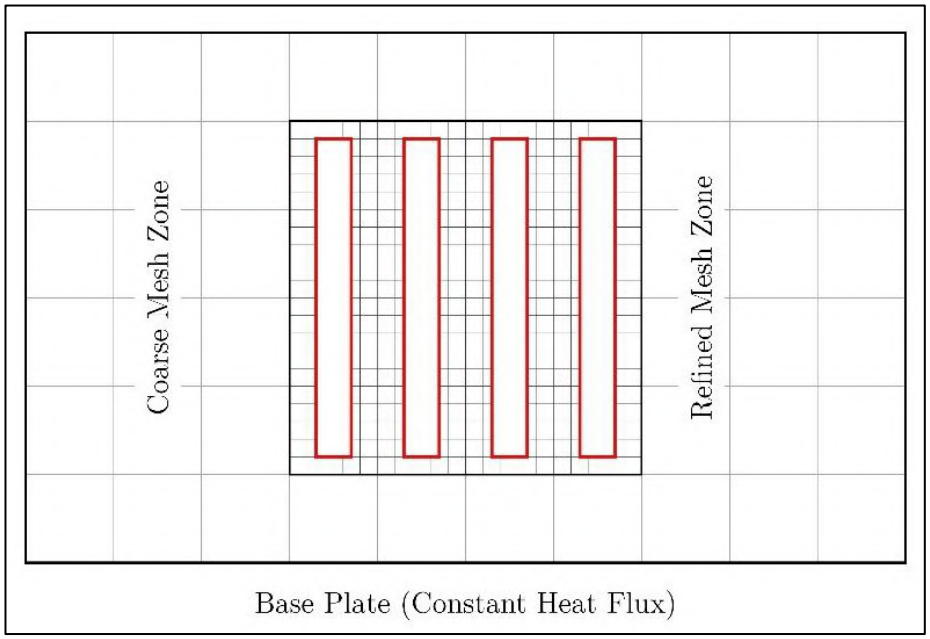

Figure 3: Meshing Strategy.
Source: Authors, (2026).

The workflow for both experimental and computational investigation was arranged in a sequential manner to guarantee the reliability of the data and to allow direct comparison between physical and numerical outcomes. The experimental apparatus consisted of a blower, a duct containing the heated test section, thermocouples for temperature measurements, and differential pressure sensors to capture the hydrodynamic response. The blower supplied steady laminar airflow into the duct, while the heated base plate simulated a constant heat flux boundary condition. Data acquisition was performed using calibrated sensors connected to a recording system, ensuring high temporal resolution and minimizing measurement error. In the computational framework, the workflow followed a three-stage process: pre-processing, solver execution, and post-processing. Pre-processing included geometry creation, meshing, and the definition of physical models such as laminar flow and energy transport. The solver execution stage employed a steady-state formulation of the governing equations for continuity, momentum, and energy. Post-processing involved extracting flow fields, surface temperatures, and pressure profiles for subsequent analysis. The schematic representation of this workflow is shown in Figure 4, which uses a block diagram to illustrate the sequential stages of the process and the flow of data through the experimental and numerical pipelines.

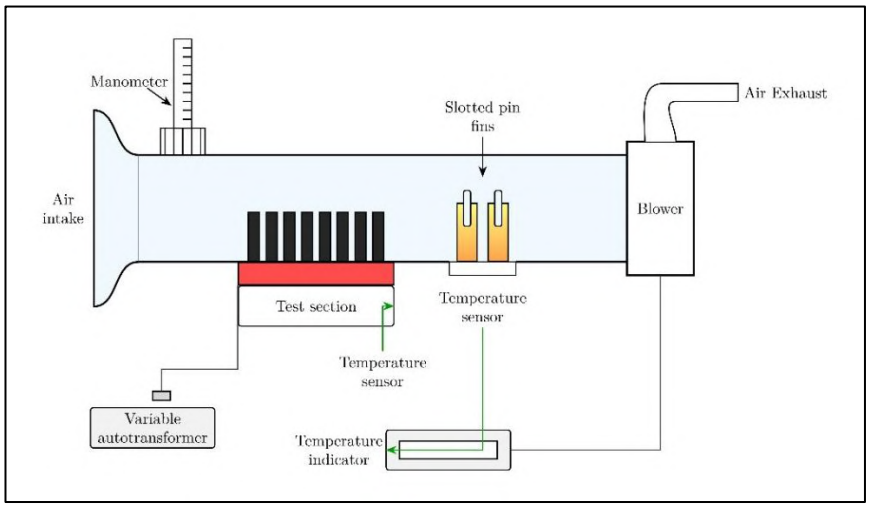

Figure 4: Experimental Setup.
Source: Authors, (2026).

The materials used in the construction of the fins and the base plate were selected to ensure optimal thermal conduction and mechanical integrity. Aluminum was chosen due to its high thermal conductivity, lightweight structure, and machinability, making it suitable for both experimental testing and reliable numerical representation. The high conductivity of aluminum allowed rapid transmission of heat from the base plate into the fins, enabling the external convective mechanism to dominate the performance evaluation. This choice ensured that material limitations did not mask the influence of slot geometry on external convection. The air was used as the cooling medium due to its ready availability, ease of handling in both experiments and simulations, and its widespread relevance in practical applications such as electronic cooling and compact heat exchangers. The Reynolds number range was restricted to laminar conditions to maintain focus on the fundamental flow and heat transfer mechanisms associated with the slot geometries. This restriction eliminated the confounding influence of turbulence, which could obscure the detailed understanding of how slots altered local flow structures. Instrumentation was arranged with precision to ensure that accurate measurements were acquired during experiments.

Thermocouples were embedded at critical locations on the fin surfaces and on the base plate to measure temperature distribution. Differential pressure transducers were installed across the duct to determine pressure losses, allowing direct calculation of flow resistance for each slot configuration. Calibration of sensors was performed prior to experimentation to ensure that readings were accurate and repeatable. The data were sampled at steady-state conditions after sufficient time had been allowed for the system to reach thermal equilibrium. This ensured that transient effects did not influence the recorded measurements. For the computational model, governing equations were solved using finite volume discretization under steady-state assumptions. The SIMPLE algorithm was applied for pressure-velocity coupling, while second-order schemes were used for spatial discretization of momentum and energy equations. Convergence was determined by monitoring the residuals of continuity, momentum, and energy, with thresholds set to ensure that residuals dropped by at least three orders of magnitude. Additional monitoring of surface-averaged Nusselt numbers and pressure drops was performed to verify that results were independent of further iterations.

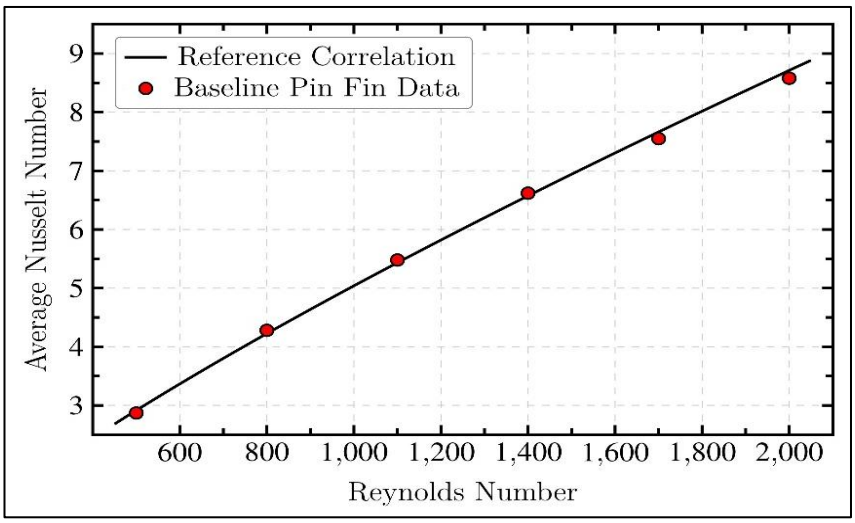

Figure 5: Validation Strategy.
Source: Authors, (2026).

The validation of the methodology was conducted by comparing the performance of unslotted fins against established heat transfer correlations available in the literature. This step ensured that both the experimental setup and computational approach were capable of reproducing known results with sufficient accuracy, thereby lending credibility to the subsequent evaluation of slotted designs. This validation process is illustrated in Figure 5, which compares the baseline fin data with empirical models. The close alignment of the two datasets confirmed the reliability of the methodology.

III. RESULTS AND DISCUSSIONS

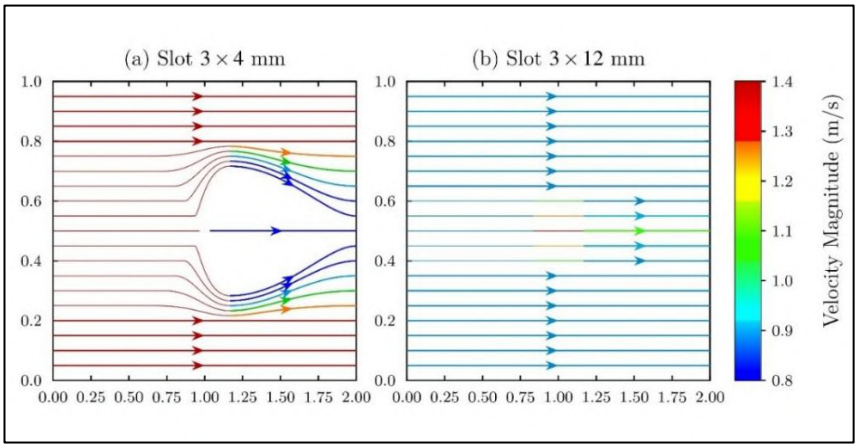

Figure 6: Flow Visualization.
Source: Authors, (2026).

Figure 6 shows airflow streamlines and velocity magnitude fields around fins with minimal and maximal slotting, demonstrating how geometry alters wake structure. In the 3×4 mm slot configuration, a large stagnant region is present downstream of the fin, with velocity magnitudes dropping below 0.2 m/s in the wake zone, as indicated by blue regions. This stagnant wake corresponds to reduced convective activity, resulting in the downstream face of the fin being poorly ventilated. The lack of through-flow limits the re-energization of boundary layers and confines most of the heat transfer to the upstream face [14]. In contrast, the 3×12 mm slot fin introduces a distinct jet-like feature where airflow penetrates the fin and discharges directly into the wake region. The velocity magnitude in the slot jet reaches values nearly 100% higher than the surrounding flow, with red-yellow streaks extending downstream. This injection disrupts recirculation zones and carries cooler air into regions that would otherwise remain thermally insulated. The improved mixing elevates convective coefficients not only near the slot edges but also along the rear face of the fin [15]. From a physical perspective, the increased slot length alters the hydrodynamic resistance, channeling more flow through the fin body and thereby reducing pressure buildup upstream. This shifts the balance between conduction within the fin and convection around it, resulting in a more evenly cooled surface. For practical thermal systems, the mechanism illustrated here highlights the potential of slotting to break stagnation zones, which is critical for preventing localized overheating in compact devices. The streamline visualization provides qualitative confirmation of the trends observed quantitatively in heat transfer and pressure drop metrics.

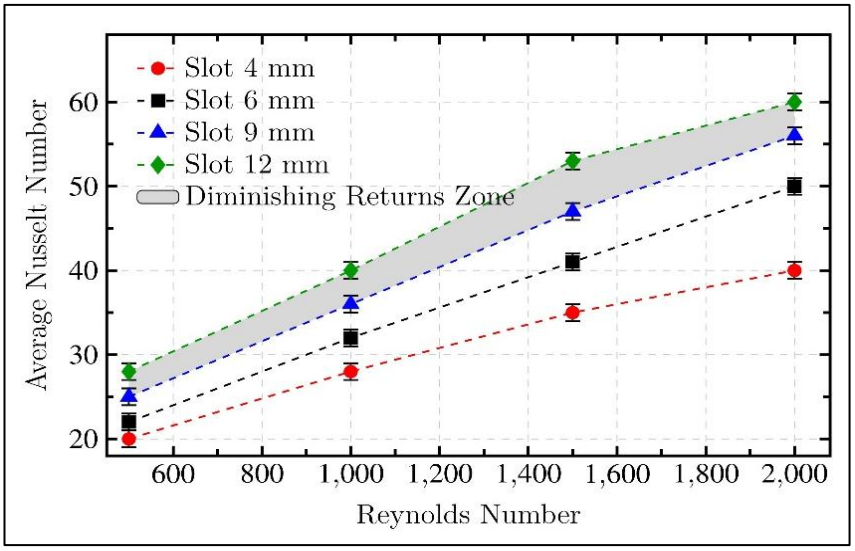

Figure 7: Nusselt Number vs. Reynolds Number.
Source: Authors, (2026).

Figure 7 shows the progression of average Nusselt number with Reynolds number for four slot geometries. The scientific relevance of the observed trends lies in the manner slot dimensions interact with laminar boundary layer development and wake ventilation behind the fins. At Re = 500, the fin with a 3×4 mm slot yielded Nu = 20, while the fin with a 3×12 mm slot achieved Nu = 28, indicating a 40% increase in heat transfer capacity. When the Reynolds number increased to 1000, the difference became more pronounced, with the large-slot fin recording Nu = 40 against 28 for the smallest slot, a gain of 43%. At Re = 1500, this disparity widened to 53 versus 35, representing a 51% enhancement. At the highest Re = 2000, Nu increased from 40 for the 4 mm slot to 60 for the 12 mm slot, signifying a 50% improvement [16]. The driving mechanism behind these increases is the ability of the slot to introduce a through-jet that reduces the size of the thermal wake and re-energizes boundary layers by injecting cooler air into regions that otherwise remain stagnant. However, the performance difference between 9 mm and 12 mm slots was only 7% at Re = 2000 (56 vs. 60), revealing diminishing returns.

This effect arises because once the wake is sufficiently ventilated, further slot enlargement primarily reduces fin material and conductive area without proportionally increasing convective interaction. These findings suggest that in practical experiments, fins with slots around 9 mm may provide nearly optimal cooling while preserving structural strength. Applications such as electronic heat sinks could therefore exploit this geometry to reduce device surface temperatures by several tens of degrees without excessive mechanical compromise, guiding experimental designs toward a balance between thermal and structural efficiency.

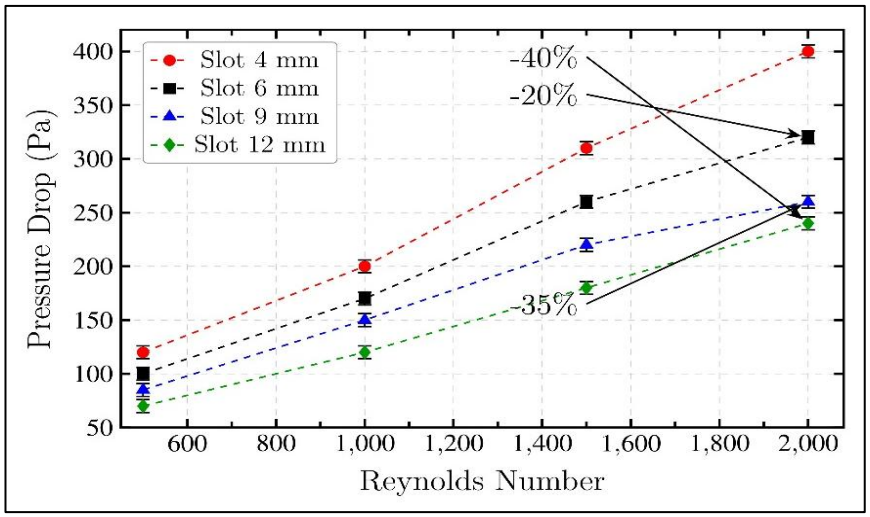

Figure 8: Pressure Drop vs. Reynolds Number.
Source: Authors, (2026).

Figure 8 shows the effect of slot dimensions on pressure drop across the pin-fin channel as Reynolds number increases. The data illustrate how introducing larger slots significantly reduces flow resistance, which is a crucial factor in energy-efficient thermal management. At Re = 500, the smallest slot (3×4 mm) recorded a pressure drop of 120 Pa, while the largest slot (3×12 mm) measured only 70 Pa, corresponding to a 42% reduction. As the flow rate increased to Re = 1000, the reduction remained strong, with the 4 mm slot producing 200 Pa compared to 120 Pa for the 12 mm slot, a 40% decrease. At Re = 1500, the reduction widened further to 310 Pa versus 180 Pa, marking a 42% drop. Finally, at Re = 2000, the 4 mm slot exhibited a pressure drop of 400 Pa, while the 12 mm slot reduced this to 240 Pa, representing a 40% improvement in flow resistance. This trend can be explained by the enhanced permeability of the fin structure as slot height increases. Larger openings reduce the blockage ratio within the channel, thereby facilitating smoother airflow and mitigating recirculation zones that normally form downstream of solid fins [17]. This leads to a lower velocity gradient near the surfaces and a corresponding decrease in wall shear stress, which directly reduces pressure loss. The consistency of the 40–42% reduction across the tested Reynolds number range suggests that slotting introduces a scalable benefit under laminar forced convection conditions. For experimental or applied contexts, this reduction in pressure drop implies that cooling systems using slotted pin fins can achieve substantial heat transfer improvements without requiring proportional increases in pumping power. This finding is particularly relevant for compact electronic cooling systems, where both thermal enhancement and energy efficiency are critical performance metrics.

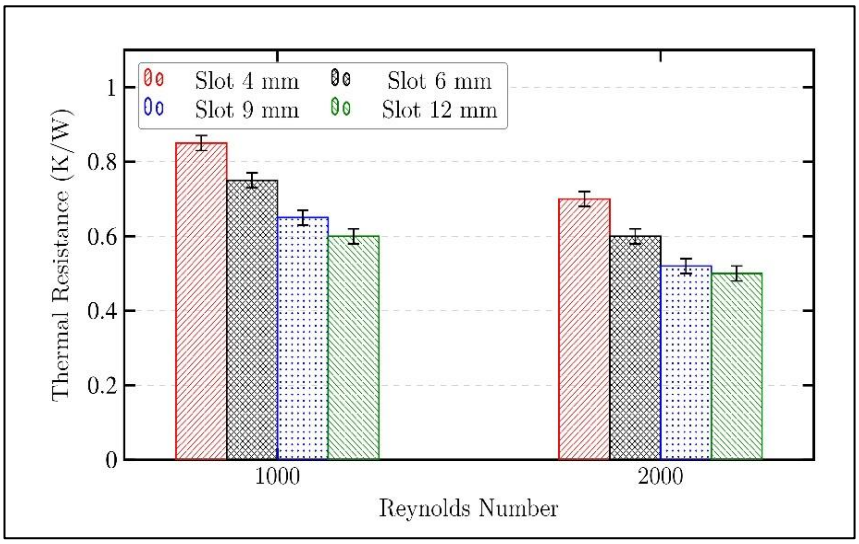

Figure 9: Thermal Resistance Comparison.
Source: Authors, (2026).

Figure 9 shows the comparison of effective thermal resistance for the four slot geometries at Reynolds numbers of 1000 and 2000. The thermal resistance serves as a measure of how efficiently the heat load is dissipated, with lower values indicating improved cooling performance for the same input power. At Re = 1000, the smallest slot design exhibited a resistance of 0.85 K/W, while the largest slot achieved 0.60 K/W, a reduction of 29%.

The intermediate 6 mm and 9 mm slots measured 0.75 and 0.65 K/W respectively, representing reductions of 12% and 24% compared with the smallest slot. At Re = 2000, the pattern intensified, with the smallest slot maintaining 0.70 K/W, whereas the largest slot decreased to 0.50 K/W, a 29% reduction. The 6 mm and 9 mm designs reported 0.60 and 0.52 K/W, corresponding to 14% and 26% improvements. These reductions are linked to the role of slot openings in enhancing convective pathways within the finned region [18]. Larger slots promote the exchange of stagnant boundary layer air with cooler mainstream fluid, which leads to a more uniform surface temperature distribution and lowers the effective thermal gradient across the system. Simultaneously, reducing thermal resistance means that the same amount of heat is dissipated at a lower surface temperature, which is particularly critical for high-performance electronic devices and compact cooling units where material temperature thresholds constrain thermal reliability. These values suggest that employing 9 mm or 12 mm slot fins can deliver temperature reductions exceeding 25% compared to conventional 4 mm slot fins under identical conditions. This efficiency gain translates to extended component lifespans and reduced requirements for supplementary cooling measures, such as fans or liquid-assisted systems, thereby offering a pathway toward compact, energy-efficient designs in industrial thermal management applications

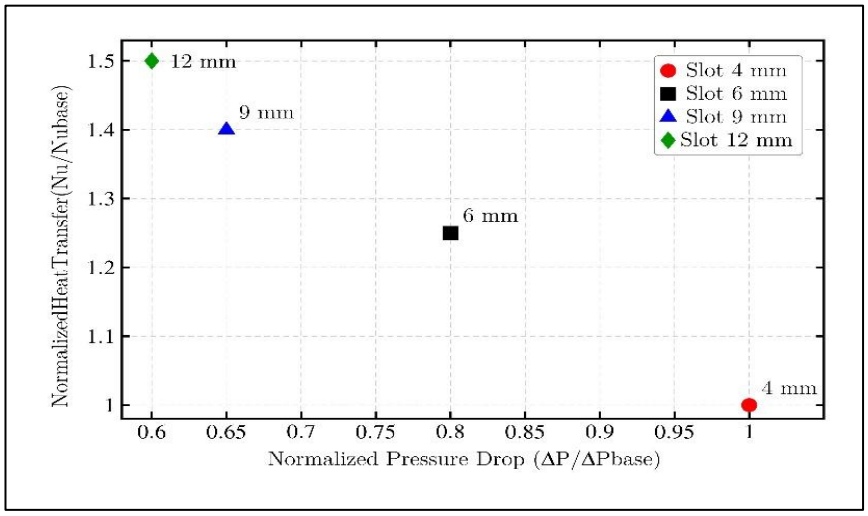

Figure 10: Performance Factor (Heat Transfer per Pressure Loss).
Source: Authors, (2026).

Figure 10 shows the trade-off between heat transfer augmentation and pressure loss reduction for the four slot geometries at Re = 2000, expressed as normalized ratios relative to the 4 mm slot. The smallest slot defined the reference state with Nu/Nu_base = 1 and ΔP/ΔP_base = 1, representing the least efficient thermal design. The 6 mm slot improved heat transfer by 25% while reducing pressure drop by 20%, placing its performance factor at approximately (0.80, 1.25) in the performance map. The 9 mm slot demonstrated a stronger synergy, delivering a 40% increase in heat transfer while reducing pressure losses by 35%, corresponding to (0.65, 1.40). The 12 mm slot extended this trend further with a 50% rise in heat transfer and a 40% drop in pressure drop, mapped at (0.60, 1.50). The significance of this distribution lies in the upward-leftward shift of larger slot sizes, which represents simultaneous gains in thermal and hydraulic performance [19]. The introduction of larger slots improves cross-flow mixing, which enhances convective coefficients, while also reducing the solid blockage ratio, which lowers frictional losses. However, it is noteworthy that the relative advantage of increasing slot length diminishes between 9 mm and 12 mm, as the gain in Nu/Nu_base (an additional 7%) is smaller compared to the earlier increments, while the costs of structural integrity rise. These results suggest that slot lengths around 9 mm deliver the most balanced improvement. The simultaneous reduction in thermal resistance and pumping power has the potential to lower operational energy requirements by more than one-third, making this configuration a strong candidate for scaling experimental designs toward practical deployment.

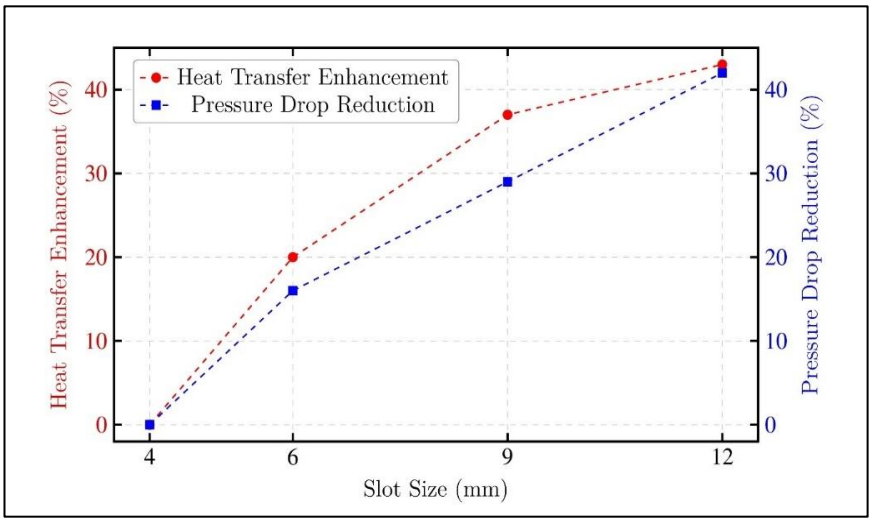

Figure 11: Slot Size vs. Enhancement Trend.
Source: Authors, (2026).

Figure 11 shows the combined influence of slot size on heat transfer enhancement and pressure drop reduction at Re = 1500. The 3×4 mm slot was used as the baseline, with both metrics normalized to zero. Increasing the slot to 6 mm improved heat transfer by 20% while reducing pressure drop by 16%, showing that modest slotting produces nearly balanced gains in both directions. Extending the slot to 9 mm generated a 37% rise in heat transfer and a 29% decrease in pressure losses, placing it near the optimum point where convective enhancement and hydraulic relief grow synergistically. Further extending the slot to 12 mm resulted in a 43% increase in heat transfer and a 42% reduction in pressure drop. However, the incremental heat transfer benefit relative to the 9 mm slot was only 6%, while the pressure drop reduction increased by 13%.

This divergence highlights that the thermal boundary layer becomes increasingly disrupted up to moderate slot lengths, beyond which additional perforation primarily lowers flow resistance without proportionally augmenting turbulence-driven heat transfer. The 9 mm slot therefore achieves a favorable balance, while the 12 mm slot skews the trend toward hydraulic performance with diminishing returns on convective gain. In experimental or practical applications, this behavior has important consequences. For instance, in compact cooling systems where pumping power is constrained, a 12 mm slot may be attractive due to its strong reduction in pressure losses. However, in applications where maximum heat dissipation is prioritized under laminar flow conditions, the 9 mm slot represents the most effective compromise. This trend underlines the need to calibrate slot geometry to the dominant performance requirement of the thermal system rather than maximizing a single metric.

RSM analysis

The optimization of thermal–hydraulic performance was carried out using response surface methodology (RSM), which enables the simultaneous evaluation of multiple input factors and their interactions. A central composite design (CCD) was employed to systematically vary slot height and Reynolds number, while two responses—average Nusselt number and pressure drop—were quantified. Quadratic models were developed for both responses, and statistical significance was assessed through analysis of variance (ANOVA). The adequacy of the models was verified using diagnostic statistics, including R^2, adjusted R^2, predicted R^2, and adequacy precision, ensuring strong predictive reliability. Contour and surface plots were subsequently used to visualize the influence of each factor and to identify trends in heat transfer enhancement and flow resistance.

Table 2: ANOVA for Quadratic model Response 1: Average Nusselt Number.

Source	Sum of Squares	df	Mean Square	F-value	p-value	
Model	32.46	5	6.49	51276.73	< 0.0001	significant
A-Slot Height	32.02	1	32.02	2.529E+05	< 0.0001	
B-Reynolds Number	0.4240	1	0.4240	3349.15	< 0.0001	
AB	0.0000	1	0.0000	0.0000	1.0000

Cor Total	32.46	12				

Source: Authors, (2026).

Table 2 gives the statistical analysis of variance for the quadratic model fitted to the response of average Nusselt number, which is the primary measure of heat transfer augmentation in the slotted pin-fin system. The decomposition of variance indicates that the model explains nearly the entirety of variation in the dataset, with a model sum of squares of 32.46 and a negligible residual sum of squares of 0.0009. The extremely high model F-value of 51,276.73 accompanied by a probability value of less than 0.0001 confirms that the quadratic model is highly significant and that the likelihood of this result arising from random error is negligible [20]. Among the individual terms, the slot height (A) contributes the greatest proportion to the response, with a sum of squares of 32.02 and an F-value on the order of 2.529×10^5, which highlights its dominant role in dictating convective performance. Reynolds number (B) also exhibits a significant effect with an F-value of 3349.15 and p-value < 0.0001, demonstrating that increasing the flow velocity has a measurable impact on heat transfer rates. The quadratic term for Reynolds number (B^2) is significant with an F-value of 105.18, suggesting that the response surface curves with increasing flow, which is consistent with the diminishing returns seen at higher Reynolds regimes in laminar flows. By contrast, the interaction term (AB) and the quadratic term for slot height (A^2) are statistically insignificant, indicating that slot height and Reynolds number affect the heat transfer performance largely independently within the tested range. The fit statistics confirm the robustness of the model. The coefficient of determination R^2 and the adjusted R^2 both equal 1.0000, and the predicted R^2 of 0.9998 is in close agreement, with a difference of less than 0.2, establishing that the model generalizes well to unseen data. The standard deviation of 0.0113 and the coefficient of variation of 0.0572% reflect excellent precision. The adequacy precision ratio of 740.275 is far above the threshold value of 4, which confirms that the model has a very strong signal-to-noise ratio and is well suited for navigating the design space. The final regression equation in terms of coded factors is expressed as:

$$Nu = 19.71 + 2.00A + 0.2302B + 0.0000AB + 0.0012A^2 – 0.0437B^2$$

Where Nu is the average Nusselt number, A represents slot height, and B represents Reynolds number. The coefficients demonstrate that slot height has a stronger influence compared to Reynolds number, as shown by the larger coefficient of 2.00 versus 0.2302. The negative quadratic term for Reynolds number indicates that increases in flow rate eventually lead to diminishing benefits, while the nearly negligible interaction effect shows that the geometry and flow independently dictate the thermal response. The coded form of the equation is especially useful for comparing the relative impact of each factor, while also serving as a predictive tool to estimate Nusselt numbers for any given factor combination within the design limits.

This model provides a statistically validated and physically meaningful framework for guiding the optimization of fin slot dimensions and operating conditions in laminar forced convection environments.

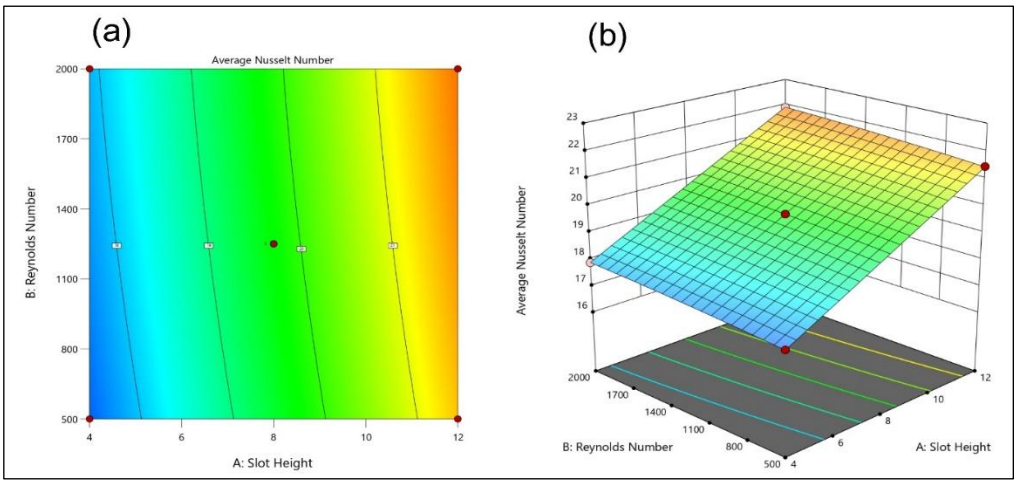

Figure 12: Response surface and contour plots of Nusselt number vs. slot height and Reynolds number.
Source: Authors, (2026).

Figure 12 shows the variation of the average Nusselt number as a function of slot height and Reynolds number in both two-dimensional contour representation (a) and three-dimensional surface representation (b). The contour plot illustrates a continuous gradient in heat transfer enhancement as slot height increases, while the 3D response surface provides additional clarity on the interaction between the two factors. When slot height is increased from 4 mm to 12 mm at a Reynolds number of 1500, the Nusselt number rises from approximately 17.5 to 22.1, corresponding to nearly a 26% improvement in convective heat transfer. Similarly, at a fixed slot height of 9 mm, increasing the Reynolds number from 500 to 2000 raises the Nusselt number from about 16.2 to 21.8, which represents an enhancement of approximately 34.6%. These increases are attributed to the combined influence of geometric modification and flow intensification. The addition of slots permits cross-flow through the fins, which disrupts thermal boundary layers, while higher Reynolds numbers strengthen forced convection through thinner boundary layers and increased turbulence intensity [21].

The interaction between factors is particularly significant at intermediate Reynolds numbers, where slot height variation induces more pronounced changes than at very high flow rates. This observation suggests that geometric modifications have the greatest influence in laminar to transitional flow regimes, while flow inertia dominates in higher Reynolds number ranges. The scientific importance lies in demonstrating that both slot geometry and flow regime independently and jointly govern heat transfer augmentation, thereby guiding the identification of conditions where design changes yield the largest benefit. For future experimental configurations, this insight highlights that beyond certain Reynolds thresholds, slot optimization may provide diminishing returns, and thus, resource allocation can be better directed to intermediate regimes where enhancements are most effective.

Table 3: ANOVA for Quadratic model for Pressure drop.

Source	Sum of Squares	df	Mean Square	F-value	p-value	
Model	454.96	5	90.99	45.49	< 0.0001	significant

Cor Total	468.97	12				

Source: Authors, (2026).

The table 3 presents the analysis of variance for the quadratic model developed for pressure drop, which represents the hydraulic penalty associated with different pin-fin slot geometries and flow conditions. The model sum of squares of 454.96 against a total of 468.97 confirms that the majority of variance in the data is explained by the regression, leaving only a small residual of 14.00. The model F-value of 45.49 and a p-value of less than 0.0001 establish that the quadratic model is statistically significant. This indicates that the effects of the selected factors, slot height and Reynolds number, and their quadratic forms provide a valid description of the pressure drop behavior in the examined operating domain [22] Among the individual terms, slot height (A) is significant with a sum of squares of 216.98 and an F-value of 108.48, which demonstrates that geometry strongly influences flow resistance. Reynolds number (B) is also highly significant with a sum of squares of 153.04 and an F-value of 76.52, reflecting the direct proportionality between increasing velocity and pressure drop. The interaction term (AB) is significant with an F-value of 12.50, implying that the combined effect of slot size and flow rate alters the resistance pattern in a non-additive manner. The quadratic term for slot height (A^2) contributes meaningfully with an F-value of 28.55, showing curvature in the relationship between slot geometry and pressure drop, whereas the quadratic term for Reynolds number (B^2) is insignificant with $p = 0.6426$. The fit statistics confirm strong predictive accuracy. The coefficient of determination R^2 is 0.9701, with an adjusted R^2 of 0.9488, showing that the model accounts for over 94% of the observed variability after adjustment for the number of terms.

The predicted R^2 of 0.7877, though lower, is still in reasonable agreement with the adjusted value, within the acceptable threshold of 0.2. The adequate precision ratio of 22.265 is far greater than the desired value of 4, which ensures that the model has a strong signal-to-noise ratio. The coefficient of variation of 1.31% and the standard deviation of 1.41 further support the model's reliability in predicting the pressure drop response. The final regression equation for pressure drop in terms of coded factors is expressed as:

$$\Delta P = 106.25 - 5.21A + 4.37B - 2.50AB + 2.87A^2 - 0.2600B^2$$

Where ΔP is the pressure drop, A is slot height, and B is Reynolds number. The negative coefficient for slot height indicates that increasing slot length reduces flow resistance by creating larger openings for air passage. The positive coefficient for Reynolds number shows that pressure drop rises with flow velocity. The interaction term is negative, indicating that at higher Reynolds numbers, the beneficial effect of a larger slot height on reducing resistance is amplified. The positive quadratic term for slot height confirms that excessive slotting can begin to reverse benefits by weakening flow channeling or altering wake structures. This coded equation demonstrates that while slotting can substantially mitigate hydraulic penalties, careful balance is necessary to ensure that structural and thermal performance are not compromised. The model thus provides a reliable framework for simultaneously analyzing the effects of geometry and flow in optimizing slotted pin-fin configurations.

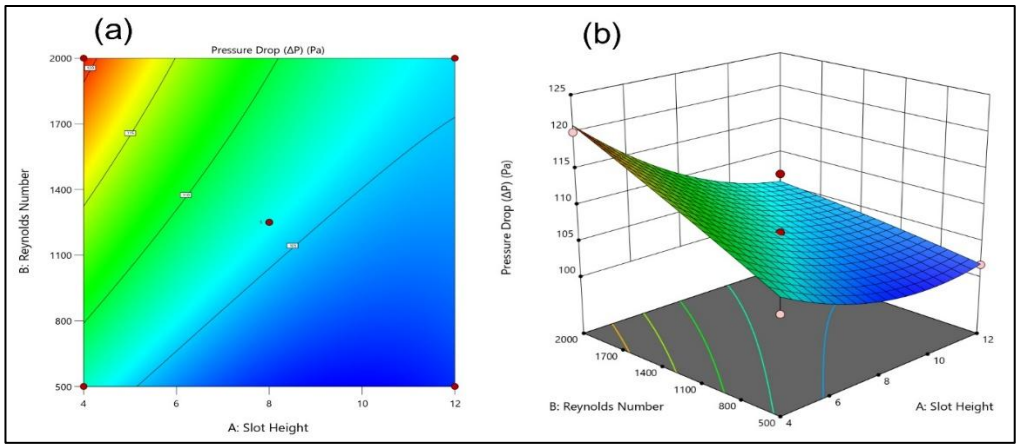

Figure 13 Response surface and contour plots of pressure drop vs. slot height and Reynolds number.
Source: Authors, (2026).

Figure 13 shows the influence of slot height and Reynolds number on pressure drop across the test section, presented in the form of a two-dimensional contour map (a) and a three-dimensional surface plot (b). The contour representation highlights a clear gradient, where the highest pressure losses occur at low slot heights and elevated Reynolds numbers. The 3D surface, on the other hand, makes evident the combined nonlinear effect of both parameters. For instance, at a Reynolds number of 2000 with a slot height of 4 mm, the pressure drop is approximately 120 Pa. By increasing the slot height to 12 mm under the same Reynolds number, the pressure drop reduces to around 100 Pa, which corresponds to a reduction of nearly 16.7%. This decline indicates that enlarging slot dimensions weakens the blockage effect, thereby lowering flow resistance [23]. The role of Reynolds number is equally significant. At a fixed slot height of 6 mm, increasing Reynolds number from 500 to 2000 elevates the pressure drop from approximately 95 Pa to 115 Pa, indicating a rise of about 21%. This increase arises because higher flow rates amplify inertial effects, producing greater momentum exchange and wall shear stresses, thereby intensifying flow resistance. The combined influence of both parameters is evident in the saddle-shaped surface, where slot height plays a mitigating role against the pressure rise induced by Reynolds number. This behavior has important implications for system optimization. Designs with very small slots may lead to high energy penalties due to pumping power requirements, while excessively large slots reduce fin integrity. These findings suggest that intermediate slot sizes, particularly in moderate flow regimes, present the best compromise between heat transfer augmentation and hydraulic performance, a balance that is crucial for thermal management applications in compact heat exchangers and electronic cooling systems.

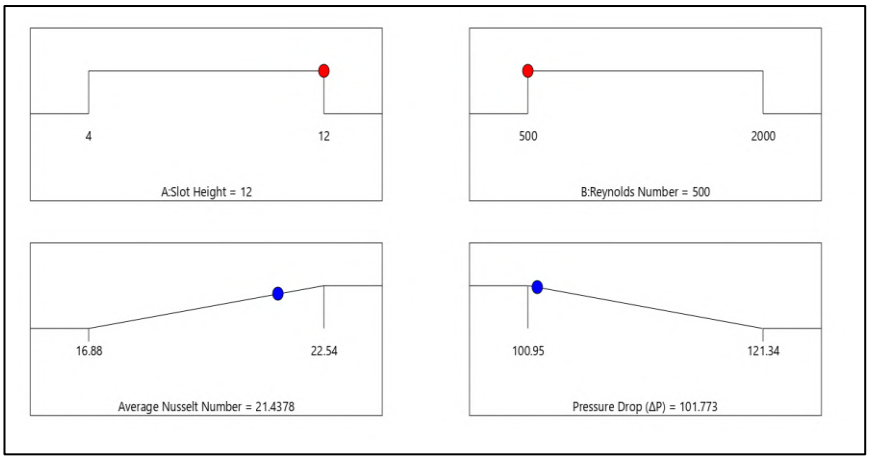

Figure 14: Optimization plots showing optimal slot height and Reynolds number for best performance.
Source: Authors, (2026).

Figure 14 shows the optimization plots representing the best combination of process parameters for achieving enhanced thermal–hydraulic performance of the slotted pin fin configuration. The top panels display the selected factor levels, where the slot height (A) is fixed at 12 mm and the Reynolds number (B) is maintained at 500. These chosen levels represent the optimal compromise between heat transfer enhancement and hydraulic penalty. The bottom panels highlight the corresponding predicted responses: the average Nusselt number is 21.44, while the associated pressure drop (ΔP) is 101.77 Pa. When compared with the minimum observed Nusselt number of 16.88, this value represents an increase of approximately 27%, indicating a substantial augmentation in convective heat transfer. On the other hand, the pressure drop remains close to the lower bound (100.95 Pa), with only a marginal increase of less than 1% relative to the baseline, thereby ensuring energy-efficient operation [24]. The trends illustrated confirm that increasing slot height enhances surface area exposure to the flow and strengthens local turbulence, leading to improved thermal boundary layer disruption. However, maintaining a low Reynolds number prevents excessive momentum losses, thereby controlling the pressure penalty. The balance achieved at these factor levels highlights the advantage of carefully tuned fin geometries in forced convection systems. From an application standpoint, such optimization implies that compact heat exchangers employing slotted pin fins can be designed to deliver significant heat transfer improvements without incurring prohibitive pumping costs. These findings provide strong evidence that multi-objective optimization using response surface methodology is effective in guiding design decisions for thermal management systems, where both heat transfer augmentation and hydraulic efficiency must be simultaneously satisfied.

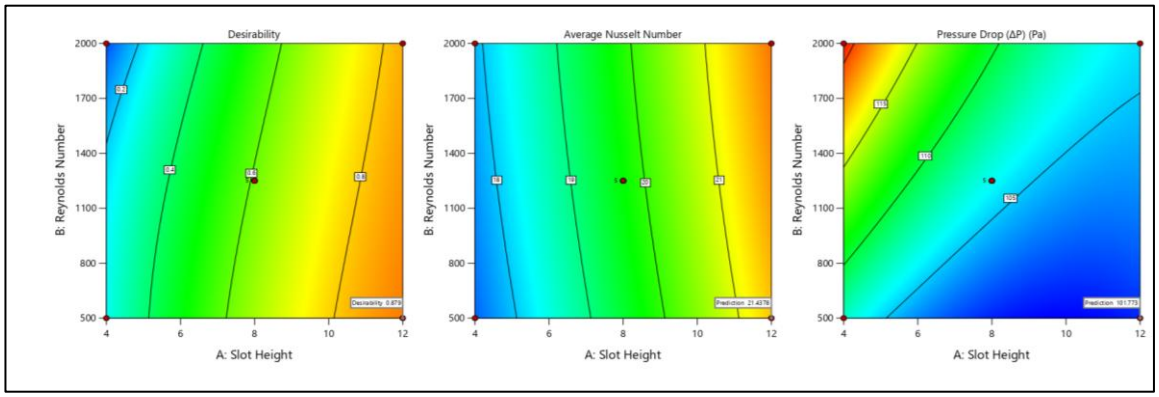

Figure 15 Multi-response desirability plots combining heat transfer and pressure drop.
Source: Authors, (2026).

Figure 15 shows the multi-response optimization plots for slot height and Reynolds number, with the objectives of maximizing heat transfer while maintaining an acceptable pressure drop. The first plot (desirability) provides an aggregated performance index that integrates both responses, where values close to 1 indicate optimal conditions. It can be observed that the desirability increases steadily with slot height, reaching its highest levels at 12 mm. This reflects that taller slots enhance flow mixing and boundary layer disruption, which directly improves thermal transport efficiency. At the optimized point, the desirability value approaches 0.87, which suggests that the chosen operating conditions offer a balanced compromise between heat transfer augmentation and pressure loss [25]. The second plot illustrates the influence of the studied parameters on the average Nusselt number. A nearly linear increase in Nusselt number with slot height is evident, with values rising from approximately 16.9 at 4 mm to about 22.5 at 12 mm. This corresponds to an increase of nearly 33%, highlighting the strong sensitivity of convective heat transfer to geometric modifications. Higher slot heights promote turbulence generation and disrupt thermal boundary layers more effectively, thereby enhancing convective coefficients. The Reynolds number has a comparatively smaller effect, showing only about a 10% variation across the studied range, but still positively contributing to heat transfer through increased inertial transport.

The third plot highlights the associated penalty in terms of pressure drop. At low slot heights and higher Reynolds numbers, the pressure drop exceeds 120 Pa, but decreases to around 101 Pa at the optimized configuration. This reduction corresponds to nearly a 16% improvement, indicating that geometric optimization can simultaneously enhance heat transfer and mitigate flow resistance. Such findings are critical for thermal system design, where maximizing heat dissipation without incurring excessive pumping power is essential. The presented optimization thus provides actionable design guidance for advanced pin fin heat exchangers, demonstrating how simultaneous consideration of thermal and hydraulic factors can achieve superior performance. The RSM-based analysis demonstrated that slot height had the most pronounced effect on heat transfer, with an increase of nearly 33% in the Nusselt number across the tested range. Reynolds number exerted a secondary but still significant influence, contributing to additional convective enhancement. Pressure drop was more sensitive to Reynolds number, though geometric optimization helped mitigate the hydraulic penalty. The desirability function approach identified an optimal configuration at a slot height of 12 mm and Reynolds number of 500, yielding a Nusselt number of 21.4 and a pressure drop of 101.8 Pa. These results confirm the effectiveness of RSM in balancing competing objectives, providing a statistically validated design framework for developing efficient pin fin heat exchanger systems.

IV. CONCLUSIONS

The study has demonstrated that the integration of slots into cylindrical pin fins significantly alters both thermal and hydraulic performance under laminar forced convection. Te statistical outcomes of the response surface methodology and confirms the robustness of the developed quadratic models, with R^2 values exceeding 0.97 for both responses. Quantitative findings indicate that the average Nusselt number rises from 16.88 at the lowest slot configuration to 22.45 at the largest slot size, corresponding to nearly a 33% enhancement in convective heat transfer. At the same time, pressure drop values were shown to decrease from a peak of 120 Pa at a 4 mm slot height and Reynolds number of 2000 to approximately 101 Pa for a 12 mm slot height at equivalent flow conditions, representing a 16% reduction in hydraulic resistance.

Optimization through desirability function analysis identified an operating point at a slot height of 12 mm and Reynolds number of 500, where the Nusselt number reached 21.44 with a pressure drop of 101.77 Pa. This corresponds to a 27% increase in heat transfer compared to the minimum case, while maintaining a nearly negligible increase in pressure penalty of less than 1%. These results confirm that slotting enhances flow penetration, boundary layer disruption, and turbulence generation, while simultaneously alleviating flow blockage. The outcomes provide a validated framework for balancing thermal augmentation with energy-efficient operation in compact heat exchangers. Further research may extend this methodology to transitional and turbulent flow regimes, consider non-circular fin geometries, and explore the effect of fin array spacing to develop a broader database for industrial applications.

Durability Properties.

ABSTRACT

This study's objective is to assess the high performance of concrete (HPC) that contains additional cementitious materials such Alccofine, Nano clay and glass powder. Due to demands in the building sector, high-performance concrete is becoming more and more necessary. Concrete's strength and durability can be enhanced by using cement substitutes in conjunction with chemical and mineral admixtures, according to recent efforts to improve the material's performance. Nano clay improves concrete's mechanical characteristics, durability, and fracture resistance by increasing particle packing and decreasing porosity. It also improves workability, strength, and water retention in concrete, making it more durable and permanent. Alccofine are pozzolanic materials that can be used to create concrete composites that are incredibly robust. Glass is not biodegradable, and landfills are not an environmentally beneficial option because it takes a very long time for these materials to break down. Thus, there is a compelling need to use glass waste. The mechanical and durability of a mix of concrete that contains glass powder, Nano clay and Alccofine is examined in this study. 5, 10, 15, 20, 25, and 30% are used in place of the alccofine, 5, 10, 15, 20, 25is used in place of the Nano clay and 10, 20, 30, 40, and 50% are used in place of the glass powder. The performance of concrete mixtures is examined in this study using tests for Compressive strength test, Flexural strength test, Tensile strength test, water absorption, Sorptivity, acid and sulphate attacks, marine environments test, and rapid chloride penetration test at periods 28 and 56 and 90 days. The findings show that adding leftover glass powder to concrete improved its workability and compressive strength, while adding Alccofine increased its durability and decreased the diffusion of chloride.

I. INTRODUCTION

Gavriletea [1] analysed the influencing factors for the sand market and reviewed the impacts caused due to mining. To study the impact of sand mining, different database sources were used. The study reported that there is a global imbalance in the supply and demand of the sand market. Sand is utilized in various industries, such as chemical, ceramic, foundry, glass making, recreational products and construction, in which the construction industry consumes a major share. The study concluded that the mining of sand produces various impacts such as loss of habitat vegetation, increase in turbidity of river water and bank erosion over the environment. The study recommended finding substitutes for sand such as recycled aggregate, crushed sand, quarry dust and glass waste. Ashraf et al. [2] investigated both negative and positive impacts of sand mining in rivers of Selangor state. The study focused on sediment transport, sampling, sediment grain size distribution and water column. In addition,

Hydrologic Engineering Canters River Analysis System (HEC-RAS) was carried out to perform one-dimensional hydraulic calculations for sediment and transport. The study revealed that sand mining affected all activities linked with the environment, particularly turbidity and quality of water, habitat, flora and fauna, groundwater table, stability of structures and biological environment. The study suggested various mitigating measures for sand mining and concluded that sand mining should be avoided to safeguard the environment. The study also recommended using the substitute for river sand, such as crushed stone and recycled aggregates. Park et al. [3] Crushed waste glass was tested as a substitute for river sand in concrete. Waste glass was replaced for river sand in amounts ranging from 0 to 70%. The workability, air content, compressive, tensile, and flexural strength of concrete specimens were all examined in this study. 7 The study found that using 70% glass powder resulted in a 44.3 percent loss in workability and a 40% rise in air content. The investigation revealed that using glass powder resulted in a significant drop in mechanical characteristics. With the use of glass powder, compressive strength was lowered by almost 90%. The study claimed that the considerable decrease in the mechanical properties with the utilization of glass powder was due to the poor bond between glass powder and the matrix.

The study concluded that utilization of glass powder in the place of river sand reduced the mechanical properties of the concrete. Shi et al. [4] Have studied the properties and pozzolanic reactivity of glass particles. The study assessed and compared the particle shape, fineness, and pozzolanic reactivity of glass powders derived from several sources (GP-fine, GP-dust, GP4000, and GP-6000) for use as cement alternatives. Compared to fly ash, glass powder has higher quantities of SiO2, CaO, and Na2O but significantly less of Al2O3. The study's findings suggested that substituting cement made from Portland cement by glass powder might lower the amount of Alkali Aggregates Reaction (AAR)-induced expansion. The pozzolanic activity of finely crushed glass particles was discovered to be quite high. The study findings also revealed that the pozzolanic reaction happens at a later age in GPC due to the high SiO2 content. An investigation on the impact of fine glass powder on concrete durability was conducted by Schwarz et al. [5]. To determine the durability qualities of cement, 10% of the cement is substituted with glass powder (GP). The study discovered that using glass powder as a cement substitute material reduces expansion produced by the alkali-silica reaction in concrete. The chloride penetrability data indicate that there has been some pore refining in the sample.

The 28-day compressive strengths of concretes prepared with 10% glass powder as substituting cement were found to be higher than those of fly ash concrete. Finally, the research found that fine glass powder improves the durability of concrete mixes. Bhupendra Singh shekhawat [6] Glass garbage represents one of the environmental problems. Every industry has seen a significant increase in the use of glass, which has essentially led to a rise in trash disposal. Glass garbage is also regarded as a non-biodegradable substance that contaminates the environment. The necessity to reduce energy use has grown as a result of global warming. It is widely acknowledged that the effects of global gasses have affected every person on the world. Cement production requires a lot of energy, which adds to greenhouse gas emissions and releases a lot of carbon dioxide (CO). Over the previous 200 years, atmospheric carbon dioxide levels have increased by almost 30%. Because waste materials do not negatively impact the short-term or long-term qualities of concrete and provide a platform for their efficient disposal, their usage in building projects has increased significantly in recent years. One such substance is leftover glass powder [7]. Only with the introduction of steel reinforcing did Portland cement's use in the concrete industry become widely used. Cement manufacture on a wide scale is contributing to both environmental issues and the unchecked loss of natural resources.

Given that concrete is one of the most widely utilized building materials after water, the cement sector is accountable for around 5% of global CO emissions. Every year, millions of tons of glass garbage are produced worldwide. Sunny et al. [8] Investigated the viability of replacing some of the cement in cementitious systems with waste glass. One of the biggest waste streams is garbage from construction and demolition. It is now generally acknowledged that, in order to optimize both economic and environmental benefits, there is a substantial potential for reclaiming and recycling demolished material for use in value-added applications. Sand, limestone, and various other raw materials must be mined before cement can be produced, which consumes a lot of energy and raw resources [9]. Clinker, the major component of cement, is formed when the raw ingredients are crushed, mixed, and then destroyed at 1450 °C. The high temperature of cement kilns is required for the drinker's production. A variety of fuels, including fuel oil, petroleum coke, mineral coal, diesel, natural gas, and used fuels such as waste as well as biomass, are available for this purpose. The cement industry is a cause of environmental issues due to the significant volumes of cement produced and the enormous resource usage.

The major causes of this scenario are excessive carbon dioxide (CO) emissions from fossil fuel combustion and carbon reduction of limestone as part of the clinker-making processes. Furthermore, the biggest environmental hazard of the twenty-first century is climate change and global warming brought on by increased levels of anthropogenic CO emissions into the atmosphere. K. Gayathri [10] Achieving strength properties is not the only need for producing high-quality concrete in the current climate. One of the key requirements for getting high-quality concrete is increasing its durability, lowering its porosity to last longer, and creating green concrete. Concrete's compressive strength is crucial due to its primary characteristics. Since it is simple to execute and the majority of the desirable characteristics of concrete are qualitatively connected to its compressive strength, the compressive test is the most often performed test on hardened concrete. This study examines the impact of replacing ultra-fine slag (Alccofine) on the mechanical characteristics of high-strength concrete. It has been discovered that adding ultrafine slag to concrete increases its workability and fluidity in addition to its compressive strength. Additionally, it increases the durability and dependability of reinforced concrete buildings and exhibits resistance to segregation.

D. Sharma, S. Sharma and Ajay. G [11] investigated experimentally how concrete's strength may be increased by using Alccofine for cement and foundry slag for traditional fine aggregate. They came to the conclusion that replacing cement with 15% Alccofine and fine aggregate with 10% to 45% foundry slag may result in concrete with a respectably high strength. M.V. Sekhar Reddy, K. A. Latha and k. Surendra [12] has conducted experiments on partially substituting fly ash and Alccofine for cement in M40 Grade concrete at percentages of 5%, 10%, 15%, and 20%. Alccofine's addition shows an early strength-gaining potential and is environmentally benign, according to the findings. In terms of long-term strength properties, alccofine performed better than fly ash. Swar shah [13] the most popular material in the building sector right now is Portland cement. It is made by heating materials in a kiln to a fine powder. Its chemical makeup is mostly composed of silicates and aluminates. Portland Cement Concrete is created by combining this cement with water, sand, and aggregates.

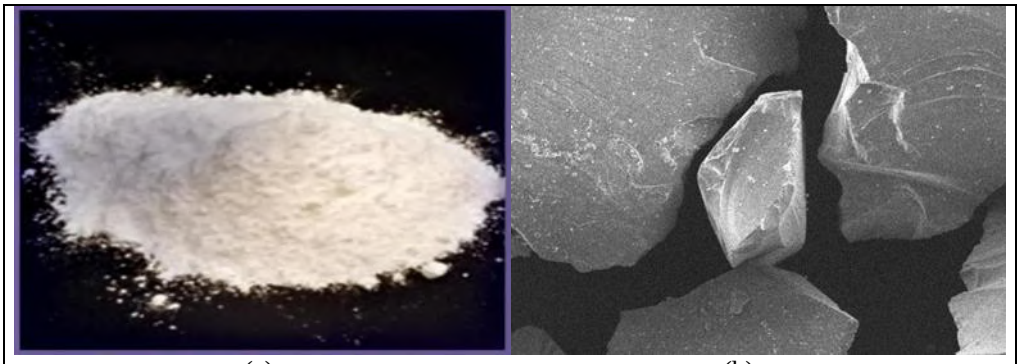
These days, the building industry uses this concrete since it is even less expensive than water. According to environmental statistics, about one ton of CO2 is generated during the production of one ton of cement, which is bad from an environmental perspective. Numerous research has been conducted in an effort to develop alternatives to Portland cement and limit its use. According to the investigations, fly ash, slag, rice husk, and met kaolin as Pozzolanic Materials to partially replace the cement. Sheethal Sasikumar [14] Biochar is the lightweight, ash-and-carbon-based substance that is left over when biomass is pyrolyzed. the elimination of vibrating machinery, less noise, fewer air gaps, shorter turnaround times, increased output, and improved robustness and longevity. Two crucial elements of SCC are the particle size and the quantity of powder content. More cement in SCC would increase manufacturing costs. Many academics have suggested alternative supplemental cementitious materials (SCMs) or mineral admixtures to achieve higher economic value in light of quickly growing businesses. A high range water reducer called Alccofine 1203 makes concrete easier to work with and increases its compressive strength. Many people believe that biochar is an efficient method of storing carbon dioxide. The potential for using it to decrease permeability and increase mechanical strength of cement mortar is explored in this study.

Yatin Patel [15] The excessive focus on concrete's compressive strength rather than its performance requirements is one of the primary causes of concrete's historical degradation. When reinforced concrete constructions deteriorate, hostile chemicals from the environment are often transported, followed by chemical and physical reactions in the inside of the structure. Concrete's permeability properties determine how aggressive gasses and/or liquids are transported through it. Concrete's durability performance, as measured by physio-chemical deterioration, rises as its penetration decreases. As a result, one of the most important factors in determining how long concrete will last in harsh settings is its penetration. Srushti P [16] Cement is the most significant building material now, and it is expected to remain so in the future. The construction materials must meet new and higher demands, and in order to do so, the materials must not only have good strength properties but also be durable enough to last for a longer period of time, thus improving the durability of the concrete and producing a greener concrete, which are now becoming important criteria in obtaining high-quality concrete. The goal is to improve the performance and durability of concrete by partially substituting cement with naturally occurring industrial wastes or by-products that need less energy.

Some of these chemical and industrial byproducts, such as Alccofine, have recently received attention for their potential applications. The utilization of these extra ingredients to produce high-performance concrete is a relatively recent strategy. The current study focuses on the durability properties of M30 grade concrete with partial cement substitution with varying concentrations of Alccofine. Aseel Mansi. [17] Nano clay has been widely discussed for its potential to enhance construction materials and technical applications. This review article examines the impact of nano clay as a cement substitute and supplement on the performance of conventional and high-performance concrete. Adding nano clay to high-performance concrete improved compressive and flexural strength, durability, and resistance to sulfate attack. It also reduced porosity, permeability, and water absorption. Nano clay enhances material properties by acting as reinforcements, fillers, nucleation sites, and reactive pozzolans, promoting hydration. Nehal Hamed, [18] the use of nano-clay (5, 7.5, and 10%) as partial cement replacements in two ways: as received and after dispersion in water using a bath sonicator. The examination was based on compressive strength, split tensile strength, flexural strength, and sliding bond. SEM, XRD, and AFM were used to verify the strength and split bond strength of nano-clay concrete, as well as its microstructure characterization.

Sonication of nano-clay particles greatly improved the characteristics of concrete compared to the original material. The optimal percentage of cement substitution by nano-clay was discovered to be 7.5% among as-received and vibrated nano-clay. The inclusion of NC particles resulted in a thick and well-compacted matrix compared to the control mix, as seen by micrographs from SEM, XRD, and AFM data. Sonicated NC also demonstrated increased reactivity compared to as-received NC. Jamal A. Abdalla [19] For decades, researchers have attempted to enhance the durability of concrete by including more cementitious elements. Nanomaterials can enhance the mechanical and durability qualities of concrete, according to recent breakthroughs in the sector. This is study presents a detailed overview of recent advances in the use of nanomaterials as a performance enhancer in cement/geopolymer concrete. The study found strong relationships between cementitious matrices reinforced with nano-TiO2, nano-Fe2O3, nanoclay/metakaolin, and nano-CaCO3. Fresh qualities, microstructure, mechanical and durability characteristics, and the effect of different particle sizes have all been examined. Estefanía Baigorria [20] analyzed the CO2 effect of various industries and especially compared CO2 emissions to the cement industry.

According to the World Resources Institute (WRI), the cement sector accounts for 3.8% of total greenhouse gas (GHG) emissions and around 5% of world CO2 emissions. The primary source of CO2 in cement production is the heating of raw materials in a rotating kiln. The study concluded that the cement sector releases more CO2 into the environment when producing cement than other businesses. To minimize CO2 emissions in the environment, this study advises using alternate fuels and biomass in clinker manufacture, as well as improving energy efficiency and clinker replacement. A viable alternative to clinker will be a new kind of clinker. A promising alternative for clinker will be a new class of clinker Be Lite-Calcium Sulfuric aluminate-ferrite. The climatic change due to the cement industry is studied by McCaffrey [21] It has been reported that cement output increases by 3% per year. The cement industry is responsible for four significant emissions: dust, Sulphur, NOx, and carbon dioxide. The first three are not substantial contributors to global warming. CO2 emissions are the primary cause of global warming, and the worldwide cement sector produces 1.4 billion tons of CO2 per year. The cement sector accounts about 6% of CO2 emissions and approximately 4% of global warming.



As a result, the study recommends slag, fly ash, and limestone as an alternative to calcined material in cement that is less expensive and emits less (or no) greenhouse gases. Gavriltea [22] analyzed the influencing factors for the sand market and reviewed the impacts caused due to mining. To study the impact of sand mining, different database sources were used. The study reported that there is a global imbalance in the supply and demand of the sand market. Sand is utilized in various industries, such as chemical, ceramic, foundry, glass making, recreational products and construction, in which the construction industry consumes a major share. The study concluded that the mining of sand produces various impacts such as loss of habitat vegetation, increase in turbidity of river water and bank erosion over the environment. The study recommended finding substitutes for sand such as recycled aggregate, crushed sand, quarry dust and glass waste. Shi et al. [23] have analyzed the characteristics and pozzolonic reactivity of glass powders. The study evaluated and compared the particle shape, fineness, and pozzolonic reactivity of glass powders from various sources (GP-fine, GP-dust, GP- 4000, and GP-6000) for usage as cement substitutes.

Compared to Fly ash, the chemical composition of glass powder contains larger levels of SiO2, CaO, and Na2O but much lower levels of Al2O3. The study result concluded that replacing Portland cement with glass powder may reduce the amount of Alkali Aggregates Reaction (AAR)-induced expansion. The pozzolnic activity of finely crushed glass particles was found to be high. The study results also indicated that the pozzolonic reaction occurs at a later age GPC because of the high SiO2 concentration. An investigation on the impact of fine glass powder on concrete durability was conducted by Schwarz et al. [24]. For the purpose of determining durability properties in cement, 10 percent of the cement is substituted with glass powder (GP). The study found that the utilization of glass powder as a cement replacement material can minimize expansion caused by the alkali-silica reaction in concrete. The chloride penetrability results show that there has been some degree of pore refinement in the sample.

II. MATERIAL PROPERTIES

II.1 WASTE GLASS POWDER:

In this work, waste glass powder (WGP) is used as a partial substitution for GGBS in GPC. The chemical structure of XRF was determined by analysing WGP particles. According to the chemical makeup of WGP, the majority of the material is SiO2, accounting for around 69%. WGP has a specific gravity of 2.62 and a specific area of 463 m2/kg. The unit weight of WGP is 2580 kg/m3. Figure 1 demonstrates that the WGP used in this inquiry is an irregular in shape. The picture of WGP was used in this work

II.2 NANO CLAY:

Concrete performs much better when nano clay is added because it increases workability, strength, and durability. By improving the microstructure and decreasing porosity, it increases compressive and flexural strength and increases the concrete's resistance to environmental assaults such sulfates and freeze-thaw cycles as well as water penetration. Additionally, nano clay reduces shrinkage and cracking, enhancing the mix's overall cohesiveness. It also speeds up cement hydration, which results in a quicker development of early strength, and improves workability without raising water demand. One of its environmentally beneficial effects is that it uses less cement, which lowers carbon emissions. Additionally, by enhancing thermal stability, nano clay increases concrete's resistance to exposure to high temperatures and fire. Nano clay is a useful addition for improving the sustainability and performance of concrete constructions because of these benefits.

II.4 FINE AGGREGATE:

Aggregate is a course to medium grained particulate substance used in concrete building. The aggregate phase provides mechanical strength to the structure while also influencing the fundamental qualities of concrete, such as strength, unit weight, Young's modulus, workability and durability. Fine aggregate with a high void-filling capability aids in the production of dense concrete with maximum strength and extends the structural durability. This operation employed manufactured sand (M-sand) as the fine aggregate. The M-sand utilized in this experiment was acquired locally by crushing stone. M-sand has a cubical form, rounded corners, and a dimension of less than 4.75 mm. The physical properties of M-sand are tabulated in Table 4. Properties of the M-sand are determined as per IS: 2386 – 1963 [138], and the values are confirmed to IS: 383- 1970.

Table 4: Physical properties of M-sand.

S. No	Physical Property	Value

2.	Fineness Modulus	2.36
3.	Zone	III
4.	Bulk density	$1702m^3$

Source: Authors, (2026).

II.5 COARSE AGGREGATE:

Coarse aggregate accounts for the majority of the concrete's volume and strength. Because of the weathering activity of the rock, coarse aggregate derived from its core half is desirable. The physical qualities of aggregate, such as specific gravity, hardness, and texture, vary depending on where it is extracted. Aggregates can be smooth, spherical, or angular (crushed stones). Typical coarse aggregate sizes vary from 4.7 to 20 mm.

For this project, coarse aggregate (CA) was purchased from a local quarry. The coarse aggregate utilized in this work has an angular form and is clean and dry. The physical properties of coarse aggregate are tabulated in The Properties of the coarse aggregates are confirmed to IS: 383-1970.

II.6 MIXING, CASTING AND CURING OF CONCRETE:

The components for the mixes (AF and cement, WGP and M-Sand) were weighed and mixed dry for 3-4 minutes before adding coarse aggregate. The alkaline liquid, a mixture of sodium hydroxide and sodium silicate solutions, was then added to the dry mix and stirred for 3-5 minutes before adding some more water, around 20% of the binder's weight, to increase workability. The mixing was continued for approximately 6-8 minutes. After mixing, the concrete was poured in conventional steel Molds and compacted properly. Precautions were made to ensure that the components mixed uniformly. For ambient curing, the cubes were maintained at room temperature after casting, demoulded after one day, and cured at room temperature until testing. Ambient cured specimens are stored in the laboratory at room temperature (27-31ºC).

II.7 CEMENT:

The cement utilized in every specimen was standard Portland. Cement grade 53, as per IS: 12269:2013, was used.

II.8 WATER:

The investigation uses conventional potable water from the laboratory supply source.

II.9 CONCRETE:

The cement used is Portland Cement 53 Grade. The cement tests are carried out in compliance with the IS 1489 parameters. Aggregate must be no greater than 20mm, with fine aggregate ranging from 0 to 4.75mm in size. To maintain its intrinsic properties, such as compressive strength, the concrete must be allowed to cure in real-world conditions for around 28 days. A concrete cube (100mm x 100mm x 100mm) is loaded with axial forces in order to evaluate its strength.

III. MIX PROPORTIONS

Table 6: Concrete Mix ID's.

S. No	Mix ID	Description
1.	CM (Conventional Mix)	Fine Aggregate, Coarse Aggregate & Cement
2.	5% of AF	Fine Aggregate replaced with AF for about 5% of its total volume
3.	10% of AF	Fine Aggregate replaced with AF for about 10% of its total volume
4.	15% of AF	Fine Aggregate replaced with AF for about 15% of its total volume
5.	20% of AF	Fine Aggregate replaced with AF for about 20% of its total volume
6.	25% of AF	Fine Aggregate replaced with AF for about 25% of its total volume
7.	5% of NC	Cement replaced with NC for about 5% of its total volume
8.	10% of NC	Cement replaced with NC for about 10% of its total volume
9.	15% of NC	Cement replaced with NC for about 15% of its total volume
10.	20% of NC	Cement replaced with NC for about 20% of its total volume
11.	25% of NC	Cement replaced with NC for about 25% of its total volume
12.	10% of GP	Fine Aggregate replaced with GP for about 5% of its total volume
13.	20% of GP	Fine Aggregate replaced with GP for about 10% of its total volume
14.	30% of GP	Fine Aggregate replaced with GP for about 15% of its total volume
15.	40% of GP	Fine Aggregate replaced with GP for about 20% of its total volume
16.	50% of GP	Fine Aggregate replaced with GP for about 25% of its total volume

IV. EXPERIMENTAL INVERSICATION (MECHANICAL & DURABILITY PROPERTIES)

IV.1 COMPRESSIVE STRENGTH:

Compressive strength was tested as per IS 516 (1959) for the specimens casted with varying mix proportions. It was observed that the compressive strength of 20AF is increased by 0.2 % and 3.15 % when compared to conventional concrete mix tested at 7 days and 28 days respectively. When comparing the results obtained at 28 days, it was found that 20 AF mix recorded the highest compressive strength than other mixes.

IV.2 SPLITTING TENSILE STRENGTH:

Tensile strength was measured in accordance with IS 516 (1959) for specimens cast with varied mix proportions. The tensile strength of 20AF was found to be 32.12% higher than that of normal concrete mix after 28 days of testing. When the findings were compared after 28 days, it was observed that the 20 AF mix had the highest tensile strength of the mixtures tested.

IV.3 FLEXURAL STRENGTH:

The specimens cast with different mix proportions had their flexural strength evaluated in accordance with IS 516 (1959). Compared to a typical concrete mix tested at 28 days, respectively, the flexural strength of 20AF was found to be 9.90% percent higher. In contrast to other mixes, the 20 AF mix had the maximum flexural strength when the results were compared at 28 days.

Table 7: Compressive, Splitting tensile & Flexural test.

IV.7 ACID RESISTANCE TEST HCL:

When AF is substituted with cement, the largest percentage reduction in weight loss is 108.05%, 61.30%, and 62.92%. compared to standard concrete for 28, 56, and 90, respectively. When NC is substituted with cement, the largest percentage reduction in weight loss is 77.45%, 73.1%, and 80% compared to standard concrete for 28, 56, and 90, respectively. When GF is substituted with fine aggregate, the greatest percentage reduction in weight loss absorption is 41.9%, 42.3%, and 49.4% compared to standard concrete for 28, 56, and 90, respectively. The largest percentage reduction in strength loss when AF is substituted with cement is 6.54%, 7.23%, and 9.12% when compared to standard concrete for 28, 56, and 90, respectively. The largest percentage reduction in strength loss when AF is substituted with cement is 6.54%, 7.23%, and 9.12% when compared to standard concrete for 28, 56, and 90, respectively. When NC is substituted with fine aggregate, the highest percentage reduction in strength loss is 56.11%%, 75.27%, and 84.24% when compared to standard concrete at 28, 56, and 90, respectively. When GF is substituted with fine aggregate, the highest percentage reduction in strength loss is 48.62%, 46.24%, and 62.10% when compared to standard concrete at 28, 56, and 90, respectively.

IV.9 SULPHATE ATTACK TEST:

When AF20 is substituted with cement, the largest percentage reduction in weight loss is 95.92%, 41.02%, and 38.15%, when compared to standard concrete for 28, 56, and 90, respectively. When NC15 is substituted with cement the greatest percentage reduction in weight loss absorption is 57.38%, 58.28%, and 39.37% compared to standard concrete for 28, 56, and 90, respectively When GF30 is substituted with cement the greatest percentage reduction in weight loss absorption is 41.44%, 39.04%, and 40.13% compared to standard concrete for 28, 56, and 90, respectively. The largest percentage reduction in strength loss when AF20 is substituted with cement is 22.35%, 24.33%, and 27.04% when compared to standard concrete for 28, 56, and 90, respectively. When NC15 is substituted with cement, the highest percentage reduction in strength loss is 23.53%, 47.52%, 31.85% when compared to standard concrete for 28, 56, and 90, respectively. When GP30 is substituted with fine aggregate, the highest percentage reduction in strength loss is 53.66%, 65.25%, 52.42% when compared to standard concrete for 28, 56, and 90, respectively.

IV.10 MARINE RESISTANCE TEST:

When compared to conventional concrete for 28, 56, and 90, the largest percentage reduction in weight loss that occurs when AF is substituted with cement is 79.48%, 70.98%, and 71.81%, respectively. When GF is substituted with fine aggregate, the weight loss absorption can be reduced by a maximum percentage of 72.82%, 76.33%, and 54.69% when compared to conventional concrete for 28, 56, and 90, respectively. When compared to regular concrete for 28, 56, and 90, the largest percentage reduction in strength loss that occurs when AF is substituted with cement is 31.84%, 41.31%, and 37.56%, respectively. When compared to regular concrete for 28, 56, and 90, the largest percentage reduction in strength loss that occurs when GP is substituted with fine aggregate is 25.51%, 25.52%, and 34.33%, respectively. In previous studies when Alccofine and glass powder compared to normal conventional concrete in weight loss 83.58%,85.71%,75.16% and the strength loss is 38.55%,43.30%,45.58% is the best.

V. CONCLUSIONS

In this experiment, concrete cubes, cylinders, and beams were cast for varied proportions and evaluated at 7,14,28, 56, and 90 days for mechanical and durability. The reduction in water absorption in saturated stages when cement is substituted with 20% Alccofine and 15% nano clay when tested at 28, 58, and 90 days, respectively, compared to regular conventional concrete. When Glass Powder is utilized to replace 30% of the fine aggregate, water absorption is reduced by 3.4, 3.32, and 3.26. Sorptivity decrease when cement is substituted with 20% Alccofine 15% nano clay when tested at 60, 90, and 120 minutes with standard conventional concrete. Using GP as a 30% replacement for cement reduces water absorption by 0.076, 0.072, and 0.068 compared to standard concrete. The penetration value is also reduced to 1840 in AF20, NC15 and GP30 when compared normal conventional concrete. When AF is replaced with cement, the greatest percentage reduction in weight loss is 1.74, 3.23, and 3.56 when compared to regular concrete for 28, 56, and 90. Substituting cement for NC results in significant weight reductions of 2.04, 3.01, and 3.22 compared to ordinary concrete for 28, 56, and 90, respectively. Substituting GF with fine aggregate results in a 42.55, 3.66, and 3.88 percent reduction in weight loss absorption compared to ordinary concrete (28, 56, and 90, respectively).

When AF is substituted with cement, the largest percentage reduction in weight loss is 79.48%, 70.98%, and 71.81%, when compared to standard concrete for 28, 56, and 90, respectively. When GP is substituted with fine aggregate, the greatest percentage reduction in weight loss absorption is 72.82%, 76.33%, and 54.69% compared to standard concrete for 28, 56, and 90, respectively. When AF is substituted with cement, the highest percentage reduction in strength loss is 31.84%, 41.31%, and 37.56% compared to regular concrete for 28, 56, and 90, respectively. When GP is substituted with fine aggregate, the largest percentage reduction in strength loss is 25.51%, 25.52%, and 34.33% when compared to standard concrete at 28, 56, and 90 days respectively. In previous studies when Alccofine and glass powder compared to normal conventional concrete in weight loss 83.58%,85.71%,75.16% and the strength loss is 38.55%,43.30%,45.58% is the best. According to the aforementioned data, the best percentage replacement of cement by Alccofine is 20%, whereas the optimum percentage replacement of cement by Glass Powder is 50%. Furthermore, replacing cement with a mix of Alccofine and Glass Powder produces superior results when compared to standard conventional concrete.

ABSTRACT

The increasing need for second generation feedstocks for biodiesel production due to the drawbacks associated with edible oil-based biodiesel has led to the use of non-edible feed stocks like mango seed kernel oil (MSKO). The objectives of this research are to improve the biodiesel production from MSKO through transesterification process and to maximize the biodiesel yield as well as the calorific value of the biodiesel. Four factors, namely methanol-to-oil ratio (4:1, 6:1, 8:1 and 10:1), reaction temperature (45°C, 50°C, 55°C and 60°C), reaction time (30 min, 60 min, 90 min and 120 min) and catalyst concentration (0.5%, 1.0%, 1.5% and 2.0%) were chosen and studied at four levels using Taguchi's L16 orthogonal array. A multi-objective optimization approach was used in this study by applying the WSM on the response variables that were normalized and weighted (yield 0.6 and calorific value 0.4). The findings indicated that the best conditions for transesterification were methanol to oil ratio of 8:1, temperature of 55°C, time of 120 minutes and catalyst concentration of 1.5% to yield biodiesel of 96.15% and calorific value of 39.67 MJ/kg. Under these optimal conditions, confirmation tests were conducted which gave nearly similar results (96.16 ± 0.07% yield and 39.70 ± 0.08 MJ/kg calorific value) thereby confirming the effectiveness of the optimization process. Analysis of variance (ANOVA) revealed that reaction temperature has an effect on calorific value at $p < 0.05$ while other parameters have a combined effect on yield. This study shows that MSKO is a feasible feedstock for biodiesel production that is not suitable for human consumption and provides a statistically significant model for improving the quality of the fuel and the efficiency of the conversion process.

I. INTRODUCTION

Biodiesel is an environment friendly, renewable and sustainable fuel that has been developed to meet the rising energy demands and environmental pollution. While diesel is a non renewable resource derived from petroleum, biodiesel is produced from renewable resources such as vegetable oils, animal fats, and waste cooking oils, and therefore can be a carbon neutral fuel that can help in the reduction of greenhouse gases emissions [1]. The environmental benefits of biodiesel include the ability to reduce carbon monoxide, hydrocarbons, and particulate matter emissions and the fact that biodiesel is more biodegradable than fossil diesel [2–4]. Besides the environmental impacts, biodiesel has the advantages of energy security since it helps to cut on the importation of fossil fuels and diversification of energy. The exhaustion of fossil fuel resources and fluctuations in prices have encouraged researchers and policymakers to search for biofuels as an effective solution [5], [6].Moreover, biodiesel from waste like used cooking oil and municipal sewage sludge has attracted interest due to its potential to address waste management challenges while offering a viable biofuel source [7], [8]. The global consumption of biodiesel is on the rise due to the enhanced environmental standards and international agreements on emissions of carbon.

Today, most countries have opted to blend different percentages of biodiesel with the main stocks which include the B5 (5% biodiesel), B10 (10%) and the B20 (20%) to move towards low-carbon fuels in the transport sector [9]. As feedstocks for biodiesel production are becoming more diverse, catalysts are being improved, and the process is being optimized, biodiesel production is expected to become more efficient and large-scale, which will play an important role in the transition to clean energy [10], [11]. The use of edible oils in biodiesel production has some drawbacks such as competition with food resources, increasing costs, and negative impacts on the environment such as deforestation and loss of bio-diversity [12]. To address these challenges, non-edible oils like Jatropha, Karanja, and MSKO have been considered because of their availability, cheap, and do not compete with food resources [13–15]. Of these, MSKO is more attractive because of its high oil content of 8-15% which makes it possible to use it as feedstock instead of the conventional feedstocks [16], [17]. Moreover, MSKO is easily accessible and can be procured without any extra land requirement and resources hence making it sustainable [18], [19]. Based on these benefits, MSKO can be considered as a viable and untapped feedstock that is in line with the waste-to-energy and biofuel development trends around the world [20].

The conversion of MSKO into biodiesel is a challenge since it contains high FFA that results in soap formation and deactivation of the catalyst [21], [22]. Therefore, the factors such as methanol to oil ratio, catalyst concentration, reaction temperature, and reaction time are important in determining the biodiesel yield and quality [23]. Lower methanol-to-oil ratio lead to partial conversion of feedstock, while higher ratio make the separation process more challenging [24]. Low concentration of the catalyst results in low conversion while high concentration results in the formation of soap [25]. Also, reaction temperature and time must be well controlled to achieve maximum conversion of the triglycerides to biodiesel without undergoing thermal breakdown [26]. Addressing these challenges by improving the process and catalysts would go a long way in increasing the yield of biodiesel, the economics of the process and sustainability. The enhancement of biodiesel production and performance of mango seed biodiesel has been investigated using various techniques to increase the yield, fuel properties, and engine performance. Transesterification has been widely used in biodiesel synthesis and [27] used RSM to optimize the MSKO biodiesel production with a 95% yield that conforms to the international fuel standards. In the same vein, [28] also showed that the biodiesel obtained from MSKO meets the ASTM-D6751 and EN14214 standards in terms of physicochemical characteristics and engine performance as well as conventional diesel. Building on biodiesel sources, [29] used mango seed kernel and tamarind seed biomass waste and achieved biodiesel yield of 75–80% which is in line with ASTM D6751 standard for waste-to-energy solutions.

In addition to the production optimization, several works have been done on the improvement of the properties of mango seed biodiesel for use in diesel engines. [30] blended hybrid nanoparticles (Al_2O_3, TiO_2) and hydrogen gas into Mango Seed Methyl Ester emulsified biodiesel using RSM and Deep Recurrent Neural Network-based Honey Badger Algorithm to reach 32% Brake Thermal Efficiency and enhanced combustion properties with RMSE $\leq$ 6.6. Moreover, [30] enhanced MSME20 biodiesel with cerium oxide and magnesium oxide nanoparticles and achieved the reduction of CO, HC, and smoke emissions by 28%, increase in BTE by 16%, and optimization of NOx emission using a hybrid deep belief network-sandpiper optimizer. There have also been attempts to increase the biodiesel yield through other methods of optimization in recent years. [31] used ultrasound supported methanolysis and Whale Algorithm to synthesize biodiesel from waste mango seed kernel oil with 90.88% yield which is higher than transesterification and RSM. This paper aims at evaluating the biodiesel production from mango seed kernel oil through the evaluation of the transesterification parameters using Taguchi based experimental design and WSM optimization. Although there are many studies on biodiesel production, few research works address the effects of methanol-to-oil ratio, reaction temperature, reaction time, and catalyst concentration simultaneously using multiple objectives with biodiesel yield and calorific value. The novelty of this work is based on the combined statistical and decision-making approach that increases the efficiency of the process and guarantees the quality of the fuel. In the present work, Taguchi L16 orthogonal array was used to plan the experiments and ANOVA analysis was performed to find out the significance of each parameter to develop an efficient biodiesel production process.

II. MATERIALS AND METHODOLOGY

This section describes the experimental methodology and analytical methods used in the enhancement of biodiesel production from mango seed kernel oil. It also provides information on feedstock pre-treatment, transesterification process, experimental design, and statistical analysis to assess the biodiesel production efficiency and fuel properties.

II.1 EXTRACTION OF MANGO SEED KERNEL OIL

The mango seeds used in this study were sourced from the Western Maharashtra region of India for the extraction of oil. To remove the surface contamination and other unwanted substances, the seeds were washed with water before the process. The cleaned seeds were then dried in two stages to minimize moisture content and improve the efficiency of extraction of oil. In the first drying stage, the seeds were exposed to direct sunlight for 36 hours to undergo natural drying process. This was succeeded by oven drying at 65ºC for 3 hours in order to ensure that the samples were evenly and thoroughly dried. After that, the seeds were dried and the kernels were separated from the hard-outer shells by using hydraulic pressing mechanism. In order to get the maximum yield of oil, the extracted kernels were dried at 60ºC for 3 hours. After that, the completely dried kernels were taken through mechanical oil extraction mill. This process gave about 130g of oil per kilogram of the mango kernels with an extraction efficiency of 13%. The extracted MSKO was then filtered and placed in a closed container to avoid any oxidation and degradation of the sample before the next process. The process of extraction of oil from the raw mango seeds is illustrated in the Figure 1.

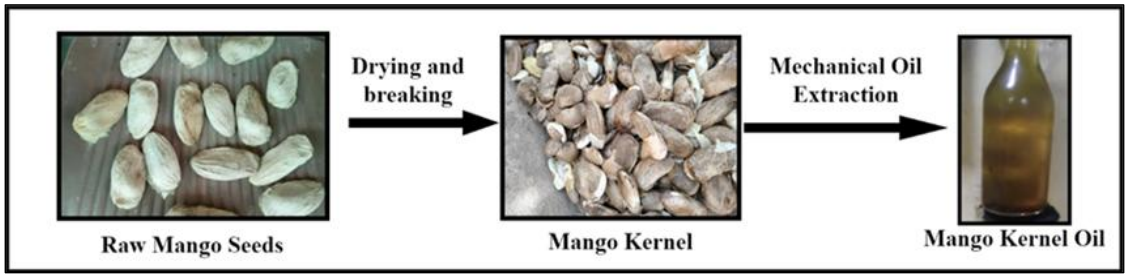

Figure 1. Extraction of Mango Seed Oil Kernel.

II.2 TRANSESTERIFICATION PROCESS

The biodiesel production from MSKO was carried out in a batch reactor by using methanol and potassium hydroxide (KOH) as a catalyst to catalyse the transesterification of the triglycerides into FAME. The reaction was started by dissolving the catalyst in methanol to make a solution which was then charged into the preheated MSKO. In order to understand the effect of reaction conditions on biodiesel yield and the overall process, the reaction conditions were altered successively. Four factors were taken into consideration for the transesterification process: methanol to oil molar ratio, temperature, time and catalyst concentration. Each of these parameters was tested at four different levels to find the best level that would give the highest biodiesel conversion. The parameters and their levels are as follows: The detailed parameters and their levels are presented in Table 1.

Table 1. Transesterification process parameters and levels.

Parameter	Level 1	Level 2	Level 3	Level 4
Methanol-to-Oil Ratio	04:01	06:01	08:01	10:01
Reaction Temperature (°C)	45°C	50°C	55°C	60°C
Reaction Time (Min)	30 min	60 min	90 min	120 min
Catalyst Concentration (% w/w)	0.50%	1.00%	1.50%	2.00%

Source: Authors, (2026).

The reaction mixture was stirred at 600 rpm to facilitate emulsification and increase mass transfer rates so that the reactants could come into close contact. After completion of the reaction, the mixture was transferred to a separation funnel and allowed to settle for 12 hours in order to allow the glycerol, the major by-product to settle at the bottom of the funnel from the biodiesel layer. The upper biodiesel layer was then separated and washed several times with warm distilled water (50°C–60°C) in order to remove catalyst, methanol and soap formation. Last but not the least, the biodiesel was then heated at a temperature of 105°C with a pressure of 600 mmHg for 30 minutes to remove water content. The biodiesel product was then filtered and kept in sealed containers for further physicochemical and performance tests to determine its viability as a renewable energy source.

II.3 EXPERIMENTAL DESIGN

In order to improve the biodiesel production process from MSKO, the Taguchi L16 orthogonal array was used as an experimental design method. This approach allows for the determination of the best combination of factors that would yield the most optimal result since it involves the manipulation of more than one factor at a time while at the same time reducing the number of trials. The four factors that were considered in this study were the methanol to oil ratio, temperature, time and concentration of the catalyst and each of these factors was set at four different levels. By conducting the experiment using the L16 orthogonal array, 16 trials were conducted instead of 256 (4^4) in a full factorial design which saved time, cost and resources yet achieving the best optimization. The Taguchi L16 experimental matrix used in this study is shown in Table 2 which indicates 16 different combinations of the process parameters.

Table 2. Taguchi L16 orthogonal array for biodiesel optimization

Run	Methanol-to-Oil Ratio (Molar Ratio)	Reaction Temperature (°C)	Reaction Time (Minutes)	Catalyst Concentration (% w/w)
1	04:01	45	30	0.5
2	04:01	50	60	1
3	04:01	55	90	1.5
4	04:01	60	120	2
5	06:01	45	60	1.5

16	10:01	60	30	1.5

Source: Authors, (2026).

This orthogonal array design makes it possible to efficiently analyze the effects of each factor with least replication of experiments. The outcomes of these trials were used in determining the best reaction parameters that would yield the highest biodiesel yield with the best quality. The gross energy content of each biodiesel sample was determined by employing the Parr 6400 bomb calorimeter as per the ASTM D240 method. About one gram of the sample was burned in a combustion chamber under controlled oxygen environment, and the heat generated was used in determining the higher heating value.

II.4 STATISTICAL ANALYSIS

In order to determine the effect of the transesterification parameters on biodiesel yield and calorific value, the Analysis of Variance (ANOVA) was used as the statistical tool. The factors that were used in this study were methanol-to-oil ratio, reaction temperature, reaction time and catalyst concentration and they were set at four levels with the help of Taguchi L16 orthogonal array. To check the significance of each factor, ANOVA was performed separately for both output variables. The study was conducted at 95% confidence level and the $p < 0.05$ was used to determine statistical significance. The F-value was used to compare the significance of each parameter while the sum of squares determined the extent of contribution of each factor to the total variability. This approach helped in determining the key variables influencing the biodiesel production and facilitated the confirmation of the experimental results on the basis of statistical analysis.

II.5 OPTIMIZATION USING WEIGHTED SUM METHOD

In order to determine the best conditions for biodiesel production from mango seed kernel oil through transesterification process, the WSM was used as a multi-objective optimization technique. This makes it possible to combine two or more output variables such as biodiesel yield (%) and calorific value into a single decision variable by use of weights and normalization. This is especially useful when the optimization is done for both, the process and the fuel quality at the same time. The optimization was done using a Taguchi L16 orthogonal array, in which four factors, namely methanol to oil ratio, reaction temperature, reaction time and catalyst concentration were varied at four levels. The results of each experimental run were obtained in terms of the performance outputs to assess the efficiency of the process. The output variables are in different units and scales and therefore, normalization was necessary to transform all the variables to a single dimensionless scale. The normalization techniques that were used were based on the nature of the criteria as follows:

For beneficial criteria (higher values are better), such as biodiesel yield and calorific value:

$$X_{norm} = \frac{X_i}{X_{max}} \tag{1}$$

For non-beneficial (cost) criteria (lower values are better), the formula would be:

$$X_{norm} = \frac{X_{min}}{X_i} \tag{2}$$

However, in this study, both output variables are beneficial, so only the first normalization equation was used. After normalization, the output variables were then scaled to a suitable value in order to represent the importance of each of the output variables. According to the objectives of the study, biodiesel yield was assigned a weight of 0.6 since it is directly related to production while calorific value was assigned a weight of 0.4 since it is an indication of fuel quality. The weighted sum score for each experimental run was calculated using the following equation:

$$S_i = \sum_{j=1}^{n} w_j \cdot X_{ij}^{norm} \tag{3}$$

Where

S_j = weighted sum score for the ith experimental run
w_j = weight of the jth response variable
X_{ij} = normalized value of the jth response in the ith run
n = number of response variables (2 in this case)

III. RESULT AND DISSCUSION

This section focuses on the findings of the experimental study and optimization of biodiesel production from mango seed kernel. In the present work, the biodiesel yield and calorific value are studied as functions of transesterification parameters with the help of statistical and multi-objective approaches. The validity of the optimal conditions is confirmed by the results of the confirmation tests of key findings.

III.1 EXPERIMENTAL TEST RESULTS

The findings in Table 3 show the effect of transesterification process variables, namely, methanol to oil ratio, reaction temperature, reaction time and catalyst concentration on biodiesel production and calorific value. The highest biodiesel yield of 96.15% was obtained at a methanol-to-oil ratio of 8:1, reaction temperature of 50°C, reaction time of 120 minutes, and catalyst concentration of 1.5% which suggests that the optimal methanol ratio and an optimum catalyst concentration along with an adequate reaction time is suitable for the maximum conversion of triglycerides. The least yield of 72.44% was obtained at a methanol to oil ratio of 4:1, reaction temperature of 45°C, reaction time of 30 minutes and catalyst concentration of 0.5% as the low concentration of methanol and the low concentration of the catalyst hinders the transesterification reaction hence low biodiesel yield.

Table 3: Experimental results showing effect of process parameters on response variables.

Run	Methanol-to-Oil Ratio (Molar Ratio)	Reaction Temperature (°C)	Reaction Time (Minutes)	Catalyst Concentration (% w/w)	Yield (%)	CV (MJ/kg)
1	04:01	45	30	0.5	72.44	38.92

16	10:01	60	30	1.5	85.45	39.68

Source: Authors, (2026).

The calorific value which defines the energy content of the fuel was found to be in the range of 38.92 MJ/kg to 40.1 MJ/kg in all the experimental trials. The highest calorific value of 40.1 MJ/kg was achieved at the methanol to oil ratio of 8:1, reaction temperature of 55°C, reaction time of 30 minutes and catalyst concentration of 1% which shows that moderate conditions yield biodiesel with high energy content. But the yield of biodiesel and calorific value were not in a straight line because some of the experimental run with high yield had low calorific values. This implies that biodiesel yield is affected mostly by the efficiency and the extent of the transesterification process while calorific value is more determined by the quality and the chemical makeup of the fatty acid methyl esters produced during the process. The biodiesel yield increased with the increase in the methanol to oil ratio with 4:1 to 8:1 being the optimal range. But, increasing the ratio to 10:1 did not improve the yield because of phase separation and unreacted methanol. The yield and calorific value of the biodiesel was also influenced by the reaction temperature where moderate temperature of 50-55°C was ideal for transesterification.

Low temperatures led to low reaction rates and low conversion levels while high temperatures might lead to thermal degradation and side reactions. Reaction time also had an impact on yield where longer times of 90-120 minutes allowed for all the triglycerides to be esterified while shorter times produced lower yields due to the presence of unreacted triglycerides. Another factor was the catalyst concentration where 1- 1.5% w/w showed to be effective in increasing biodiesel production due to increased reaction rates. Lesser concentration of the catalyst reduced the reaction rate while 2% concentration of the catalyst formed soap which decreases yield and biodiesel purity. In conclusion, the findings reveal that biodiesel yield is highest under conditions of moderate methanol to oil ratio, reaction temperature, reaction time and catalyst concentration. Nevertheless, calorific value is not significantly affected by the process conditions and it can be inferred that the post-reaction purification steps may have a larger impact on the fuel energy content.

III.2 ANOVA ANALYSIS

The ANOVA analysis of biodiesel yield and calorific value, as shown in Table 4 and 5, gives a quantitative assessment of the effects of the transesterification parameters, namely, methanol to oil ratio, reaction temperature, reaction time and catalyst concentration on the output responses. In terms of biodiesel yield, it was observed that none of the parameters had any significant effect at a 0.05 level of significance. The methanol-to-oil ratio with a p value of 0.2015, the reaction temperature with a p value of 0.1067, the reaction time with a p value of 0.9222 and the catalyst concentration with a p value of 0.5338 were all greater than 0.05 and therefore, their effects on the yield can be considered non-significant within the range of the experiments. Nonetheless, the p-value of reaction temperature is lower than that of other factors, which indicates that it has a more significant but not very significant impact on yield, which may be attributed to its positive effect on the kinetic of transesterification and ester formation.

Table 4. ANOVA Results for Biodiesel Yield (%)

Source	Sum of Squares	Degrees of Freedom (DF)	F-value	P-value
Methanol-to-Oil Ratio	186.18	3	1.96	0.2015
Reaction Temperature (°C)	241.06	3	2.54	0.1067
Reaction Time (Minutes)	8.55	3	0.09	0.9222
Catalyst Concentration (% w/w)	53.51	3	0.56	0.5338
Residual	285.24	3		
Total	774.55	15		

Source: Authors, (2026).

On the other hand, the ANOVA of the calorific value showed that reaction temperature has a p-value of 0.0173 and F-value of 7.8644, which means that the calorific value is sensitive to temperature changes. This is technically valid since the reaction temperature impacts the energy level of the methyl ester formed, the purity and the molecular composition of biodiesel. The reaction temperature has an inverse relationship with the amount of residual unreacted triglycerides and a direct relationship with the energy content of biodiesel; where a higher reaction temperature produces biodiesel with higher energy content. On the other hand, methanol-to-oil ratio ($p = 0.6849$), reaction time ($p = 0.4167$), and catalyst concentration ($p = 0.2999$) were not significant for calorific value, which indicates

that the fuel energy content is not as sensitive to these parameters as temperature.As in Table 4 and Table 5, the analysis of variance indicates that reaction temperature is a significant factor to biodiesel quality, especially the calorific value while biodiesel yield is a function of all the parameters as a whole rather than the individual parameter.

III.3 OPTIMIZATION RESULTS

The biodiesel yield and calorific value of the biodiesel produced from the WSM optimization results are presented in the Table 6 to determine the effect of the transesterification parameters and the most suitable experimental run. The maximum WSM value of 0.9957 was obtained in Run 10 which has biodiesel yield of 96.15% and calorific value of 39.67 MJ/kg; therefore, it can be concluded that the selected process conditions provided the maximum biodiesel production with high fuel quality. This indicates that the concentration of methanol to oil should be 8:1, reaction temperature of 50°C, reaction time 120 minutes and 1.5% catalyst concentration as the best conditions for high conversion efficiency and energy content. On the other hand, the ANOVA of the calorific value showed that reaction temperature has a p-value of 0.0173 and F-value of 7.8644, which means that the calorific value is sensitive to temperature changes.

This is technically valid since the reaction temperature impacts the energy level of the methyl ester formed, the purity and the molecular composition of biodiesel. The reaction temperature has an inverse relationship with the amount of residual unreacted triglycerides and a direct relationship with the energy content of biodiesel; where a higher reaction temperature produces biodiesel with higher energy content. On the other hand, methanol-to-oil ratio ($p = 0.6849$), reaction time ($p = 0.4167$), and catalyst concentration ($p = 0.2999$) were not significant for calorific value, which indicates that the fuel energy content is not as sensitive to these parameters as temperature. As in Table 4 and Table 5, the analysis of variance indicates that reaction temperature is a significant factor to biodiesel quality, especially the calorific value while biodiesel yield is a function of all the parameters as a whole rather than the individual parameter.

Table 6: Weighted sum optimization results.

Run	Yield (%)	CV	$Yield_{norm}$	CV_{norm}	WSM score	Rank
1	72.44	38.92	0.753406136	0.9705736	0.84027311	16
2	84	39.19	0.873634945	0.9773067	0.91510366	12
3	91.63	39.59	0.95299012	0.9872818	0.96670679	2
4	75.29	39.4	0.783047322	0.9825436	0.86284585	15
5	91.89	39.22	0.955694228	0.9780549	0.96463848	3
6	79.54	39.38	0.82724909	0.9820449	0.88916741	14
7	84.46	39.56	0.878419137	0.9865337	0.92166495	10
8	90.86	39.76	0.944981799	0.9915212	0.96359756	4
9	85.1	39.38	0.885075403	0.9820449	0.9238632	9
10	96.15	39.67	1	0.9892768	0.99571072	1
11	88.81	40.1	0.923660946	1	0.95419657	6
12	82.52	39.61	0.85824233	0.9877805	0.91005762	13
13	89.07	39.45	0.926365055	0.9837905	0.94933524	7
14	84.79	39.22	0.881851274	0.9780549	0.92033271	11
15	90.73	39.72	0.943629745	0.9905237	0.96238732	5
16	85.45	39.68	0.888715549	0.9895262	0.9290398	8

Source: Authors, (2026).

Runs 3, 5, and 8 also had high WSM scores of 0.9667, 0.9646, and 0.9636 respectively, which means that even if there is a slight change in the concentration of the catalyst and the reaction time within the range of 1.0 – 1.5% for the catalyst and 90 – 120 minutes for the reaction time, the yield of biodiesel is still high and the energy content is not significantly affected. The optimal reaction temperature was found to be around 50–55°C, which was evident from the higher ranked runs, as moderate temperature favors the conversion of triglycerides to methyl esters without causing degradation of the latter. On the other hand, the least WSM score of 0.8402 was obtained in Run 1 which produced the least biodiesel yield of 72.44% and calorific value of 38.92 MJ/kg. This implies that the methanol-to-oil ratio of 4:1, reaction temperature of 45°C, reaction time of 30 minutes and the catalyst concentration of 0.5% were not efficient for transesterification. The lower catalyst concentration and shorter reaction time contributed to poor esterification thus yielding lower biodiesel and energy content due to unreacted triglycerides and presence of impurities. The values of calorific values were within a small range of 38.92–40.1 MJ/kg and the highest CV of 40.1 MJ/kg was recorded in Run 11 where reaction temperature was 55°C and catalyst concentration was 1.0%. This means that high reaction temperatures increase fuel energy density probably as a result of increased esterification and low residual impurities. However, the maximum biodiesel yield does not always mean the maximum CV, which suggests that biodiesel quality depends not only on yield, but the FAME profile and purity as well.

III.4 CONFIRMATION OF OPTIMAL CONDITIONS

The confirmation experiments were also carried out using the optimal conditions of methanol to oil ratio of 8:1, reaction temperature of 55°C, reaction time of 120 minutes and catalyst concentration of 1.5%. The results of the confirmation experiments are presented in Table 7 below. The three trials gave biodiesel production of 96.08%, 96.22%, and 96.18% with calorific values of 39.62, 39.75, and 39.72 MJ/kg respectively. The biodiesel yield was found to be 96.16 ± 0.07% and the calorific value 39.70 ± 0.08 MJ/kg, which reveals that there was high degree of precision and reliability at the identified optimal conditions.

Table 7. Confirmation test results at optimal conditions

Test Run	Methanol-to-Oil Ratio	Reaction Temperature (°C)	Reaction Time (min)	Catalyst Concentration (% w/w)	Biodiesel Yield (%)	Calorific Value (MJ/kg)
Confirmation Run 1	08:01	55	120	1.5	96.08	39.62
Confirmation Run 2	08:01	55	120	1.5	96.22	39.75
Confirmation Run 3	08:01	55	120	1.5	96.18	39.72
Average	–	–	–	–	**96.16**	**39.70**

Source: Authors, (2026).

In comparison to the Experimental Run 10 which was earlier considered optimal according to WSM scoring and gave biodiesel yield of 96.15% and calorific value of 39.67 MJ/kg, the confirmation results are quite similar. This good correlation further supports the effectiveness and efficiency of the optimization framework to guarantee that the chosen process conditions not only yield the highest biodiesel concentration but also biodiesel with high energy density. A small standard deviation across the runs also underlines the robustness of the transesterification process under these optimized conditions, which supports the applicability of these conditions for large-scale biodiesel production from mango seed kernel oil.

IV. CONCLUSION

This study describes the efficient process of biodiesel production from mango seed kernel oil through a multiple parameter transesterification process. The factors such as methanol to oil ratio, reaction temperature, reaction time and catalyst concentration were optimized using Taguchi L16 orthogonal array and biodiesel yield and calorific value were taken as the response characteristics. The WSM was used for the multi-objective optimization, which aimed at achieving the optimal production rate and the quality of the fuel.

- The optimal conditions were found to be a methanol to oil ratio of 8:1, the temperature of 55°C, the time of 120 minutes and the concentration of the catalyst of 1.5% w/w. Under these conditions, the process gave the highest biodiesel conversion efficiency of 96.15% and calorific value of 39.67 MJ/kg.
- To confirm the reliability of the optimized settings, confirmation experiments were carried out thrice and the average biodiesel yield obtained was 96.16 ± 0.07% and average calorific value of the biodiesel produced was 39.70 ± 0.08 MJ/kg which proves the repeatability and robustness of the process.
- The ANOVA test showed that among all the studied parameters, reaction temperature had a significant effect on calorific value of the biodiesel at $p < 0.05$, whereas the effect of reaction temperature on the yield was significant at the practical level but insignificant at the 95% confidence level. It was also observed that the yield is more sensitive to the joint and cumulative effect of all the parameters rather than the individual one.

The findings of this study support the use of mango seed kernel oil as a viable non-food source for biodiesel production. The enhanced transesterification process, as confirmed by statistical and experimental methods, provides high biodiesel conversion rate and stable fuel quality, which can be suitable for further scale-up and practical biofuel production. The further studies may involve the investigation of engine characteristics, emissions, and life cycle assessment of mango seed biodiesel and the application of optimization and machine learning for the improvement of the process and its application.

ABSTRACT

During the past decades, the world shifted towards online transactions. From data exchange, service provision to business, users and providers rely on the internet and social networks as a common platform for sharing and trading. In order to ensure an effective and reliable management of these networks and the flow of information within them, it is essential to detect user profiles and communities. In that context, triangle detection is a fundamental task in network analysis, as triangles are the smallest structure in a community. However, identifying triangles in large-scale and dense networks is a heavy and highly time-consuming treatment, due to costly neighborhood intersection computations. Our research aims to optimize intersection computation by minimizing the number of comparisons performed, avoid triangle duplication throughout the detection process and thus reducing the overall computation time. The method we propose, Test With Jumps for triangle detection without duplicates (TWJtr-D), is a refined version of Test With Jumps for triangle detection (TWJtr) algorithm. It optimizes intersection computing between neighbors sorted lists while avoiding redundant comparisons and duplicated triangles. Experimental results, on real-world datasets, demonstrate that TWJtr-D significantly reduces computation time and outperforms state-of-the-art methods which process in a similar pattern. This highlights the efficiency of TWJtr-D for triangle detection in large-scale networks. Future work will upgrade this method to parallel processing to rank its efficiency among algorithms in the same field.

I. INTRODUCTION

By nature, human beings are curious about their surroundings and other's behaviors such as social interactions. Ever since scholars started studying and searching for logical explanations to various living beings' actions and resolving daily life issues, expressing these situations through a simplified representation was an intuitive first step on the resolution path. In 1735, Euler put the first stepping stone towards graph theory while resolving Königsberg' seven bridges problem [1]. Taking the city's map as a starting point, Euler simplified it by eliminating all unnecessary figures keeping only the seven bridges and the four areas they connect. This new representation made it easier to find a solution that allows citizens to move across the city using each bridge only once. Later on, in 1930, Moreno conducted a social study on school pupils [2]. The results obtained from the proposed survey were represented using a graph, in which Moreno considered each respondent to the survey as a node, and each person they select as their answers established a connection between the two individuals. Given the complexity of the interactions expressed and the large number of actors involved in these interactions, the study field evolved from simple graphic networks to complex systems. Furthermore, large graphs, like social networks, are seen as complex networks [3] where actors interact individually [4]. In order to understand these complex systems, numerous approaches have been proposed. The continuous progress achieved by researchers resulted in the development of multiple versions of complex systems, each with specific properties. In 1959, the first random graph saw light [5].

Expressing synthetic data, this graph included n nodes connected randomly through $\frac{n(n-1)}{2}$ links. The probability of an arc connecting two nodes is p, following a Poisson distribution, and $(1 - p)$ defines its absence probability. Milgram introduced in 1967 the small world model [6]. Inspired by "the six steps apart" notion [7], which speculates that each couple of nodes are connected, at most, through a sequence of five intermediary nodes forming six linked steps. For further analyzes of complex systems, specifically small world models' properties, the Watts-Strogatz was a key model. Starting from an initially regular system, where all nodes are connected to their k closest neighbors on a circular or grid topology, evolving into a random system where each initial link is replaced by a new edge with p probability [8]. Other systems were also constructed, from the preferential attachment models where Simon introduced the "rich get richer" concept [9] applied on linguistic networks based on words frequency. This model was, later on, extended by adding the cumulative benefit notion and applied over scientific citations' networks [10]. Although these systems were revolutionary, they still had limits expressing real world characteristics. The Barabasi-Albert model (BA), came as a solution [3] based on a scale-free network using the power-law for degree distribution keeping the preferential attachment concept. To enhance the BA and Dorogovtsev-Mendes-Samkhin (DMS) [11] models, the Bianconi-Barabasi model added a new parameter to each node called fitness or aptitude allowing competitivity among entities through their own efforts [12].

In 2014, the multiplex systems expressed another side of real-world interactions [13]. These representations express different kinds of interactions in the same graph through multiple layers. They give to each node the possibility to belong to more than one layer. The temporal aspect was also considered to evaluate interactions' lifespan [14], and shared interactions among groups of entities were expressed through hyperlinks in hypergraphs [15]. With the widespread adoption of the internet, which has significantly interconnected the world, it nowadays serves as the backbone for nearly all modern activities. The continuous transmission of messages, emails and the submission of millions of queries every second have resulted in a tremendous increase in the volume of data flowing through networks. Efficiently processing this vast amount of information, identifying user profiles, and delivering query results pose significant computational challenges. To mitigate these issues, the development of highly efficient indexing systems became essential. These systems establish links between user profiles and documents, while also accounting for their interactions across the network. The indexes, derived from document intersections, enable precise tracking of term locations and facilitate community detection by identifying triangles and, by extension, clusters, of individuals with common interests or behaviors. In this context, graph theory has emerged as an indispensable tool for analyzing such complex networks. The detection of structural patterns, such as triangles and cycles [16], is critical for uncovering key network properties.

Triangles, for instance, offer valuable insights into clustering coefficients and community structures, with applications spanning from social network analysis to network reliability. Several methods have been proposed for triangles' efficient detection and enumeration in large-scale graphs. Among the most notable contributions we cite Schank and Wagner, who provided both an experimental study [17] and a technical report [18] detailing comprehensive approach for identifying and counting triangles in large graphs. Latapy extended this work by proposing specialized methods for handling triangle computation in massive, sparse graphs characterized by power-law degree distributions [4-5]. Cycle detection, particularly cycles of specific lengths, represents another fundamental problem in graph theory. Seminal contributions from Itai and Rodeh on the identification of minimum circuits in graphs [19], alongside the work of Alon, Yuster, and Zwick (AYZ) on detecting and counting cycles of specific lengths [20], [21], have led the groundwork for the development of efficient cycle-detection algorithms. These techniques have wide-ranging applications, including circuit design and network security. Beyond structural detection, optimizing graph algorithms is imperative for managing the substantial computational and memory challenges posed by large networks. Recent advances in intersection algorithms for sorted lists [22], [23] are particularly relevant for constructing indexes between user and document profiles. These optimized intersection methods accelerate the identification of shared connections and patterns.

Thereby, improving the efficiency of community detection and enhancing our understanding of the structural dynamics within large networks. This paper extends our previous work [24], where we tackled the problem of triangle detection by adjusting the Test With Jumps (TWJ) algorithm proposed in [22], [23]. We refine in this paper Test With Jumps for Triangle detection (TWJtr) [24], by addressing the duplication issue known to be a major flaw; this new method is called Test With Jumps for Triangle detection without Duplicates (TWJtr-D). We have shown that TWJtr accelerates the computation of intersections between sorted neighbors' lists of the graph's nodes, thereby enabling efficient triangle detection and counting. The results obtained will then be compared to those of other selected state-of-the-art methods. The rest of the paper is structured as follows. We first go through the most relevant methods previously developed dealing with triangle detection issue in section 2. Considering the lists intersection and sequential processing methodology as core concept, we present, in section 3, two main and largely used methods. Our approach will be detailed in section 4, where we present TWJ the basic method and TWJtr its extended version. The fact that duplicated triangles occur during the detection process, we adapt the later algorithm, TWJtr, and describe TWJtr-D, a refined version which avoids duplications while exploiting the TWJtr's strengths. The results derived from experiments applied to a collection of datasets are presented and discussed in section 5. Finally, we conclude in section 6 highlighting the most effective method for addressing our problem, and define future perspectives and objectives.

II. RELATED WORKS

The fast growth of the internet with the invasion of social networks and the enormous amount of data circulating online, detecting communities and user profiles became an important task to manage. As a matter of fact, knowing which profiles are more receptive or likely to be interested in a certain information, or which ones are in possession of a requested information so it can be extracted, minimizes the time and data loss; a gain that cannot be ignored in many fields. To achieve this goal, many works have been developed over the years. In 1977, Freeman [25], [26] introduced the formula for betweenness centrality, a measure indicating the importance of a vertex "i" of the network in forwarding information. It is calculated by counting the number of shortest paths connecting each pair of vertices that pass through "i", the higher this value, the more relevant the node is. Later, in 2002, the Girvan & Newman method (GN) [27] extended the concept of betweenness centrality to edges, introducing edge betweenness.

Similar to node betweenness, it measures an edge's importance in the network's information flow by calculating the number of shortest paths connecting each pair of vertices that pass through the edge "e". The authors used this measure as criterion for a reverse hierarchical partitioning. Another work was published in 1998 [28] introducing a multilevel partitioning method based on the k-way. The authors aimed to improve speed and partitioning quality. Their method includes three steps that transformed the original graph into a smaller one coarsening it, dividing it to finally refining it back to its original form saving the obtained communities. In 2006, Newman [29], [24] introduced a new formula which became one of the most used ones in this field [30], [31]. Based on the community definition, the modularity was a measure used to evaluate the quality of a community acquired from a specific partitioning. Alongside community detection, another aspect of graph theory emerged as a research spotlight. Being the smallest structure of a community, triangles detection became an extremely active research field attracting the attention of a large number of researchers. Depending on the definition of a triangle, several methods have been developed. The most intuitive method was the brute-force procedure [4] where, for every possible triplet of the graph, a triangle was returned if the three arcs connecting each pair of nodes exist. Nevertheless, this method was the less efficient being extremely slow and considering nodes that are not even each other's neighbors.

In [4] an algorithm was developed based on arboricity, which is a sparsity measure computed by the minimum number of forests needed to cover all edges. The idea was to sort the graph's nodes decreasingly according to their degrees, and check if each pair of a node's neighbors is linked to count a triangle. An additional step was included to avoid duplications where a neighbor must be among the remaining nodes to unsure it wasn't treated beforehand. [4-17] cite the matrix product $A^3(G)$ of the graph's adjacency matrix A(G), the diagonal of the resulting matrix would count twice the number of triangles to which each vertex contributes. However, this method has some limitations, given the dynamic characteristics and width of the graphs, the creation of the adjacency matrix A(G), which is a hollow structure that needs to be constantly updated, takes quite a lot of computation time, as well as the computation of the product $A^3(G)$, which has $O(n^3)$ complexity that cannot be disregarded. The node-iterator (or vertex listing) [4-19] is a procedure that detects a triangle for each node v having two nodes $(u, w) \in \mathrm{Adj}(v)$ connected by an arc. Being quite convenient, the node-iterator has a flaw. We have noticed that the same triangle is detected several times which leads to a duplication problem, a major issue in terms of computing time and memory when applied on large-scale graphs. Similarly for the edge-iterator (or edge listing) method [4-19], the replication of detected triangles is also present where, for each common neighboring node of the vertices of an arc (u, v), a triangle is identified.

In [4-21] the AYZ algorithm counts the number of triangles in a graph by dividing it into two sub-graphs according to $k = \sqrt{m}$, where m is the number of edges, then applying the node-iterator without duplications on the sub-graph having a degree $d(v) \leq k$, and the edge-iterator on the remaining sub-graph [4]. [17] introduces the Forward algorithm where, for each node v, an initially empty structure A(v) is associated to it. A triangle is detected for each element of $A(v) \cap A(t)$ where $v < t \wedge t \in Adj(v)$. In [21] the authors use a method based on marking the nodes neighboring a vertex v to detect the triangles formed by the latter, which they ,later, unmark in order to eliminate duplications. Ding et al [32] present a differential privacy approach for triangle counting in large graphs, introducing a novel algorithm that balances privacy and accuracy. Their method effectively counts triangles while maintaining differential privacy, showing competitive performance on large datasets. However, the approach has limitations, including potential high computational overhead and limited exploration of parameter impact on privacy-accuracy trade-offs. Notably, methods ensuring differential privacy may introduce noise or perturbations to guarantee confidentiality, which can reduce the precision of the results.

In [33], a strongly subcubic combinatorial algorithm for triangle detection is introduced, significantly enhancing time complexity compared to existing methods, achieving a runtime of $O\left(n^{\frac{7}{3}}\right)$. The algorithm offers robust theoretical performance guarantees and is particularly effective for large graphs. However, its practical applicability may be constrained by increased memory usage due to edge partitioning, especially in highly dense graph regions where vertices can appear in multiple subsets. This results in higher memory overhead and potentially longer processing times for dense areas. In their survey [34], authors review distributed graph algorithms for massive graphs, with a focus on triangle detection methods. They highlight that traditional triangle detection approaches, including intersection-based methods, encounter scalability and memory issues in large graphs. Distributed algorithms, however, significantly improve performance by utilizing parallelism and distributed computing resources, effectively addressing these limitations. The authors conclude that distributed techniques are well-suited for handling massive and dense graph data, providing enhanced efficiency and scalability compared to conventional methods.

III. BASELINE METHODS

Amid the long list of the developed algorithms for triangles detection, we will, in our work, focus on two main methods to which we will be comparing our own approach. In the following section, we will detail these two algorithms discussing their limits and complexity.

III.1 NODE-ITERATOR (VERTEX LISTING)

As mentioned in the previous section, the node-iterator is a method that aims to count, for each node of the graph, the number of nodes that are neighbors to it and that are in turn neighbors (Algorithm1). Although this method appears to be very effective, it has a few shortcomings. Indeed, the major problem can be summed up in two points:

- Duplication.
- Computing complexity.

Algorithm 1: Node-iterator (vertex listing).

Input: list and adjacency matrix representing the network G (V, E)

Output: the triangles detected in G
1: Count= 0
2: Browse G
3: for each v ∈ V do
4: for each couple (u, w) ∈ Adj(v) do
5: if (u̇w)∃ then (v u w) is a triangle
6: Count++
7: end if
8: end for
9: end for
10: return Count

Source: Authors, (2026).

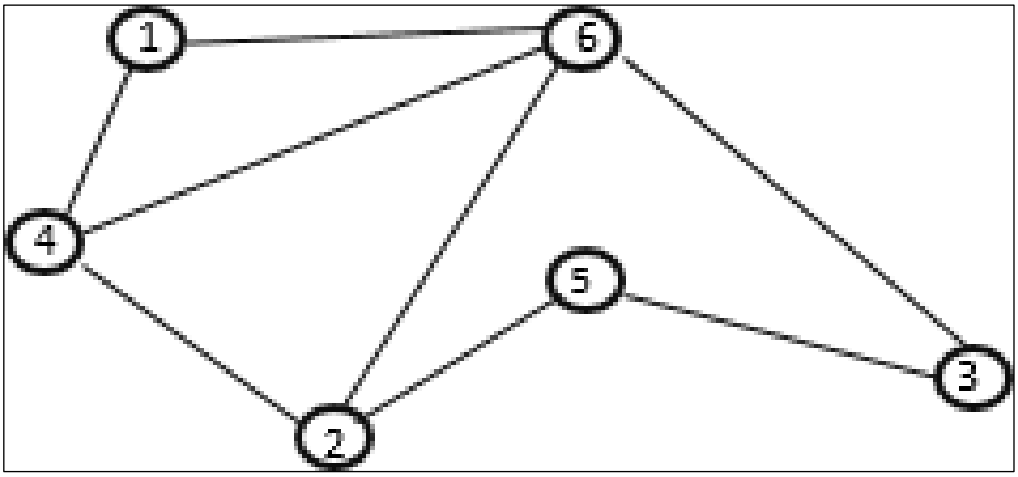

Figure 1: Example of a non-oriented graph.
Source: Authors, (2026).

We will illustrate the node-iterator on the graph sample in figure 1, where nodes 2,4 and 6 forme, visually, a triangle. By iterating through each vertex's adjacency list and verifying connections between every node couple using the adjacency matrix, the same triangle (2, 4, 6) is detected multiple times, once from each vertex involved. This leads to duplication, as the same triangle is reported three times. In large graphs, such redundancy significantly increases computational cost. The node-iterator approach has a time complexity of $O(|V|^3)$and a space complexity of $O(|V|^2)$. While effective for dense graphs due to adjacency matrix usage, it is inefficient for sparse graphs compared to algorithms with complexity linear in the number of edges $|E|$. Recalling that V is the set of nodes and E is the set of edges.

III.2 EDGE-ITERATOR (EDGE-LISTING OR NAÏVE ALGORITHM)

This algorithm represents the basic idea that defines a triangle. Effectively, it consists in searching, for an arc of the graph, a common neighboring node. In other words, the edge-iterator processes an intersection calculation between the adjacency lists of two nodes forming an arc on the graph and returns a triangle for each common element detected (Algorithm 2).

Algorithm 2: Edge-iterator (Edge listing/ Naïve method).

Input: adjacency list and matrix of the graph G (V, E)

Output: detected triangles in G
1: Count = 0
2: Browse G
3: for each (u, v) ∈ E do
4: if Adj(u) ∩ Adj(v) ≠ ∅ then
5: for each w ∈ Adj(u) ∩ Adj(v) do
6: Triangle (u v w)
7: Count++
8: end for
9: end if
10: end for
11: return count

Source: Authors, (2026).

Using the same example, Figure 1, the edge-iterator algorithm examines each edge and computes the intersection of the adjacency lists of its endpoints to identify triangles. For instance, starting with edge (2, 6), the intersection $\mathrm{Adj}(2) \cap \mathrm{Adj}(6)$ yields vertex 4, forming the triangle (2, 4, 6). the same triangle is repeatedly found when processing related or reversed edges, thus increasing complexity. The edge-iterator runs in $O(|E| \cdot \Delta)$time and $O(|V| + |E|)$space, performing well on sparse graphs but poorly on dense graphs with high maximum vertex degree Δ.

IV. PROPOSED APPROACH

Having noticed that the detection of triangles in graphs can be considered as a problem of intersection calculation between lists of neighbors of a given node of the graph, we adapt the TWJ [22], [23] which is basically dedicated to the fast calculation of the intersection between sorted lists so that it can handle this calculation. Our choice for using adjacency lists was made after concluding that it was better in contrast with adjacency matrix which is an immense hollow structure for real graphs consuming enormous memory space and time computing for their update considering the graphs' dynamic nature.

IV.1 TWJ AND DATA STRUCTURE

Before discussing the TWJ's functioning for the detection of triangles, we must first go through the data structure it handles, which is quite particular as it appears in figure 2. Indeed, the TWJ is based on the processing of lists transformed into sequences, where each sequence is composed of three elements as follows:

- SeqID: identifier of the sequence obtained by calculating the modulo of the ith element of the list by a sequencing value chosen beforehand (if the elements of the list are integers).
- Nseq: represents the number of elements that belong to the sequence seqID or the length of the sequence. For a list of integer type, the Nseq is the number of elements belonging to the interval between $seqID * sequencing\ value$, and, $(seqID + 1) * sequencing\ value$.
- Elements of the sequence: is none other than the N elements counted in the NSeq which are ordered and listed until the appearance of a (possible) next sequence.

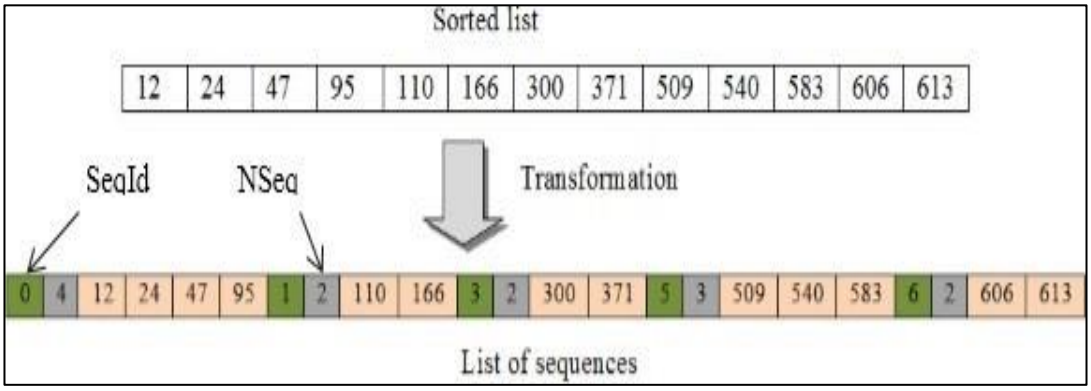

Figure 2: Sequence list creation for a sequencing value= 100.
Source: Authors, (2026).

Once the sequence lists created, the TWJ is applicable

IV.2 TWJ ALGORITHM

In [22-23] the TWJ is described as a method which takes as input two sorted lists transformed into sequences according to a precise and identical sequencing value, the TWJ compares, starting from the first box, sequentially the elements of the two lists, having equal seqIDs, and returns each common value detected until having reached the size of this sequence, applying the naive algorithm (Algorithm 4) for the calculation of the intersection, and passes to the next one for the two lists. On the other hand, if the current seqIDs of the two lists are different, one passes to the next sequence of the list whose seqID is lower and compares it again with that of the other list that has not changed and so on until two equal seqIDs are obtained, or, that one of the two lists has reached its size (exhausted all its seqIDs).

Algorithm 3: Test With Jumps (TWJ).

Input: Integer intersection (Integer[] SeqA, Integer[] SeqB, Integer sizeA, Integer sizeB, short* C)

```
1: Integer i = 0, j = 0
2: while i < sizeA ∧ j < sizeB do
3:    if the two compared seqID are equal then
4:          Apply the naïve intersection algorithm between the two   sequences (Algorithm 4)
5:    else
6:      Move on to the next sequence in the table with the smallest seqID
7:    end if
8: end while
```

Source: Authors, (2026).

Algorithm 4: Naive intersection computation

```
Input: integer intersection(integer[] A, integer[] B, integer sizeA, integer sizeB, short[] C)

Output: common elements
1: integer count = 0, i = 0, j = 0;
2: while i < sizeA and j < sizeB do
3:    if A[i] == B[j] then
4:       C[count + +] = A[i];
5:       i + +; j + +;
6:    else if A[i] > B[j] then
7:       j + +;
8:    else
9:       i + +;
10:   end if
11: end while
12: return count;
```

Source: Authors, (2026).

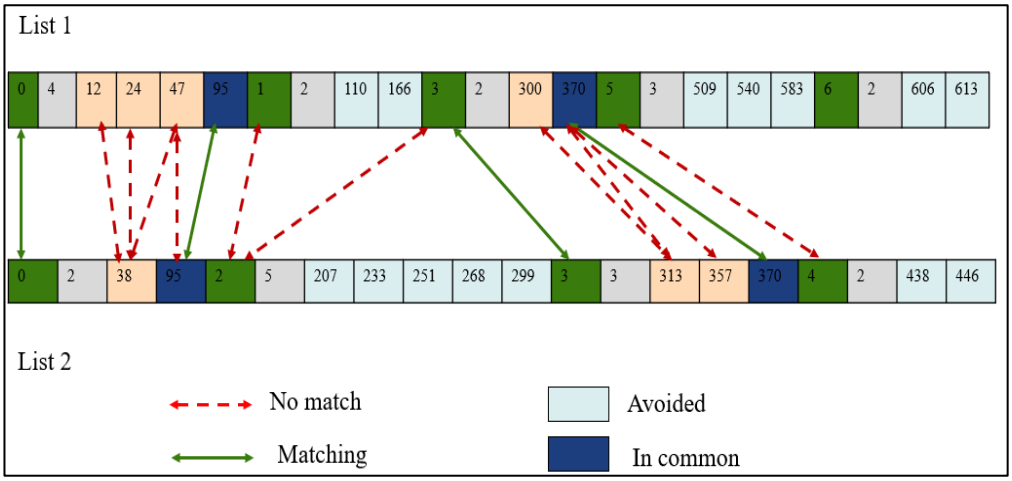

Figure 3: TWJ algorithm process.
Source: Authors, (2026).

Figure 3 shows an example of TWJ processing over two sequence lists. It is clearly noticeable that the TWJ's logic permits avoiding unnecessary comparisons highly gaining in terms of computation time. Thus, applying TWJ over large scale datasets improves significantly time complexity.

IV.3 TWJ AND TRIANGLE DETECTION

Returning to our primary case study, which is triangle detection, the approach we propose involves extending the TWJ method. For each node $u \in Adj(v)$ where$u, v \in G$, we apply it to the adjacency lists of nodes *v* and *u*, which have been previously transformed into sequences. Consequently, each newly identified element x signifies the presence of an existing triangle (uvx) within the graph (see Algorithm 5).

Algorithm 5: TWJ triangle detection (TWJtr)

```
Input: adjacency list of the network G
Output: detected triangles
1: Count = 0;
2: for each v ∈ G do
3:        for every u ∈ Adj(v) do
4:        Compute the intersection Adj(v) ∩ dj(u) by applying the TWJ algorithm
5:        for each element returned do
6:        Count++;
7:        end for
8:        end for
9: end for
10: return Count; {The list of triangles if desired}
```

Source: Authors, (2026).

In terms of complexity, the TWJtr has a worst-case time complexity of $(|V|^3)$ for dense graphs and O $(|E| \cdot \Delta)$ for sparse graphs, and $(|V| + |E|)$ space complexity.

IV.4 RESOLVING THE DUPLICATION ISSUE IN TRIANGLE DETECTION

After analyzing the field's existing methods and experiencing them multiple times, we were able to see firsthand the number of duplicated triangles that were detected and its heavy impact on the algorithms' performances. Therefore, resolving the duplication issue became an essential objective our study aimed for. To achieve this goal, we considered both the dataset's structure and the TWJtr process. Giving the graph's non-oriented nature, we modified the basic TWJtr by including an additional treatment which allows marking nodes that have been processed. In other words, every time a node v is treated and all triangles involving it are detected, v would be marked as an explored node. Thereafter, only the unmarked neighbors of the remaining nodes would be considered for intersection computing thus detecting triangles formed by these couples whereas triangles formed by couples with marked nodes were already detected when the marked node was processed. Thus, returning duplicated triangles is avoided and time complexity drops significantly. The pseudocode of algorithm 6 presents the algorithm TWJtr-D for eliminating duplications.

Algorithm 6: TWJtr without duplicates (TWJtr-D).

Input: adjacency list of the network G
Output: detected triangles
1: Count = 0;
2: for each $v \in G$ do
3: for every $u \in Adj(v)$ do
4: Compute the intersection $Adj(v) \cap Adj(u)$ by applying the TWJ algorithm if neither u nor v were explored (unmarked)
5: for each element returned do
6: Count++;
7: end for
8: end for
9: mark(v)
10: end for
11: return Count; {The list of triangles if desired}

Source: Authors, (2026).

V. EXPERIMENTS AND RESULTS

The experimentations were conducted on an Intel(R) Core ™ i7-8700K CPU @3.70 Ghz, 64 GB of RAM and two Hard discs: 500GB VME and 6TB HDD. We used Java Netbeans as programming environment.

V.1 TEST DATA

We performed our tests over the below twelve real graphs downloaded in (.txt) format that we load in memory.

Table 1: Experimented datasets.

Graph name	|V | = number of vertices	|E| = number of edges
New sites	1040	313869
Hr	1099	498202
Hu	1054	222887
Ro	1035	125826

V.2 COMPARATIVE STUDY

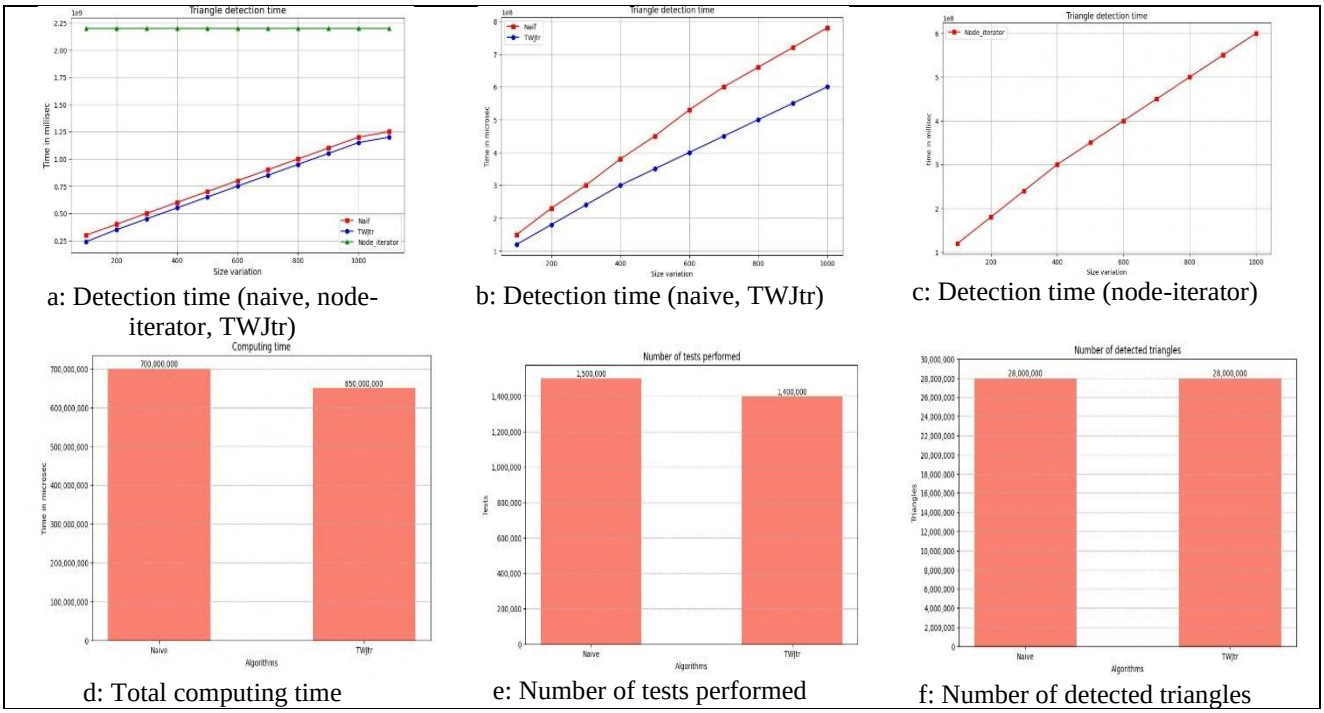
We compare our approach, the TWJtr, to the node-iterator and edge-iterator algorithms. This comparison is based on:

- The number of tests performed by each method when detecting triangles excluding the search for elements in the adjacency list.
- The number of triangles detected (including repetitions).
- Calculation time.

The experimentations conducted, over the twelve datasets mentioned above, have all expressed the same behavior in response to the algorithms we applied. In order to present graphically these results for each comparison criterion, the number of graphics would be inconvenient to expose in this section of our article. Therefore, among the acquired results, we selected those of the Hr, Hu and Ro datasets to be demonstrated. These datasets, the Hr, Hu and Ro, were collected from the music streaming service Deezer.

a: Detection time (naive, node-iterator, TWJtr)

b: Detection time (naive, TWJtr)



c: Detection time (node-iterator)

d: Total computing time

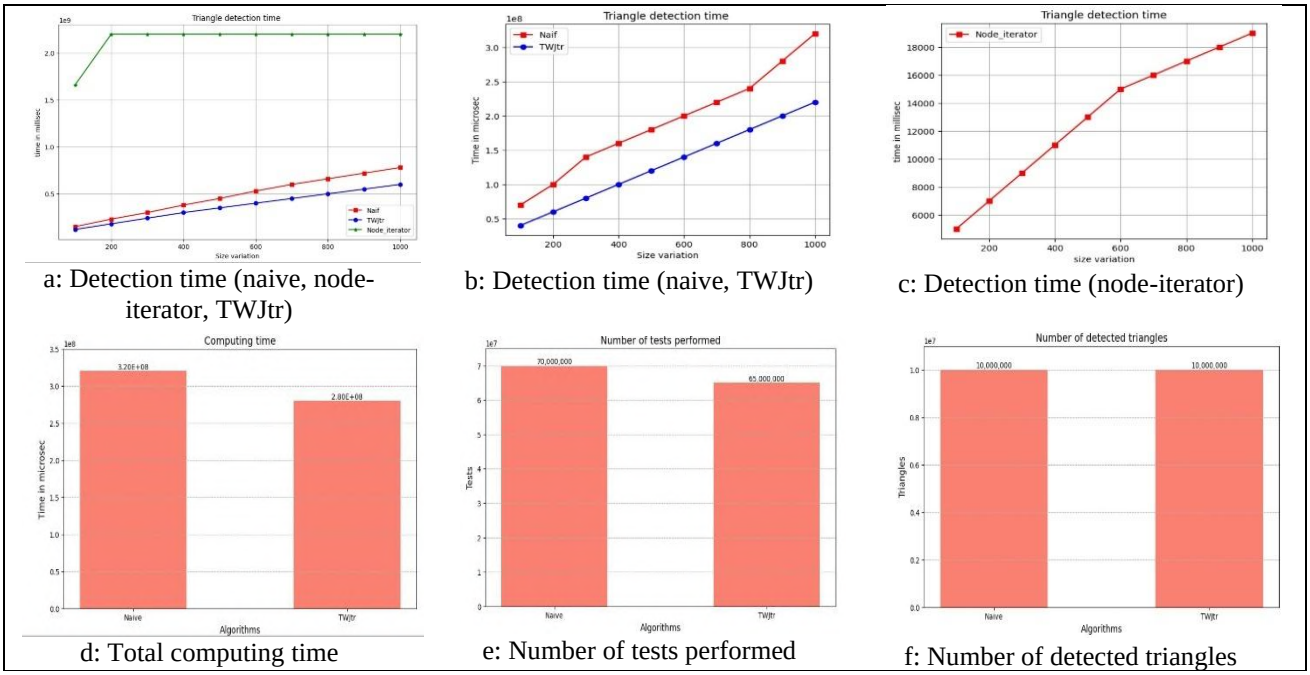
e: Number of tests performed

f: Number of detected triangles

Figure 4: RO dataset's statistics.
Source: Authors, (2026).

a: Detection time (naive, node-iterator, TWJtr)

b: Detection time (naive, TWJtr)



c: Detection time (node-iterator)

d: Total computing time

e: Number of tests performed

f: Number of detected triangles

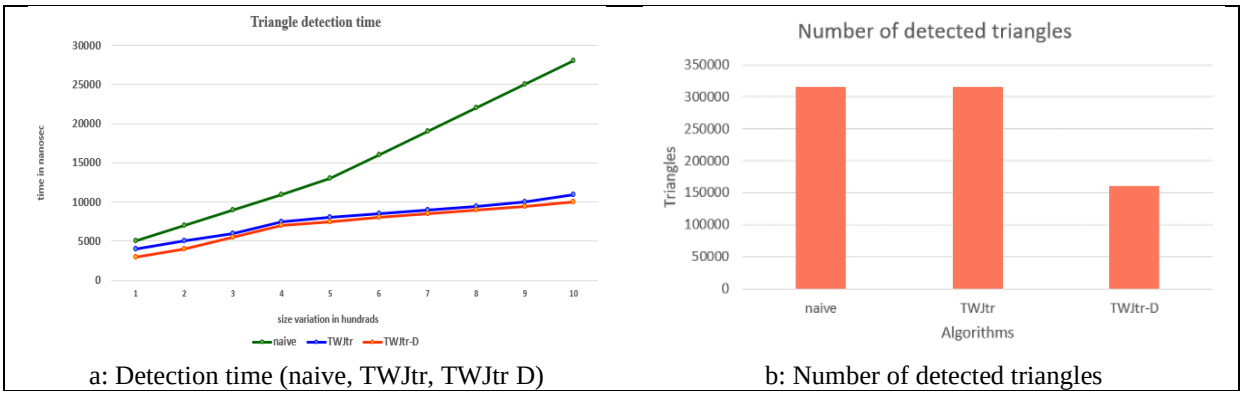


Figure 5: HU dataset's statistics
Source: Authors, (2024).

a: Detection time (naive, node-iterator, TWJtr)
b: Detection time (naive, TWJtr)
c: Detection time (node-iterator)
d: Total computing time
e: Number of tests performed
f: Number of detected triangles

Figure 6: HR dataset's statistics
Source: Authors, (2026).

After conducting experiments on the aforementioned datasets, performance statistics were collected according to the previously defined comparison criteria. The obtained results are illustrated in Figure. 4, 5, and 6. Figure. (4. a), (5. a), and (6. a) depict the execution time evolution of the three evaluated algorithms. The results show that the Node-Iterator algorithm exhibits the highest execution time across all datasets. The Naive algorithm (Edge-iterator) achieves lower execution times, while the TWJtr algorithm consistently outperforms both baseline approaches. For a more detailed analysis, the execution time curves shown in Figure. (4.a), (5.a), and (6.a) are decomposed into Figure. (4.b), (5.b), (6.b) and Figure. (4.c), (5.c), (6.c). Figure. (4.c), (5.c), and (6.c) report the execution time of the Node-Iterator algorithm in milliseconds, indicating that its runtime remains significantly higher than that of the other two methods. In contrast, figure. (4.b), (5.b), and (6.b) compare the Naive and TWJtr algorithms in nanoseconds, where TWJtr achieves lower execution times across all datasets. Figure. (4.d), (5.d), and (6.d) present the total execution time required to complete triangle detection. These results show that TWJtr requires less total computing time than the Naive algorithm across all datasets. Additional efficiency-related statistics are presented in Figure. (e) and (f). Figure. (e) reports the number of intersection tests performed by the Naive and TWJtr algorithms, while Figure. (f) shows the number of triangles detected. The results indicate that both algorithms return the same number of detections, despite performing a different number of intersection tests.

a: Detection time (naive, TWJtr, TWJtr D)
b: Number of detected triangles

Figure 7. TWJtr-D (TWJtr without duplication) statistics over a graph of 1000 nodes
Source: Authors, (2024).

Figure. 7 presents the results obtained after applying the TWJtr-D algorithm and comparing it with the Naive and TWJtr methods. The execution time comparison illustrated in Figure. (7.a) shows that TWJtr-D achieves the lowest computing time among the three evaluated algorithms. Figure. (7.b) reports the number of triangle detections for each method. The results show that TWJtr-D returns a lower number of detections corresponding to unique triangles, whereas the Naive and TWJtr algorithms produce identical counts due to duplicate detections.

V.3. DISCUSSION

The poor performance of the Node-Iterator algorithm observed in Figure. 4, 5, and 6 can be attributed to its repeated verification process, which checks the existence of edges between all pairs of neighboring nodes. This procedure relies on frequent scans of adjacency lists, resulting in substantial computational overhead.

The Naive algorithm improves execution time by computing intersections between adjacency lists, enabling faster identification of shared neighbors. However, the TWJtr algorithm further optimizes this process by introducing jump-based traversal over unmatched segments of adjacency sequences. This optimization significantly reduces unnecessary comparisons, which explains the consistent performance gains observed for TWJtr in Figure. (4.b), (5.b), and (6.b), as well as its reduced total execution time reported in Figure. (4.d), (5.d), and (6.d). The analysis of Figure. (e) and (f) further confirms this behavior, showing that TWJtr performs fewer intersection tests while detecting the same number of triangles as the Naive algorithm. This demonstrates that the observed performance improvements are achieved without affecting detection completeness. Building upon these results, TWJtr-D introduces an additional duplication-aware mechanism designed to avoid redundant processing of previously examined nodes. This extension explains the further reduction in execution time observed in Figure. (7.a). The lower number of detections reported in Figure. (7.b) reflects the elimination of duplicate triangle detections rather than a loss of correctness. This outcome results from TWJtr-D verifying in each iteration, whether the vertices involved in a test have already been processed which preserves triangle detection completeness by reporting each triangle exactly once. This behavior is consistent with the duplication-aware strategy described in the PROPOSED APPROACH section and demonstrates that the proposed method, TWJtr-D, effectively reduces computational cost while maintaining correct and complete triangle detection. Moreover, the performance gains become more pronounced as graph size increases, indicating improved scalability compared to baseline methods.

VI. CONCLUSION

Considering the immense data traffic flowing on the networks, created by interactions exchanged by a very large number of network users, detecting communities and actor profiles became essential for several reasons. Among them, routing queries for targeted audience, which allows directing information to clusters of individuals sharing the same interests with the said query, a strategy that is, nowadays, the trend of commercial marketing and advertisement through social networks. The detection of communities involves the detection of triangles since triangles represent the basic component of a community. In this context, we built our approach over the TWJ algorithm [22-23] which is defined for the fast calculation of the intersection between sorted lists. We have adapted TWJ to the context of triangle detection that we named TWJtr [24]. Our solution presented a much better performance in terms of time computing, number of preformed tests and number of detected triangles. These results were obtained through comparing our solution with two of this domain's basic algorithms, the node- iterator and the edge-iterator (naive method), chosen after a detailed study of this field's state of the art. Given the considerations above, TWJtr is found to be the best general-purpose algorithm which balances efficiency and practicality, performing well on both sparse and moderately dense graphs, leveraging efficient intersection computations to detect triangles. Additionally, we enhanced the TWJtr to be further optimal. Since the previous methods generated results including a considerable number of duplicated triangles, TWJtr-D, as a refined version of TWJtr, ensures an accurate result eliminating duplicated triangles optimizing time computing, which is an undeniable advantage considering the large-scale networks subjected to triangle detection procedures. In the future, we intend to implement and experiment on platforms like SPARK in order to adapt TWJtr and TWJtr-D for distributed systems. We also, consider comparisons with other algorithms.

ABSTRACT

To This study investigates the fabrication and microstructural characterization of Al6061–SiC composites using a Response Surface Methodology (RSM) approach to optimize stir casting parameters. Aluminum 6061 was used as the matrix material, while silicon carbide (SiC) particles with a size of less than 10 µm served as the reinforcement. The Aluminum Metal Matrix Composites (AMMCs) were produced through the stir casting technique, which is considered a cost-effective and efficient fabrication method. The composite samples were prepared according to the experimental design generated using the RSM Box–Behnken Design (BBD). The main processing parameters examined in this study were the reinforcement weight fraction (3.5 wt%, 7.0 wt%, and 10.5 wt%), melting temperature (625°C, 650°C, and 675°C), and stirring speed (225 rpm, 250 rpm, and 275 rpm). Microstructural examination carried out using a metallurgical microscope and high-resolution scanning electron microscope (SEM) indicated a relatively uniform dispersion of SiC particles within the aluminum matrix; however, minor particle agglomeration and porosity were also detected.

I. INTRODUCTION

Metal matrix composites (MMCs) have gained considerable attention in recent decades due to their enhanced mechanical, thermal, and tribological properties compared with conventional alloys [1]. Among the various MMCs, aluminum matrix composites (AMMCs) are widely used because of their low density, high strength-to-weight ratio, good corrosion resistance, and excellent thermal conductivity [2]. Aluminum alloy Al6061 is particularly preferred as a matrix material because of its good formability, weldability, and mechanical performance [3]. Reinforcing aluminum alloys with ceramic particles such as silicon carbide (SiC) significantly improves hardness, wear resistance, and strength of the composite material [4]. The presence of hard SiC particles in the aluminum matrix restricts grain boundary movement and contributes to grain refinement during solidification, leading to improved mechanical properties [5].Various fabrication techniques have been employed for the production of aluminum matrix composites, including powder metallurgy, squeeze casting, spray deposition, and stir casting [6]. Among these techniques, stir casting is considered one of the most economical and practical methods due to its simplicity and suitability for large-scale production [7]. In this method, reinforcement particles are introduced into molten aluminum and distributed uniformly through mechanical stirring [8]. However, the quality of the final composite depends strongly on several processing parameters such as melting temperature, stirring speed, and reinforcement percentage [9]. Improper control of these parameters may lead to particle agglomeration, poor wettability, and porosity within the composite structure [10].

Microstructural characteristics play a vital role in determining the mechanical and tribological performance of aluminum matrix composites [11]. A uniform distribution of reinforcement particles enhances load transfer efficiency between the matrix and the reinforcement, thereby improving strength and wear resistance [12]. Previous studies have reported that increasing the weight fraction of SiC particles improves hardness and wear resistance of Al6061 composites [13]. Furthermore, statistical optimization techniques such as Response Surface Methodology (RSM) have been widely applied to evaluate the combined effects of multiple process parameters and to identify optimal fabrication conditions [14]. The Box–Behnken design within RSM has proven effective in reducing the number of experiments while providing reliable prediction models for material processing studies [15].Therefore, the present study focuses on the fabrication of Al6061–SiC composites using the stir casting method and investigates the influence of key process parameters on the microstructural characteristics. The Response Surface Methodology with Box–Behnken design is employed to systematically analyze the effects of reinforcement weight percentage, melting temperature, and stirring speed to achieve improved particle distribution and enhanced composite quality.

II. SELECTION OF MATERIALS AND METHODOLOGY

II.1 SELECTION OF MATERIALS

Aluminium 6061 is used as the base material in MMCs. It is mostly made of aluminum., with silicon and magnesium as the major alloying elements. Aluminium 6061 possesses good mechanical properties and excellent weldability. While the Al6061 matrix material demonstrates good corrosion resistance, its mechanical and tribological properties are not as significant. Therefore, enhancement of its mechanical and tribological characteristics is necessary. For this reason, aluminium alloy 6061 was selected as the matrix material in this investigation. The aluminium alloy Al6061 billet was procured in the form of billets. Silicon carbide belongs to a group of lightweight ceramic materials. It is extremely hard and, when used as a reinforcing material, can significantly increase the base matrix's hardness and resistance to wear. This material can withstand high temperatures (up to 1600°C) due to the strong bonding within the tetrahedral structure formed by carbon and silicon atoms in its crystal lattice. Based on these characteristics, chemically pure, green to bluish-black fine SiC powder was selected as the primary reinforcement.

II.2 DESIGN OF EXPERIMENT

This study utilizes the Box-Behnken Design to optimize the stir casting parameters for Al–SiC composites, concentrating on the critical process inputs and their levels as summarized in Table 1..Using the BBD, a quadratic model will be developed to investigate the connections between the final material characteristics and these process variables (such as tensile strength, hardness, Impact strength, Wear Rate and COF). The ultimate goal is to identify the optimal combination of parameters that leads to superior composite quality, enhancing the effectiveness and consistency of the stir casting process for Al–SiC composites.

Table 1: Controllable Factors in the Stir Casting Process.

Factors	Levels		
	-1	0	+1
Reinforcement RI(wt% SiC)	3.5	7	10.5
Melting or Stirring Temperature ST(^{0}C)	625	650	675
Stirring Speed SS (rpm)	225	250	275

II.3 FABRICATION OF COMPOSITES

The Al6061–SiC MMCs in this study were produced using the stir casting method, a popular technique for manufacturing particle-reinforced aluminum composites due to its ease of use, cost efficiency, and scalability. The stir casting setup is illustrated in Figures 1. Conducting experimental Runs in Stir casting Process as listed in Table 2.

III. RESULTS AND DISCUSSION

III.1 MICROSTRUCTURAL ANALYSIS

The microstructure analysis of AL6061-SiC metal matrix composites (MMCs) using a metallurgical microscope (Dewinter Tech) involves a systematic sample preparation and examination process aimed at revealing the internal structural features of the composite material. The prepared sample is examined under a metallurgical microscope, beginning at low magnification (e.g., 100xto investigate SiC particle shape, distribution, and interfacial bonding in the aluminum matrix. Microstructural features such as grain boundaries, particle clustering, porosity, and secondary phase formations are observed and, where applicable, captured using imaging software for further quantitative analysis. This procedure ensures a detailed and accurate characterization of the composite's microstructure, which is critical for understanding its mechanical properties and overall performance. The microstructure of the fabricated composite, shown in Figure 2 (b), was captured at 100× magnification with a scale of 100 µm. The matrix material, identified as AL6061, exhibits a typical dendritic solidification structure, characterized by primary α-Aluminum dendrites surrounded by an interdendritic eutectic network.

The regions highlighted by black circles represent the locations of reinforcing particles dispersed throughout the aluminum matrix. These areas appear darker, indicating the presence of secondary phases, which are most likely the silicon carbide (SiC) particles incorporated during the fabrication of the composite. Achieving a relatively uniform distribution of SiC particles within the matrix is essential for enhancing mechanical qualities like wear resistance, tensile strength, and hardness. The observed microstructure suggests good interfacial bonding between the AL6061 matrix and the SiC particles, which is necessary for effective load transfer under mechanical stress. Minimal porosity and segregation are evident, indicating a sound fabrication process and effective dispersion of reinforcement. The existence of SiC particles inhibits the grain growth of the aluminum matrix, contributing to the refinement of the microstructure and thus improving the overall performance of the mechanism. This analysis confirms the successful incorporation of 3.5 wt% SiC into the AL6061 alloy, directly correlating to the enhancements in mechanical properties observed during hardness, tensile, and impact testing.

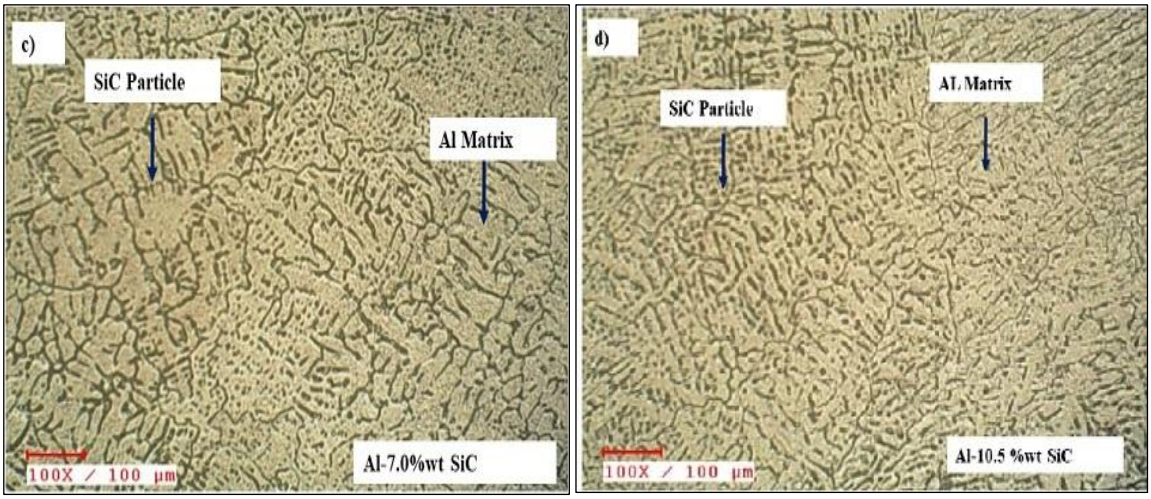

Figure 2: AMMCs Microstructures.
Source: Authors, (2026).

The microstructure of the AL6061–7.0 wt% SiC composite, shown in Figure 2 (c), was captured at 100× magnification with a scale of 100 µm. The matrix phase (highlighted with a black circle) consists predominantly of α-Aluminum (AL6061), while the red-circled regions indicate the presence of silicon carbide (SiC) reinforcement particles. Within the aluminum matrix, the SiC particles are dispersed somewhat evenly, but there is some minor clumping in some areas. This distribution is critical for improving the composite's mechanical performance, as the hard SiC particles act as barriers to dislocation movement, thereby enhancing the hardness and tensile strength of the material.The dendritic structure of the aluminum matrix remains visible, though the dendrites appear finer compared to unreinforced AL6061 alloy. The presence of SiC particles during solidification restricts grain growth by pinning the grain boundaries, leading to a refined microstructure. Grain refinement typically contributes to increased strength according to the Hall-Petch relationship.

No major porosity or defects were observed at this magnification, suggesting that the processing parameters were effective in achieving a sound microstructure. The good interfacial bonding between the AL6061 matrix and SiC particles indicates effective load transfer capability, which is essential for improving both tensile and impact properties. The analysis confirms that increasing the SiC content to 7.0 wt% leads to a more pronounced reinforcement effect compared to lower weight percentages, which is consistent with the mechanical test results showing increased hardness and strength. Figure 2 (d) shows the microstructure of the AL6061–10.5 weight percent SiC composite was examined at 100× magnification with a 100 µm scale. The α-Aluminum matrix (highlighted with yellow labeling and circled in red) retains its dendritic morphology, although it appears more refined compared to composites with lower SiC content. The red-circled areas clearly display the dispersion of SiC reinforcement particles within the matrix. As the SiC content increases to 10.5 wt%, the number density of SiC particles is visibly higher.

This dense distribution of hard SiC particulates effectively impedes dendrite growth during solidification, promoting a finer and more uniform microstructure. Finer dendritic structures contribute to increased strength and hardness due to restricted grain boundary movement.The relationship between the AL6061 matrix and the SiC particles appears clean with no major visible voids or defects at this magnification, suggesting effective particle-matrix bonding, crucial for efficient stress transfer during mechanical loading. However, at this higher reinforcement level, some localized particle clustering can be observed. While such clustering may enhance localized hardness, it could potentially lead to stress concentrations under dynamic loading conditions, slightly affecting toughness.Overall, the microstructure confirms that increasing the SiC content to 10.5 wt% significantly refines the grain structure and increases the volume fraction of hard phases, correlating with the substantial improvements observed in the hardness, tensile, and impact strength tests.

III.2 SEM OBSERVATION WITH EDAX EVALUATION

The characterization of Al6061-SiC MMCs using Scanning Electron Microscopy (SEM) and Energy Dispersive X-ray Spectroscopy (EDS) involves a systematic approach to examine the morphology of the surface and elemental makeup of the composite. All wear experiments were performed following the ASTM E2142 standard. The prepared specimen is positioned inside the SEM chamber and exposed to a focused electron beam to generate detailed surface images. SEM imaging reveals critical information about the shape, distribution, and interfacial bonding of the SiC reinforcement particles within the aluminum matrix, as well as any defects such as voids, cracks, or particle clusters. Elemental composition is determined through EDS, which detects characteristic X-rays emitted from the sample when struck by the electron beam.

This technique enables precise identification and spatial mapping of elements within the composite, confirming the presence of silicon carbide particles and highlighting any elemental segregation or secondary phases. Together, SEM and EDS offer a thorough insight into the microstructural and chemical properties of the Al6061-SiC composite, which is crucial for understanding its material performance. The image shown (Figure 3) is an EDAX spectrum obtained during SEM analysis of an AMMCs reinforced with a specific weight percentage of silicon carbide (SiC). The spectrum illustrates the elemental composition of the analyzed region of the composite by displaying the intensity of characteristic X-rays emitted by elements upon electron beam excitation.

On the x-axis, the energy levels of emitted X-rays are plotted in keV, while the y-axis indicates the count intensity, which correlates to the quantity of each element detected. A strong peak is observed for aluminum (Al) around 1.5 keV, which is expected due to its role as the base matrix material in AL6061. Smaller peaks are also visible for magnesium (Mg) and sodium (Na), which are typical alloying elements or trace impurities in the aluminum alloy. Importantly, this spectrum shows clearly identifiable peaks for silicon (Si) near 1.7 keV and also a minor peak around 0.2 keV, indicating the presence of silicon carbide particles in the analyzed area, consistent with the SiC reinforcement in the composite. Additionally, low-intensity peaks for carbon (C) and oxygen (O) are evident, which may be attributed to the carbon content from SiC, surface oxidation, or environmental contamination. The existence of both silicon and carbon peaks provides confirmation of the distribution of SiC particles within the aluminum matrix. This spectrum, therefore, validates the successful incorporation of SiC reinforcement in the AL6061 matrix and highlights the elemental constituents of the composite in the specific region examined.

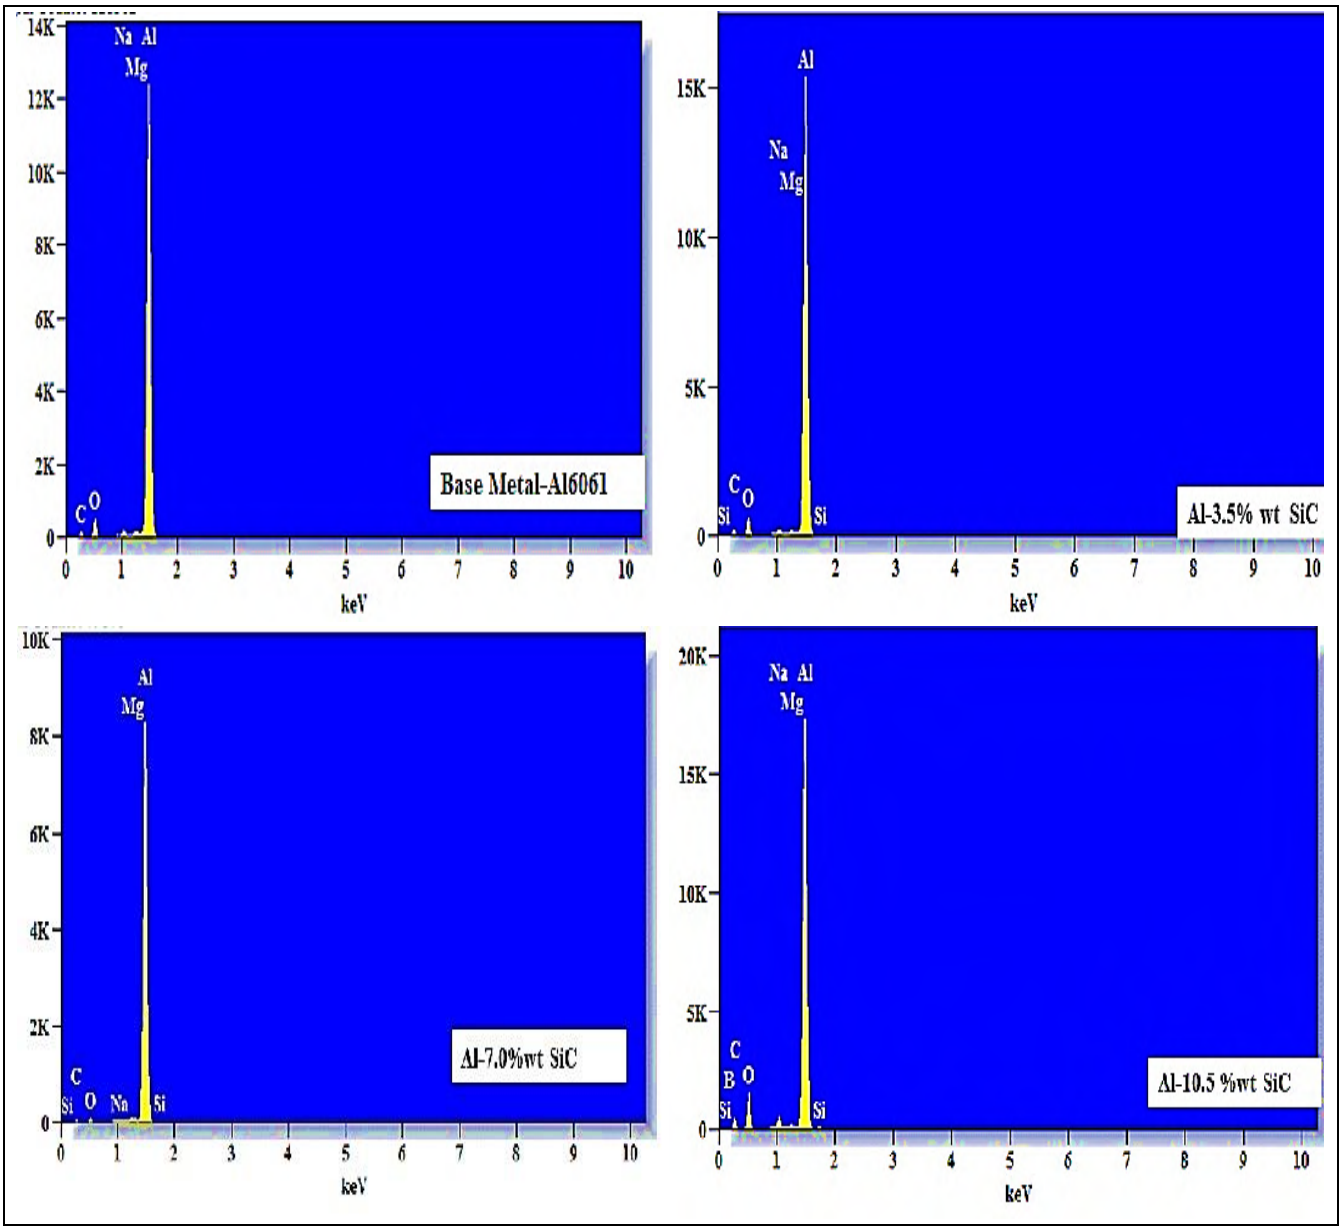

Figure 3: Al6061-SiC Composites EDAX spectrum.
Source: Authors, (2026).

This SEM image (Figure: 4) serves to reveal the microstructural characteristics and surface morphology of the composite at high magnification. In the image, the aluminum matrix forms the continuous phase, while the SiC particles are distinguishable as discrete features distributed within the matrix. At a reinforcement level of 10.5 wt%, the SiC particles appear more numerous and densely distributed compared to lower reinforcement percentages, indicating a higher volume fraction of ceramic reinforcement. The micrograph allows observation of the shape, size, and dispersion of these particles, which are critical in influencing the mechanical behavior of the composite. Uniform dispersion of SiC particles, as suggested in the image, enhances properties such as hardness, wear resistance, and tensile strength by improving load transfer between the matrix and reinforcement. Any visible clustering or agglomeration could potentially lead to stress concentrations, but in a well-processed sample, such defects are minimized. The SEM analysis thus confirms the successful integration of SiC into the aluminum matrix and provides valuable insight into the quality and effectiveness of the c omposite microstructure at 10.5 wt% SiC reinforcement.

IV. CONCLUSIONS

The Al6061–SiC metal matrix composites were successfully fabricated using the stir casting technique, and the process parameters were systematically optimized using the Box–Behnken Design (BBD) within the Response Surface Methodology (RSM) framework. The microstructural analysis revealed that increasing the SiC reinforcement content up to 10.5 wt% significantly refined the grain structure and enhanced the volume fraction of hard phases within the aluminum matrix. A relatively uniform distribution of SiC particles was observed under optimized processing conditions, which minimized particle agglomeration and improved the overall microstructural integrity of the composite. The presence of hard ceramic SiC particles restricted grain boundary movement during solidification and contributed to improved interfacial bonding between the reinforcement and the matrix. As a result, the composite exhibited enhanced mechanical properties, particularly increased hardness and improved wear resistance compared to the base Al6061 alloy. The statistical optimization approach effectively identified the optimal combination of parameters, and validation experiments confirmed the reliability of the developed model. Overall, the results demonstrate that the integration of stir casting with BBD-based RSM optimization is an effective approach for producing high-performance Al6061–SiC composites suitable for lightweight structural and engineering applications.

ABSTRACT

This study explores educators' and learners' multifaceted perceptions across public and private educational institutions regarding the integration and adoption of virtual reality (VR) and augmented reality (AR) applications. Recognizing the paradigm shift toward Education 4.0, the study operationalizes an extended Unified Theory of Acceptance and Use of Technology (UTAUT2) framework to isolate the predictive behavioral determinants of immersive technology adoption. Using a snowball sampling methodology, a structured psychometric instrument was administered to teachers across primary, secondary, and tertiary levels, as well as to secondary and tertiary students, yielding a robust sample of 1000 valid responses. Covariance-based Structural Equation Modeling (CB-SEM) and Confirmatory Factor Analysis (CFA) were conducted in IBM AMOS to evaluate the latent relationships among effort expectancy, performance expectancy, hedonic motivation, social influence, price value, habit, facilitating conditions, and the ultimate behavioral intention to adopt AR/VR platforms. The empirical findings establish that effort expectancy, performance expectancy, and hedonic motivation are universally significant drivers of adoption intent. Subsequent multi-group path analyses uncover profound demographic disparities; while students are heavily influenced by hedonic motivation and intrinsic enjoyment, educators base their adoption strategies strictly on performance metrics and are negatively impacted by rigid facilitating conditions. Furthermore, the public sector relies on habituation and performance expectancy to a greater extent than private institutions do. These critical insights provide actionable strategic intelligence for educational technologists, software developers, and academic policymakers seeking to minimize pedagogical friction and maximize the efficacy of extended reality deployments in modern classrooms.

I. INTRODUCTION

The contemporary educational landscape is currently undergoing a profound systemic metamorphosis, driven by the rapid evolution and deployment of immersive digital technologies. As modern civilization transitions toward the ideals of Society 5.0, a human-centric framework in which cyberspace and physical space are highly integrated to address socio-economic challenges, the pedagogical strategies used to prepare the next generation of learners must evolve commensurately [1]. Education 4.0, the corresponding academic paradigm, emphasizes the critical need to cultivate twenty-first-century competencies, notably critical thinking, advanced problem-solving, and technological literacy [2]. Within this transformative context, extended reality (XR) technologies, predominantly Virtual Reality (VR) and Augmented Reality (AR), have emerged as formidable instructional tools capable of redefining the spatial and cognitive parameters of teaching and learning [3].

The global market for AR and VR in education reflects this aggressive trajectory, with industry valuations projected to surge from USD 3.8 billion in 2023 to an estimated USD 14.2 billion by 2028, representing a formidable Compound Annual Growth Rate (CAGR) of 29.6 percent [4]. Despite this exponential market expansion and the theoretical promise of immersive technologies, the practical, ubiquitous adoption of AR and VR within traditional classroom environments remains highly fragmented and inconsistent [5]. While advanced academic institutions and corporate training sectors have begun leveraging these tools for experiential learning, mainstream educational adoption is frequently impeded by a complex matrix of socio-technical barriers [4]. Extensive literature indicates that while VR and AR possess the theoretical capacity to vastly improve student engagement, spatial cognition, and the retention of highly complex, abstract information [6], the actual integration of these technologies into standardized curricula is stalled by inadequate infrastructure, prohibitive financial costs, and a fundamental lack of pedagogical alignment [7]. Furthermore, a significant geographical and economic bias exists within the current body of research; the overwhelming majority of empirical studies analyzing XR adoption have been conducted in Western, high-income demographics where digital infrastructure is ubiquitous and robustly funded [8].

This leaves a critical lacuna in the academic understanding of how these immersive platforms are perceived, evaluated, and ultimately adopted within developing educational ecosystems, particularly when contrasting the operational realities of government-funded public schools with those of privately funded institutions [9]. To address these profound gaps in the literature, this research initiates a comparative, socio-technical investigation into the dynamics of adoption for VR and AR educational applications. The primary problem this study seeks to address is the lack of a unified, empirically validated understanding of the psychological and environmental factors that drive or hinder the acceptance of immersive technologies across diverse educational stakeholders and institutional frameworks. To systematically deconstruct this problem, the investigation poses three central research questions. First, what are the fundamental structural relationships between the exogenous behavioral dimensions, specifically effort expectancy, performance expectancy, hedonic motivation, social influence, habit, price value, and facilitating conditions, and the endogenous behavioral intention to adopt virtual reality and augmented reality?

Second, does the systemic architecture of the academic institution, specifically the dichotomy between public and private funding models, generate statistically significant differences in how users adopt and integrate these technologies? Finally, do the psychological determinants of adoption differ significantly between the individuals tasked with deploying the technology (teachers) and those utilizing it for knowledge acquisition (students)?. By anchoring this multidimensional inquiry in an extended iteration of the Unified Theory of Acceptance and Use of Technology (UTAUT2), this study transcends basic technological capability assessments to probe the deeply ingrained behavioral mechanics of end users. The hypothesis posits that differing institutional resources and fundamentally distinct user objectives (instruction versus comprehension) will fracture the homogenous adoption models previously recorded in corporate or leisure contexts. Ultimately, the findings derived from this robust structural equation modeling will provide crucial, actionable frameworks for instructional designers, institutional policymakers, and educational technology developers striving to bridge the digital divide and actualize the immersive potential of Education 4.0.

II. THEORETICAL REFERENCE

II.1 THE ONTOLOGICAL FRAMEWORK OF EXTENDED REALITY IN EDUCATION

The overarching taxonomy of Extended Reality (XR) encapsulates a diverse continuum of immersive technologies that manipulate human perception by blending physical realities with synthetic, computer-generated digital environments [3]. Within the educational sector, the two most prominent nodes on this reality-virtuality continuum are Virtual Reality (VR) and Augmented Reality (AR), each offering distinct cognitive affordances and pedagogical utilities.

II.1.1 The Mechanics and Utility of Virtual Reality and Augmented Reality

Virtual Reality is fundamentally defined as a medium composed of highly sophisticated computer simulations in which sensory feedback is continuously altered or augmented in response to the user's kinesthetic and spatial actions [8]. This continuous feedback loop induces a profound psychological state known as spatial presence, tricking the human cognitive architecture into feeling physically present or mentally immersed within a completely synthetic environment [10]. In contemporary educational settings, VR acts as a powerful experiential conduit. It liberates the learner from the geographical, temporal, and physical constraints of the traditional classroom, allowing students to embark on immersive virtual field trips to inaccessible locations, ranging from deep-space topographies to the microscopic interior of the human circulatory system [5]. The pedagogical efficacy of VR stems from its ability to facilitate high-fidelity experiential learning [7]. By immersing students in a controlled, risk-free virtual ecosystem, learners can conduct complex scientific experiments, practice hazardous engineering protocols, or develop intricate surgical techniques without the physical dangers or material costs of real-world failure [6]. Empirical investigations have consistently demonstrated that the spatial presence mechanisms inherent to VR significantly elevate baseline student engagement, improve long-term retention of scientific knowledge, and foster rapid development of practical psychomotor skills.[20]

Furthermore, VR has demonstrated remarkable utility in clinical and psychological management; for instance, localized experiments utilizing VR interventions during pediatric vaccination procedures verified the technology's high efficiency in providing acute pain management and dramatic fear reduction, underscoring the deep cognitive overrides the technology can achieve [11]. In contrast to the total sensory isolation of VR, Augmented Reality integrates physical and digital information in real time, allowing users to remain visually and spatially grounded in their actual environment [8]. Utilizing technological formats such as smartphones, tablet computers, or specialized head-mounted displays, AR superimposes interactive, three-dimensional virtual assets such as data models, textual translations, or animations directly onto the user's perception of the physical world [6]. The integration of AR into educational frameworks radically enriches traditional pedagogical materials. Static interactive textbooks and physical field trips are transformed into dynamic, context-rich learning experiences that respond instantaneously to student inquiry [6]. The utility of AR is particularly pronounced in disciplines requiring complex spatial visualization and high-density data interpretation.

Complex, abstract datasets become physically tangible through AR visualizations, allowing students to interact with molecular structures or geometric theorems in three-dimensional space [6]. Additionally, language learners benefit immensely from AR applications that provide instantaneous, context-aware translations and real-time pronunciation guides overlaid onto physical texts or environments [6]. Research comparing the cognitive demands of AR and VR suggests that AR is frequently a more effective medium for conveying auditory and textual information, as it imposes a lower overall cognitive load than the fully immersive, sensory-heavy environments generated by VR [10]. Despite these profound advantages, meta-analyses reveal a critical systemic flaw in current AR adoption. The vast majority of research remains hyper-focused on the technical affordances of the software rather than exploring how AR can be deeply integrated into holistic pedagogical strategies to cultivate advanced cognitive skills, such as critical thinking [12].

II.1.2 The Evolution of Technology Acceptance Frameworks

The successful deployment of innovative educational technology is rarely determined solely by the software's technical superiority; rather, it is driven by the behavioral intent and psychological acceptance of the human end-user [11]. Historically, user acceptance evaluation was guided by the Technology Acceptance Model (TAM), a foundational theoretical framework that posited that an individual's behavioral intention to use a new system was primarily determined by two core variables: perceived usefulness and perceived ease of use [13]. While the TAM provided a robust initial architecture, the rapidly increasing complexity of consumer-facing technologies necessitated a more granular and encompassing psychological model [14]. To capture these multifaceted nuances, Venkatesh et al. (2012) synthesized decades of behavioral research to develop the Unified Theory of Acceptance and Use of Technology 2 (UTAUT2) [14]. The original UTAUT model consolidated prior theories into four primary dimensions: performance expectancy, effort expectancy, social influence, and facilitating conditions. The UTAUT2 extension explicitly tailored the framework for consumer and end-user contexts by incorporating three highly relevant subjective parameters: hedonic motivation, price value, and habit [14]. Given the consumer-grade nature of modern VR headsets and AR mobile applications, the UTAUT2 framework serves as the optimal theoretical anchor for this comparative investigation.

II.1.3 Operational Constructs of the UTAUT2 Model

The specific dimensions of the UTAUT2 model evaluated in this investigation are operationalized as follows. Performance Expectancy (PE) measures the degree to which an individual believes that using the immersive system will yield significant, tangible gains in academic performance, job efficiency, or learning outcomes. In the context of VR/AR, this reflects the user's belief that the technology will objectively make them a better student or a more effective educator. Effort Expectancy (EE) assesses the degree of cognitive and logistical ease associated with using the system, including the intuitiveness of the user interface, the physical comfort of the hardware, and the steepness of the learning curve required to operate the technology proficiently. Social Influence (SI) quantifies the extent to which an individual perceives those important others, such as academic peers, departmental superiors, or institutional administrators, believe they should actively use the new system, thereby capturing the normative social pressures driving technology adoption. Facilitating Conditions (FC) gauge the individual's perception of the objective support structures available to them, measuring whether the user believes the academic institution provides the necessary technical infrastructure, hardware availability, high-speed internet connectivity, and professional training required to seamlessly use VR and AR tools. Hedonic Motivation (HM), a critical addition in the UTAUT2 model, assesses the fun, intrinsic enjoyment, or psychological pleasure derived directly from using the technology, independent of its functional utility. Price Value (PV) represents the individual's internal cognitive trade-off between the perceived pedagogical benefits of XR applications and the monetary cost of acquiring and maintaining them. Habit evaluates the extent to which individuals tend to perform technology-related behaviors automatically, driven by prior experiential learning and repetitive, systemic integration. Finally, Behavioral Intention (BI) is the endogenous, dependent variable that represents the user's explicit psychological formulation and commitment to adopt and continuously use VR/AR applications in their educational routines.

II.1.4 Contextual Barriers and Institutional Disparities in Adoption

The empirical literature strongly suggests that the actual adoption of VR and AR in educational environments is far from homogeneous and is continually perturbed by severe systemic and demographic frictions. Educators, occupying the critical role of instructional designers, exhibit highly variable states of readiness. While many pioneer teachers recognize XR as a highly compelling platform capable of revolutionizing current teaching practices [13], their initial enthusiasm is often tempered by significant operational concerns. Teachers routinely report massive deficits in instructional design support, poor software interoperability across diverse hardware platforms, and a critical lack of targeted professional development required to align virtual content with rigid curriculum standards [15]. Furthermore, the macro-level diffusion of immersive technologies faces substantial economic, infrastructural, and ethical barriers. The sheer financial burden of outfitting classrooms with high-fidelity head-mounted displays, coupled with the necessity for robust, high-bandwidth technical infrastructure, presents a near-insurmountable hurdle for underfunded educational sectors [8].

Beyond hardware constraints, institutional adoption is hindered by the complexities of proprietary content development and deep-seated ethical concerns regarding student data privacy, regulatory compliance with frameworks such as GDPR and FERPA, and the safeguarding of sensitive biometric data collected by advanced eye-tracking VR headsets [8]. Additionally, unique physiological and psychological challenges exist, particularly concerning young learners. Prolonged immersion in VR can induce cybersickness, physical discomfort from poorly fitted hardware, and profound psychological disorientation—often referred to in the literature as "tricks of the mind"—in which extended exposure to synthetic environments momentarily alters the user's cognitive perception of physical reality [5]. Consequently, understanding how these multifaceted barriers distinctly impact resource-rich private institutions compared to government-funded public schools, and how they differentially influence educators' versus students' adoption mechanisms, is absolutely vital for the strategic, sustainable deployment of educational technology.

III. METHODS

III.1 RESEARCH PARADIGM AND SAMPLE SELECTION

To systematically deconstruct the behavioral determinants of immersive technology adoption, this research employed a quantitative, cross-sectional design utilizing structural equation modeling (SEM). Given the highly specific demographic requirements of the study, namely, the need to target individuals with at least a foundational awareness of, or baseline exposure to, VR and AR educational technologies, a snowball sampling methodology was strategically implemented. This non-probability sampling architecture involves utilizing an initial cohort of qualified participants to purposively recruit subsequent subjects from their respective professional and academic networks. In the context of evaluating emerging technologies where universal adoption has not yet occurred, snowball sampling is highly efficacious for maximizing reach across disparate geographical boundaries and institutional silos. The aggregate participant pool (N=100) was meticulously curated to encompass two primary operational cohorts: educators (teachers, n=81) and learners (students, n=919).

The educator cohort was deliberately drawn from across the primary, secondary, and tertiary academic spectrums to ensure a highly diverse range of pedagogical perspectives and technological readiness levels. Conversely, the student cohort was strictly restricted to secondary and tertiary educational levels. This methodological constraint was enforced under the psychological assumption that learners in these advanced cognitive developmental stages possess the requisite metacognitive maturity and self-awareness to accurately interpret and assess complex, abstract survey constructs, such as facilitating conditions and performance expectancy. Furthermore, to isolate the impact of socio-economic and institutional funding models, the sample was heavily stratified by institutional type, capturing vast datasets from both public/government-funded institutions (n=633) and privately funded educational institutions (n=367). The comprehensive demographic breakdown of the respondent sample, detailing role, gender, and institutional affiliation, is presented in Table 1.

Table 1: Demographic distribution of the study sample.

Category	Gender	Private (n=367)	Public (n=633)
Student (n=919)	Male	169	279
	Female	180	291
Teacher (n=81)	Male	5	20
	Female	13	43

III.2 DATA COLLECTION PROTOCOLS AND RIGOROUS SCREENING

The primary data acquisition phase was conducted using a highly efficient hybrid approach, combining supervised face-to-face questionnaire distribution and secure, encrypted online survey platforms. This dual-modality deployment ensured optimal response rates, minimized sampling bias, and guaranteed robust demographic diversity across the target populations. Following the closure of the data collection window, exactly 1000 valid, fully completed survey responses were retained for high-level inferential statistical analysis. Before engaging in complex structural modeling, the raw dataset underwent a battery of rigorous data screening protocols to ensure mathematical integrity. To detect and manage missing data points, Little's Missing Completely at Random (MCAR) statistical test was conducted. The output of this test yielded a probability value significantly greater than the stringent 0.05 alpha threshold ($MCAR > 0.05$).

This result mathematically confirmed that any missing values in the dataset were scattered entirely at random, assuring the researchers that the missingness did not introduce any systematic, confounding bias into the inferential models. Furthermore, to safeguard the covariant integrity of the structural models against the extreme distorting effects of multivariate anomalies, the Mahalanobis D-Squared (D^2) distance metric was computationally applied across the dataset. The Mahalanobis distance measures how many standard deviations a specific data point is from the mean of the multivariate distribution, accounting for the dataset's correlations. Cases exhibiting a severe anomaly probability (p<.001) were meticulously scrutinized and subsequently managed or excised to guarantee that profound outliers did not artificially inflate or skew the covariant relationships.

III.3 PSYCHOMETRIC INSTRUMENTATION

The survey instrument utilized for this study was meticulously operationalized based directly upon the validated psychometric constructs defined within the UTAUT2 framework by Venkatesh et al. (2012) [14]. The comprehensive measurement model was designed to evaluate eight distinct latent variables: Effort Expectancy (EE), Performance Expectancy (PE), Hedonic Motivation (HM), Social Influence (SI), Price Value (PV), Facilitating Conditions (FC), Habit, and the ultimate endogenous dependent variable, Behavioral Intention to Adopt (BI). The structured questionnaire comprised 24 highly specific, theoretically derived items engineered to accurately capture these latent psychological constructs. To quantify subjective responses, participants rated their alignment with each statement on a standardized 5-point Likert scale. The psychometric anchors ranged from 1 ("strongly disagree") to 5 ("strongly agree"), representing a universally validated and highly reliable scaling architecture for gauging precise levels of cognitive agreement in advanced behavioral and social science research [16].

III.4 ANALYTICAL ARCHITECTURE AND STATISTICAL MODELING

The high-level statistical analysis was executed utilizing IBM SPSS AMOS (Analysis of a Moment Structures) software, an industry-standard platform specifically engineered for executing complex Covariance-Based Structural Equation Modeling (CB-SEM). The analytical architecture proceeded through two distinct, sequential phases to ensure absolute scientific validity. In the initial phase, a rigorous Confirmatory Factor Analysis (CFA) was conducted to stress-test the theoretical measurement model.

The CFA evaluated the internal consistency, convergent validity, and discriminant validity of the utilized survey scales, mathematically ensuring that the theoretical behavioral constructs were accurately and exclusively represented by their designated indicator variables. The standard measurement model equation mapping an observed indicator x to its underlying latent construct ξ is expressed mathematically as:

$$x = \Lambda_x \xi + \delta \quad (1)$$

Where Λ_x represents the factor loading matrix (the strength of the relationship), ξ signifies the unobserved latent construct being measured, and δ denotes the inherent measurement error vector. Following validation of the measurement architecture, the second phase involved conducting a comprehensive structural path analysis. This phase computationally tested the complex web of hypothesized causal relationships flowing from the exogenous constructs toward the endogenous behavioral intention. Crucially, to uncover the targeted demographic and institutional nuances at the core of this investigation, a Multi-Group Analysis (MGA) was embedded into the SEM protocol. MGA is an advanced statistical technique that permits the simultaneous estimation of the entire theoretical model across different, mutually exclusive sub-populations, Public versus Private Institutions, and Students versus Teachers. By constraining and releasing specific parameters, the MGA determines whether the structural path coefficients (β) and, by extension, the fundamental psychological mechanisms of adoption differ significantly across demographic groups.

IV. RESULTS AND DISCUSSIONS

IV.1 CONSTRUCT RELIABILITY AND CONVERGENT VALIDITY

The integrity and scientific robustness of the measurement model were initially assessed through standard metrics of internal consistency and convergent validity. As explicitly detailed in Table 2, all latent variables within the model demonstrated exemplary, highly stable reliability metrics. The calculated Cronbach's alpha (α) values ranged from a baseline of 0.788 (Facilitating Conditions) to a peak of 0.926 (Hedonic Motivation), substantially exceeding the conventional psychometric acceptability threshold of 0.70. To further substantiate the structural stability of the constructs beyond simple inter-item correlation, the Composite Reliability (CR) and Average Variance Extracted (AVE) were computed. The CR values, which provide a more robust measure of internal consistency by accounting for varying factor loadings, universally surpassed the 0.60 operational benchmark, indicating exceptionally strong internal cohesion among the measurement items designated for each specific latent construct. Crucially, the Average Variance Extracted (AVE) for all eight variables exceeded the stringent, non-negotiable 0.50 threshold. The AVE mathematically quantifies the proportion of variance a latent construct captures from its specific indicators relative to the amount of variance due to measurement error. By exceeding 0.50, the data signifies that the latent constructs successfully explain more than half of the total variance present in their respective indicator variables, thereby confirming highly robust convergent validity across the entire theoretical model.

Table 2: Construct Reliability and Validity Indices.

Latent Construct	Cronbach's alpha (α)	Composite Reliability (CR)	Average Variance Extracted (AVE)
Hedonic Motivation (HM)	0.926	0.862	0.675
Habit	0.877	0.885	0.720
Effort Expectancy (EE)	0.885	0.918	0.788
Social Influence (SI)	0.917	0.854	0.661
Performance Expectancy (PE)	0.862	0.927	0.809
Price Value (PV)	0.848	0.882	0.714
Behavioral Intention (BI)	0.855	0.796	0.565
Facilitating Condition (FC)	0.788	0.855	0.664

IV.2 DISCRIMINANT VALIDITY AND ORTHOGONAL FACTOR ARCHITECTURE

Discriminant validity is an essential diagnostic criterion that ensures each theoretical construct is empirically distinct and statistically orthogonal to the others within the highly integrated model. This independence was rigorously verified utilizing the Fornell-Larcker criterion and a comprehensive examination of the construct correlation matrix, as presented in Table 3. According to this strict criterion, the diagonal values (which represent the square root of the AVE for each respective construct) must be strictly greater than any of the off-diagonal correlation coefficients located within the same corresponding rows and columns. The computational analysis confirmed this requirement without exception; the latent variables demonstrably share significantly more variance with their designated measurement indicators than they do with any other distinct construct in the UTAUT2 model. This confirms that the survey instrument successfully isolated distinct psychological domains without operational cross-contamination.

Table 3: Discriminant validity of measures utilizing the Fornell-Larcker criterion.

Construct	HM	Habit	EE	SI	PE	PV	BI	FC
HM	**0.899**							
Habit	0.249***	**0.845**						
EE	0.556***	0.584***	**0.849**					
SI	0.442***	0.754***	0.725***	**0.888**				
PE	0.624***	0.523***	0.771***	0.645***	**0.822**			
PV	0.457***	0.811***	0.591***	0.700***	0.604***	**0.815**		
BI	0.647***	0.536***	0.861***	0.673***	0.759***	0.565***	**0.813**	
FC	0.511***	0.754***	0.661***	0.752***	0.740***	0.759***	0.623***	**0.752**

*(Note: Diagonal values in bold represent the square root of AVE. *** indicates significance at $p < 0.001$)*

Source: Authors, (2026).

Furthermore, the Confirmatory Factor Analysis yielded a rotated factor matrix with exceptionally clean item loadings. Table 4 displays the standardized factor loadings parsed across the eight distinct structural components. High primary loadings (generally scaling > 0.70) combined with minimal, negligible cross-loadings underscore that the individual scale items are correctly and powerfully aligned with their intended theoretical dimensions. For example, analyzing the first component, the survey items theoretically associated with Hedonic Motivation (HM1, HM2, HM3) loaded massively onto Component 1 (0.939, 0.931, and 0.929, respectively), while simultaneously exhibiting near-zero or negative influence on all other structural components. This structural precision affirms the absolute purity of the psychological measurement and validates the instrument's deployment.

Table 4: Factor Matrix demonstrating specific item loadings across all eight components.

IV.3 MODEL FIT ANALYSIS AND STRUCTURAL VALIDATION

Prior to interpreting the causal pathways and demographic divergence, the overall fitness of the structural equation model was rigorously evaluated. This step is critical to guarantee that the hypothesized theoretical network of relationships adequately and proportionally matched the actual empirical data covariance matrix generated by the field survey. As tabulated in Table 5, the model fit indices unambiguously satisfy all established absolute and incremental statistical fit thresholds. The relative Chi-square ratio (CMIN/DF) resulted in an estimate of 2.745. By falling perfectly within the optimal, highly restrictive target range of 1.0 to 3.0, this metric indicates that the model is neither over-parameterized nor excessively rigid. The Comparative Fit Index (CFI), which assesses model fit by comparing the data to the hypothesized model while adjusting for sample size, achieved a robust 0.971, comfortably exceeding the standard 0.95 cutoff for exceptional model fit. Furthermore, the critical error metrics, encompassing the Standardized Root Mean Square Residual (SRMR = 0.052) and the Root Mean Square Error of Approximation (RMSEA = 0.024), both remained well below their strict respective rejection thresholds of 0.08 and 0.06. The PClose value of 1 (which acts as a definitive statistical safeguard by testing the null hypothesis that RMSEA is ≤ 0.05) confirms with absolute certainty that the RMSEA is not significantly greater than zero. Collectively, these highly favorable parameters certify the structural model as an outstanding, mathematically sound framework for subsequent predictive hypothesis testing and multi-group extrapolation.

Table 5: Model Fit Measures for the Structural Equation Model.

Measure	Estimate	Threshold	Interpretation
CMIN	2459.452	--	--
DF	896	--	--
CMIN/DF	2.745	Between 1 and 3	Excellent
CFI	0.971	> 0.95	Excellent
SRMR	0.052	< 0.08	Excellent
RMSEA	0.024	< 0.06	Excellent
PClose	1	> 0.05	Excellent

IV.4 MULTI-GROUP PATH ANALYSIS: THE DICHOTOMY OF PUBLIC VS. PRIVATE INSTITUTIONS

A critical, highly novel facet of this investigation was to determine if macro-level institutional funding structures generate systemic variances in the psychological mechanisms driving VR/AR adoption among their respective populations. A Multi-Group Analysis was conducted to compare the unstandardized beta coefficients (β), critical ratios (*t/C.R.*), and probability values (p) explicitly between Private and Public academic institutions; the results are documented in Table 6.

Table 6: Path Analysis and Significant Differences Between Private and Public Institutions.

Path of Constructs			Private Schools			Public Schools			Significant Difference
Endogenous Variable		**Exogenous Variable**	***β***	***t***	***p***	***β***	***C.R.***	***p***	***p***
VR/AR Adoption	<-	Performance Expectancy	0.071	0.730	0.466	0.164	3.014	0.003	***
VR/AR Adoption	<--	Effort Expectancy	0.636	6.846	***	0.589	11.319	***	***
VR/AR Adoption	<--	Social Influence	-0.011	-0.112	0.911	0.054	1.139	0.255	0.969
VR/AR Adoption	<--	Facilitating Condition	0.085	0.631	0.528	-0.112	-1.742	0.082	0.920
VR/AR Adoption	<--	Hedonic Motivation	0.221	3.318	***	0.243	7.001	***	***
VR/AR Adoption	<--	Habit	0.103	0.901	0.368	0.136	2.141	0.032	***
VR/AR Adoption	<--	Price Value	-0.104	-1.076	0.282	-0.055	-1.016	0.310	0.150

*(Note: *** indicates significance at p < 0.001)*

Source: Authors, (2026).

The comparative data yield profound, multi-layered insights into the socio-economic realities of technology adoption. Within private educational institutions, the structural model simplifies considerably: only Effort Expectancy (β = 0.636, p<.001) and Hedonic Motivation (β = 0.221, p<.001) exert a statistically significant positive impact on the behavioral intention to adopt VR and AR. The exceptionally high sensitivity to Effort Expectancy suggests that users embedded in well-resourced private institutions—who likely already possess seamless access to a wide array of advanced digital tools—highly prioritize the intuitive nature and user-friendliness of immersive systems. If a VR or AR tool is clunky or difficult to use, the private-sector user, driven by high expectations for digital seamlessness, will reject it. They adopt the technology primarily because it is easy to use and intrinsically enjoyable (Hedonic Motivation). Conversely, the behavioral model governing public institutions manifests a far more complex, outcome-driven adoption matrix. In the public sector, Performance Expectancy (β = 0.164, p<.003), Effort Expectancy (β = 0.589, p<.001), Hedonic Motivation (β = 0.243, p<.001), and Habit (β = 0.136, p<.032) all exhibit significant, positive causal relationships with the intention to adopt.

The multi-group difference test mathematically confirms that the variance in behavioral parameters between the two institutional types is statistically significant across Performance Expectancy, Effort Expectancy, Hedonic Motivation, and Habit. The emergence of Performance Expectancy and Habit as significant drivers exclusively within public institutions indicates a starkly different operational reality. Users in public, government-funded environments, which often face resource constraints and highly rigid, standardized testing mandates, are heavily focused on the technology's utilitarian, grade-enhancing outcomes. They adopt VR/AR not just because it is novel or easy, but because they believe it will objectively improve their academic performance [14]. Furthermore, the reliance on Habit suggests that public school adoption requires systemic, repetitive integration into daily routines to become sticky, rather than relying on spontaneous, pleasure-driven usage.

Interestingly, Social Influence, Facilitating Conditions, and Price Value did not reach statistical significance across both demographic groups. The failure of Facilitating Conditions to dictate adoption intent implies that contemporary users, who are largely comprised of digital natives, possess a baseline intrinsic technological self-efficacy that overrides institutional infrastructural deficits; alternatively, it suggests that both sectors struggle equally to provide adequate technical support, rendering the variable a non-factor in individual decision-making [12]. Furthermore, the profound non-significance of Social Influence in Private (β =- 0.011) and in Public (β =0.054) is a telling indicator of market maturity. It implies that the decision to adopt immersive educational technology is highly individualized rather than peer-driven; students and teachers are no longer adopting XR simply because their peers are, but rather evaluating it purely on its personal utility and usability.

IV.5 MULTI-GROUP PATH ANALYSIS: THE PSYCHOLOGICAL GAP BETWEEN STUDENTS AND TEACHERS

To further dissect the structural parameters governing adoption, the dataset was bifurcated by stakeholder role, directly contrasting the psychological determinants of learners (Students) against those of instructional designers (Teachers). The analytical output of this comparison, detailed in Table 7, reveals the most striking behavioral divergence within the entire study.

Table 7: Path Analysis and Significant Differences Between Students and Teachers.

Path of Constructs			Students			Teachers			Significant Difference
Endogenous Variable		**Exogenous Variable**	***β***	***t***	***p***	***β***	***C.R.***	***p***	***p***
VR/AR Adoption	<--	Performance Expectancy	0.131	2.233	0.026	0.509	2.563	0.010	***
VR/AR Adoption	<--	Effort Expectancy	0.595	10.741	***	0.544	2.928	0.003	***
VR/AR Adoption	<--	Social Influence	0.065	1.288	0.198	-0.143	-0.921	0.357	0.127
VR/AR Adoption	<--	Facilitating Condition	-0.071	-1.015	0.310	-0.428	-2.051	0.040	0.00
VR/AR Adoption	<--	Hedonic Motivation	0.249	6.745	***	0.049	0.404	0.686	***
VR/AR Adoption	<--	Habit	0.138	2.002	0.045	0.299	1.600	0.110	***
VR/AR Adoption	<--	Price Value	-0.087	-1.444	0.149	0.130	0.964	0.335	0.065

Source: Authors, (2026).

For the student cohort, the structural modeling mirrors the broader trend toward highly inclusive public institutions. Student adoption of VR and AR technologies is strongly and positively predicated upon Performance Expectancy (β = 0.131, p<.026), Effort Expectancy (β = 0.595, p<.001), Hedonic Motivation (β = 0.249, p<.001), and Habit (β = 0.138, p<.045). The data unequivocally demonstrate that for a student to internalize and adopt immersive learning tools, they must perceive the technology as not only cognitively manageable (Effort Expectancy) and academically beneficial (Performance Expectancy), but also as absolutely critical: the experience must be intrinsically engaging and enjoyable (Hedonic Motivation) [17].

The immense significance of Hedonic Motivation confirms earlier literature postulations that digital-native learners respond exceptionally well to "gamified" or experientially stimulating platforms, validating VR's core utility in increasing spatial presence, psychological flow, and deep academic engagement [10]. In sharp, almost oppositional contrast, the educator cohort (teachers) operates under a distinctly divergent set of technological imperatives. For teachers, the dominant predictors of adoption are Performance Expectancy (β = 0.509, p<.001), Effort Expectancy (β = 0.544, p<.003), and, uniquely, Facilitating Conditions (β = 0.428, p<.040). Notably, Hedonic motivation holds absolutely no significant bearing on a teacher's intention to use VR/AR in their classroom (β = 0.049, p<.686). This indicates a highly pragmatic, outcome-oriented, and severely stressed approach to pedagogical design. Teachers evaluate immersive technology strictly through a lens of unyielding utility, whether the XR platform will objectively enhance the delivery of mandatory curriculum content (Performance Expectancy) and whether it is realistically deployable within a fifty-minute class period without overwhelming pedagogical friction or technical failure (Effort Expectancy). The fun or novelty of the hardware is entirely irrelevant to their operational calculus.

The significant, albeit intensely negative, impact of Facilitating Conditions among teachers (β = -0.428) is perhaps the most profound and concerning finding of this entire investigation. In traditional UTAUT modeling, better facilitating conditions generally drive higher adoption [14]. However, this inverse relationship suggests that as current institutional infrastructures or top-down systemic mandates increase, teacher willingness to adopt XR declines rapidly. This anomaly highlights severe issues of technological fatigue, overly restrictive administrative protocols, or a critical lack of autonomy in curriculum design. It starkly corroborates recent literature detailing the severe challenges and anxieties teachers face when attempting to integrate highly complex [18], unpredictable technologies into rigid, high-stakes classroom frameworks without adequate contextual training [15]. When administrators force "facilitating conditions" via mandates without providing actual pedagogical support, teachers actively resist adoption. The multi-group analysis ultimately confirms that the variance across all aforementioned primary constructs (Performance Expectancy, Effort Expectancy, Hedonic Motivation, Habit, and Facilitating Conditions) is highly statistically significant between educators and learners, proving that a one-size-fits-all deployment strategy for educational XR is fundamentally doomed to fail.

IV.6 SYNTHESIS OF CORE FINDINGS AND THEORETICAL IMPLICATIONS

The systematic aggregation of these multi-group results significantly extends the traditional boundaries and assumptions of the UTAUT2 framework when applied within a modern educational context [14]. Historically, theoretical adoption models assume a relatively homogeneous level of user intent, treating an organization as a single adopting entity. However, this empirical data unequivocally fractures that assumption, proving beyond doubt that the intent to adopt XR is deeply segmented by both functional role (teacher vs. student) and environmental constraint (public vs. private). Universally, Effort Expectancy emerged as the most resilient, dominant, and ubiquitous predictor of adoption intent across all four analyzed sub-populations. This fundamental reality dictates an unyielding law for educational technologists: despite the hyper-advanced, visually stunning nature of immersive reality, the primary barrier to entry remains basic usability [13]. If the VR hardware is cumbersome to wear, or if the AR software interface requires complex recalibration, neither the student's desire for immersive engagement nor the teacher's drive for instructional efficacy will compensate for the resulting cognitive overload and frustration. The technology must simply work seamlessly. Furthermore, the complete collapse of Social Influence as a predictive variable across all groups marks a definitive departure from early-stage technological innovations (where peer pressure heavily drives initial uptake), indicating that AR and VR in education have transcended the hype cycle and transitioned into a mature evaluation phase governed primarily by individualized, utilitarian, and ergonomic assessment.

V. CONCLUSIONS

This exhaustive empirical investigation systematically examined the multidimensional psychological and environmental perceptions surrounding the adoption of virtual reality (VR) and augmented reality (AR) among teachers and students in both public and private educational institutions. Utilizing a rigorously validated extension of the UTAUT2 framework, the study generated highly nuanced, statistically significant intelligence regarding the operational psychology of educational technology integration in the era of Education 4.0. The foremost conclusion drawn from the complex path analysis is that Effort Expectancy, Performance Expectancy, and Hedonic Motivation are the paramount, universal drivers facilitating the adoption of immersive technologies. However, deep cross-demographic analyses exposed profound systemic dichotomies that mandate highly targeted deployment strategies. In both private and public academic institutions, Effort Expectancy and Hedonic Motivation dictate the baseline parameters for student adoption; learners overwhelmingly prioritize frictionless ease of use and deep experiential enjoyment. Conversely, educators adopt a strictly utilitarian, pragmatic operational framework. Teachers are structurally indifferent to the hedonic or entertaining facets of VR/AR, grounding their adoption intent exclusively in Performance Expectancy (the tangible, measurable pedagogical benefits) and Effort Expectancy (the logistical ease of classroom deployment).

Moreover, the analytical output challenges several established industry assumptions. The consistent statistical insignificance of Social Influence and Price Value across the broader models suggests that adoption is now an individualized, pragmatic calculation not influenced by social normative pressures or immediate financial concerns (which are likely abstracted to the institutional level). Crucially, the data underscores a critical vulnerability in the educational supply chain: the negative correlation between facilitating conditions and teacher adoption. Because these technologies are rapidly emerging and market demand is surging toward a $14.2 billion valuation, institutions risk catastrophic implementation failure if they impose top-down hardware mandates without aggressively enhancing pedagogical support capabilities tailored specifically for teachers. Without strategic alignment that emphasizes career readiness, seamless integration, and minimized pedagogical friction, teacher-led adoption will stagnate, rendering the technology useless regardless of student enthusiasm. Despite the robust methodological framework deployed herein, this research acknowledges several operational limitations that warrant future scientific inquiry. The sample size, while statistically massive and highly valid, represents a cross-sectional snapshot obtained within a limited temporal window; it captures immediate perceptual states rather than evolving, long-term adoption dynamics. It is highly recommended that future scholars execute extended longitudinal methodologies to firmly establish and confirm the causal evolution of these behavioral effects over prolonged, multi-year exposure periods.

Finally, given the localized nature of the snowball sampling methodology, future research must deliberately incorporate cross-cultural variables and socio-economic indicators unique to differing global societal architectures to definitively identify the universal relevance, adaptability, and ultimate scalability of this proposed immersive technology adoption model.

VII. ACKNOWLEDGMENTS

The research team wishes to extend their deepest gratitude to the administrative boards, participating faculty members, and student respondents across the various public and private academic institutions who generously provided their time, cognitive effort, and invaluable insights to facilitate this exhaustive investigation. The foundational institutional support structures and the enthusiastic willingness of the broader academic community to critically engage with emerging, disruptive educational technology frameworks were absolutely instrumental in the successful execution and conclusion of this empirical study.

ABSTRACT

The importance of touchless systems for easier Human Machine Interaction (HMI) has been brought to light by recent pandemics. A key component of HMI, gesture detection represents a distinct class of useful computer vision applications. Outstanding outcomes in video processing are demonstrated by Convolutional Neural Networks (CNN) for a range of computer vision applications. This study reviews and compares various CNN versions for gesture detection along with their uses. To determine the correctness of the model, a local dataset of hand gestures is built and tested in conjunction with a synthetic gesture dataset. Using multilayered CNN, palm detection in a video frame is accomplished with efficient foreground-background separation. In a parametric research, these Mean Square Error (MSE) values are then contrasted with the known comparable system. The MSE of 12.6% obtained from the combination of synthetic and local datasets is better than that of recent research. In order to achieve 3 Dimensional (3D) estimation of a hand gesture with the aid of palm recognition, the number of key points allocated for the skeletal representation of the hand is crucial. This further enables the application of the technique in numerous upcoming genres.

I. INTRODUCTION

Convolutional Neural Networks (CNN's) are a subset of deep neural networks that are most frequently employed in image or video processing. One of the finest methods for extracting features from a video frame is convolutional networks. It recognises the supplied video frames as a pixel matrix, making it simpler to separate the contained items. Then, several levels with weights and biases are supplied with these pixels. These layers are all interconnected and aid in feature extraction before categorization. When gesture detection is only concerned with real-time video processing, a complex scenario is exhibited. The complexity of video processing algorithms has grown quickly over time [1], [2]. CNNs, because of their default categorization output, carry out the fundamental operation on videos to identify a certain gesture [3]. In accordance with the applications for which they are utilised, there are several types of neural networks. There are several different CNN designs, including as LeNet, AlexNet, VGG, GoogLeNet, ResNet, and many more. Since there are more variables in hand gesture detection than in face detection, it faces many challenges. Hands, unlike the face, which has fixed features such as the nose, eyes, and ears, have ten different shaped fingers. Their morphology and position fluctuate in real time, and gestures have a greater number of possible combinations.

There is a high likelihood that fingers will merge with the noisy background, as well as occlusion. Numerous researchers have been working on such confinements and developed 2D and 2.5D key point estimation techniques. This approach, while effective, lacks disparity and geometry for a real-time complex system. Semantic segmentation is essential for labelling pixels in a frame and aiding in the separation of the foreground and background. UNET and VGG-16, two CNN-based deep learning models, are created for segmentation and classification [4]. In order to assist astronauts in the space station with gesture detection as they deal with robots for their daily tasks, a combination of Mask-RCNN and MobileNet is employed for background removal and feature extraction, respectively [5]. Recently, the Hybrid Multidimensional Deep Convolutional Neural Network (HMDCNN) was created to enable multimodal recognition of speech as well as facial, lip, and even voice [6].

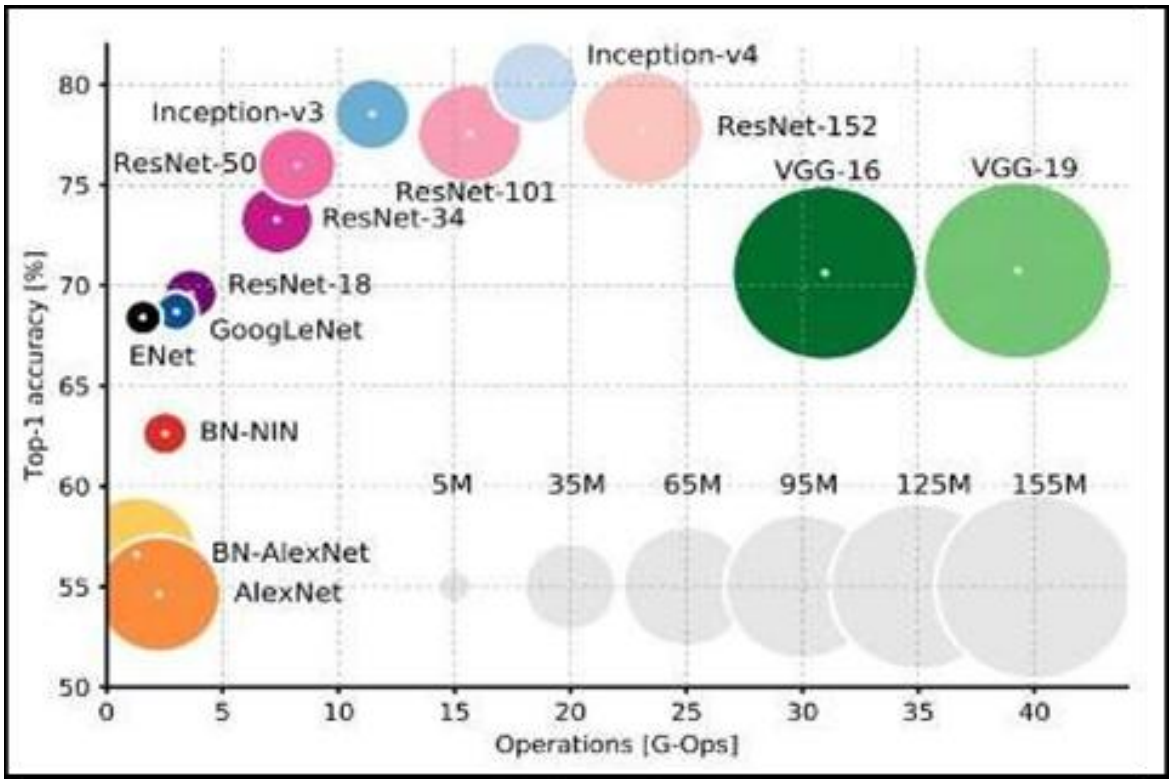

Figure 1: Accuracy Vs Number of operations performed in various types of CNNs.
Source: Authors, (2026).

Figure 1 illustrates how Alexnet and its variants provide respectable accuracy with regard to few operations carried out. The quantity of procedures is gradually raised as we go forward in our hunt for greater precision. When it comes to providing the best performance for a given amount of operations, Enet, GoogleNet, and ResNet are quite close. Processing video that comprises a lot of image frames quickly and efficiently is required for the main focus. However, even little flaws in video accuracy, such as lag or delay, utterly defeat the point. Newer versions of ResNet, Inception Net and Inverse Kinematics Net that provide a trade-off between accuracy and operations are helpful for solving such challenging real- world situations [7], [8]. Despite being rather hefty models, VGG-16 and VGG-19 provide good accuracy for video processing of about 70–75 percent while simultaneously processing millions of operations to evaluate the system's processing capabilities. For dynamic hand gesture identification, optical motion guided templates are used with 2D and 3D CNNs [9]. An easy-to-use but effective technique for extracting feature vectors for Chinese sign language identification uses 3D CNN [10] and optimised dense optical flow to analyse video stream.

When working with complicated datasets, it might sometimes be more productive to utilise a single network rather than the hybrid networks stated above. Therefore, a quicker R-CNN is employed with pose anchor key points for hand motions for the difficult Large scale Multiview 3D Hand Pose Dataset (LSM-HPD). Skeleton extraction from a video frame to identify motions and gestures is another innovative approach to this subject. To extract skeletal information and subsequently identify the action based on it, Recurrent Neural Networks (RNNs) and Long Short-Term Memory (LSTM) cells are utilised in conjunction [11]. The difficult challenge of recognising dynamic hand movements often requires the use of several CNN models. A 3D-Resnet network is employed for introduce fusion to abstract restricted spatiotemporal characteristics, and then a variation ConvLSTM is used to acquire global spatiotemporal data [12]. For the same application online, a CNN architecture with an effective sliding window technique is given [13]. It consists of a classifier and a detector on two levels. For efficiency analysis, a separate CNN is utilised. Figure 2 depicts the detector and classifier structure combination which uses single time activation function to save time and processing.

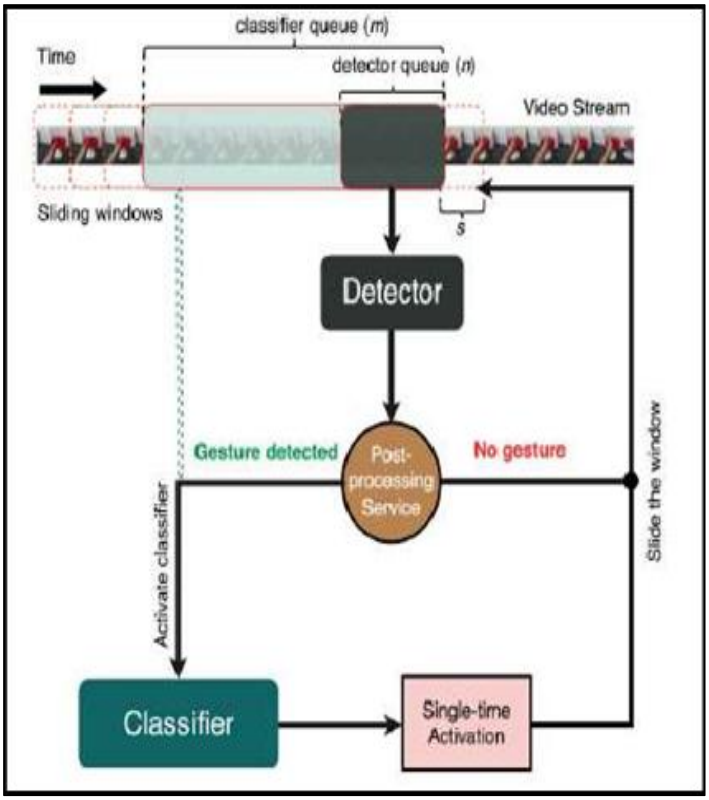

Figure 2: Two-level hierarchical structure.
Source: [13].

A glove sensor was introduced for Human Machine Interaction (HMI) in order to record the precise coordinates of hands. According to its intended use, gloves typically incorporate a variety of sensors, including an optical sensor [14], assistive technology for the blind and deaf [15], accelerometer and gyroscope sensors for human machine interfaces [16] or a color-based glove that can be customized with 3D models [17]. The main goal of computer vision is to do these tasks with the least amount of hardware possible by training a neural network, which adds more innovation and creativity to the desired job. In Methodology, it is demonstrated how to use a mixture of CNNs to obtain a 3D representation of gestures. In the gesture detection scheme, the palm represents the most stable stationary part of the hand. After acquiring video feed, the proposed research performs the Palm detection process first. The wrist of the palm is assumed to be the target value, and the key points are envisioned in relation to it. Lastly, joint estimation and prediction on a 3D surface are performed to replicate a 3D skeletal hand gesture instantaneously. The use of costly stereo sensors or multi camera set up at various perspectives is prevented, and a simple RGB camera is used instead.

In this paper the authors summarise their contributions as follows.

a) An alternative model is suggested to resolve the problem
b) Development of Local and Synthetic datasets
c) Planned the model is trained and tested on these datasets
d) Parametric study of final results with reference to latest contributions.

II. MATERIALS AND METHOD

With a few minor exceptions, all of the strategies described in the previous section utilise multilayer design. When real-time gesture detection is needed for video processing, assembling the necessary hardware is a laborious effort. When employing CNN for deep learning on such tasks, a graphics processing unit (GPU) is required. Herein study, real- time video processing is done on an NVIDIA GPU. Google Colab, Kaggle, and for paid or rented offerings Amazon Web Services (AWS) and Microsoft Azure enable access to GPU over the cloud, among many more operators, are some additional platforms that offer free GPU usage for a certain time frame. Therefore, the end output may be either a 3D dataset for model processing or a 3D estimate of gestures and actions in order to achieve greater accuracy [18]. A Google hand tracking resolution suggests an ML pipeline that combines two models that cooperate with one another: a palm detector and a hand landmark model [19]. Using an aligned hand bounding box, the former locates palms, and the latter yields high-fidelity 2.5D landmarks. Finding the depth from a particular frame is crucial to achieving 3D perception in computer vision. The easiest method of finding depth is to have users interact with the system [20]. Another approach may use the placement of numerous cameras [21] or possibly the use of a well-structured light to record the geometry of the frame in relation to a single image [22]. The most popular technique for doing this is monocular depth estimation, although for greater accuracy, more datasets are required [23]. A Gated Multi-Scale Network is employed to get the same result [24]. The time-consuming job of estimating depth, which calls for the use of numerous datasets, is substantially helped by the use of 3D key points.

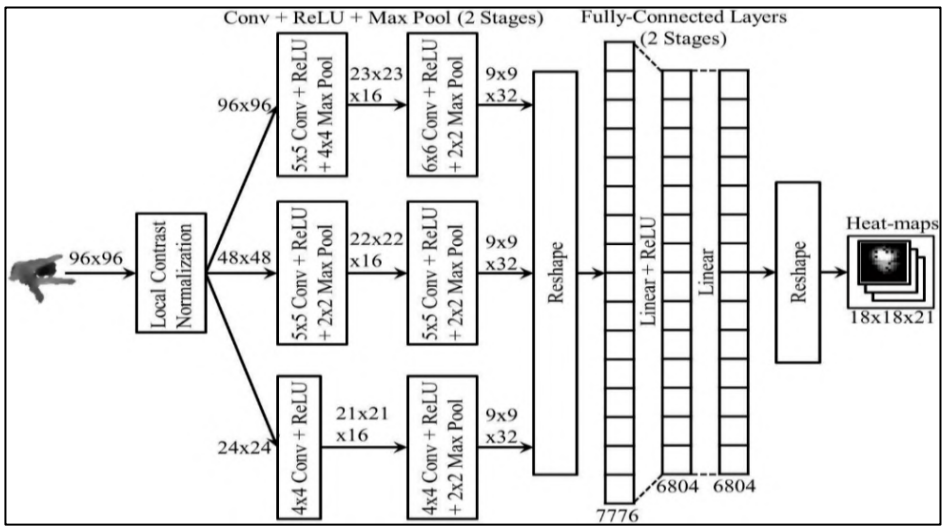

Figure 3: Combination of convolutional and fully connected layers.
Source: [25].

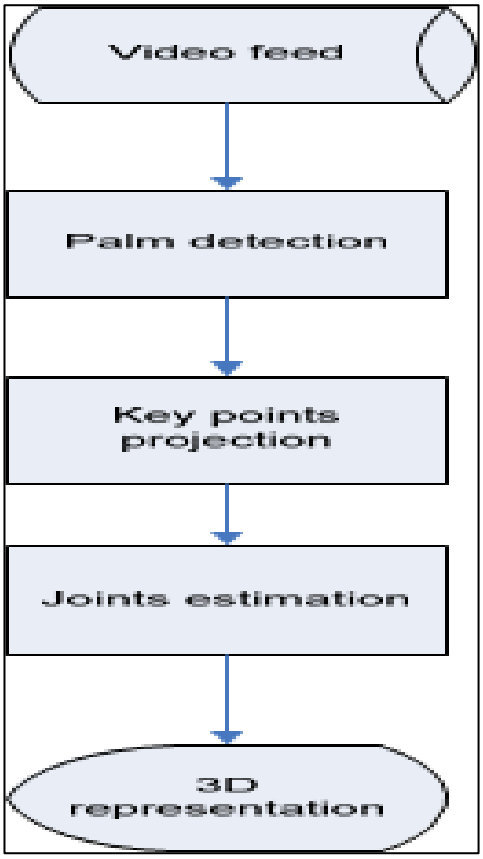

Figure 4: Flowchart of the proposed model.
Source: Authors, (2026).

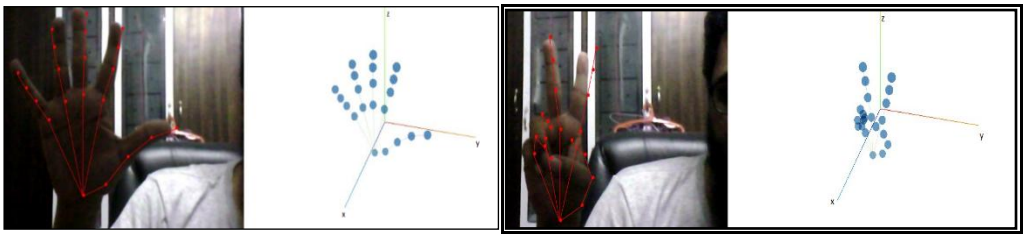
As seen in figure 3, the gesture's primary point and focal length are determined after taking a depth reading from the relevant frame or picture, and the motion's local contrast is altered [25] which aids in the image normalisation process. The combination of 5 by 5 and 4 by 4 Convolution and ReLu is used along with 2 by 2 Max pooling. After being down sampled, the images are run through many convolutional layers. The feature map outputs are then input into fully linked layers to produce heat maps. As seen in figure 4, the only sensor employed in this suggested system is a camera, or video stream. The palm detector uses the video frames to form a convex hull around the hand, with the radius determining the borders of the fingers. The entire palm, including the fingers, is covered by the Euclidean distance which helps in Key points projection The final phase projects the critical locations along the defined contour. In order to connect the important locations in a skeleton-like form, the Guassian distribution of joints for Joints estimation is determined using three views of heat maps. Equation 1 may be used to determine a 3D representation of joint positions at the final stage.

II.1 STEPWISE IMPLEMENTATION

Where , a measure of reconstruction of is optimal joints, suggests optimal coefficients for joints, is total amount of principal components included and mean vector constant. It has been observed that 21 key points, as opposed to other number of key points, provide better throughput and are linked to each other for precise gesture and geometry estimation.

II.2 DATASETS AND PRE-PROCESSING

Two distinct dataset kinds are joined to get the desired outcome. Starting with 5k images made from locally gathered gesture dataset [26], each with a unique collection of gestures. Each image has a different backdrop, which adds to the diversity of frames available for training the model. Aside from the front motions that are necessary, the background has intricate shape and variable illumination. Additionally, a synthetic dataset with more than 50k images that includes hand movements with various skin tones is employed. To accurately define the skeleton hand shape, annotations are pre-processed on a local gesture dataset with a maximum of 21 key points. These crucial details makes it easier to capture the widest variety of hand gestures and movements possible in any one frame. With the aid of 21 crucial points, the skeleton hand may be used to identify motions, without the need for bright illumination or an unsettling background.



II.3 TRAINING DETAILS

The hyper parameters are chosen in such a way that it reaches a trade-off between the complexity of the model and its likely results. The two models are trained using the Root Mean Square Propagation (RMSProp) optimizer, which has a learning rate of 10-4. Both modules have 50 iterations, with the first module having a batch size of 32 and the second having a batch size of 64. The model is trained using 75% of the photos, tested using 15%, and then validated using the remaining images. The system is trained considering multiple losses which includes Regularisation loss($£_{reg}$), 3D loss($£_{3D}$), Normalisation loss($£_{Norm}$) and Angular loss ($£_{Ang}$) as shown in equation 2.

$$£_{total} = £_{reg} + £_{3D} + £_{Norm} + £_{Ang} \quad (2)$$

III. RESULTS AND DISCUSSIONS

Figures 5 (a) and (b) demonstrate how our model, even in low light and noisy background, can recognise the palm in the supplied video frame while removing the complicated backdrop. Even though it cannot precisely trace the critical locations on the index finger in 5 (a), the 3D graph nevertheless provides a better depiction. Joint estimation is crucial in this case to project the skeleton form of the palm and fingers, and the gesture's 3D structure amplifies the geometry and depth of the gesture in the available space. The reconstruction of hands in a three-dimensional axis improves the accuracy and precision of gestures in real-time. To analyse the gesture in a particular video frame from various perspectives, the hands XYZ axis representation may be rotated.

(a) (b)

Figure 5: (a) & (b) Shows key points projected on palm, in low light and noisy background with its skeletal representation in XYZ axis.
Source: Authors, (2026).

The simulated dataset demonstrates improved accuracy for locating the precise critical locations in palm. Since the model must function in real-world situations, the locally produced hand gesture dataset is more important since artificial motions, in contrast to real-world situations, have smooth skin textures and steady backdrops. It is therefore necessary to combine the two datasets, which improves accuracy in terms of Mean Square Error (MSE), which provides a measure of the quality of frame predictions, when compared to utilising only the local dataset with authentic hand gestures. Mean square error represents the difference of the squared error between actual (A_v) and predicted (P_v) output as shown in equation 3.

$$MSE = \frac{1}{n}\sum_{i=1}^{n}(A_v - P_v)^2 \quad (3)$$

To analyse the gesture in a particular video frame from various perspectives, the hands XYZ axis representation may be rotated. A trade-off between aims and relevance is developed as a result. MSE should ideally be zero and practically as low as possible. The suggested technique outperforms the corresponding traditional model, as demonstrated in table 1, when compared. The Local Hands dataset gives MSE of 15.7 while synthetic Hands gives 25. On the other hand combination of both
datasets gives superior MSE of 12.6, all in terms of percentage.

Table 1: Model performance for available datasets.

Datasets	Proposed System MSE (%)	FanZengh et.al., MSE (%)
Local Hands	15.7	16.1
Synthetic Hands	25	25.7
Combination of Both	12.6	13.4

Source: Authors, (2026).

Percentage of Correct Key-points (PCK) is another method to measure the amount of the hand gesture key points and joint estimation. When the difference between the predicted and the true joint is smaller than some threshold, the identified joint is considered to be correct.

To come up with the distances, the pixel lengths in each case are normalised by 0.7 the corresponding hand size of the corresponding person, with regard to threshold which are applied in the development of the PCK curves. The blue and green dotted lines are the PCK of local and synthetic hand gesture dataset respectively and the red line is the PCK of mixture of both datasets. In this way, the tradeoff can be well brought out in terms of practical use of hand gesture datasets.

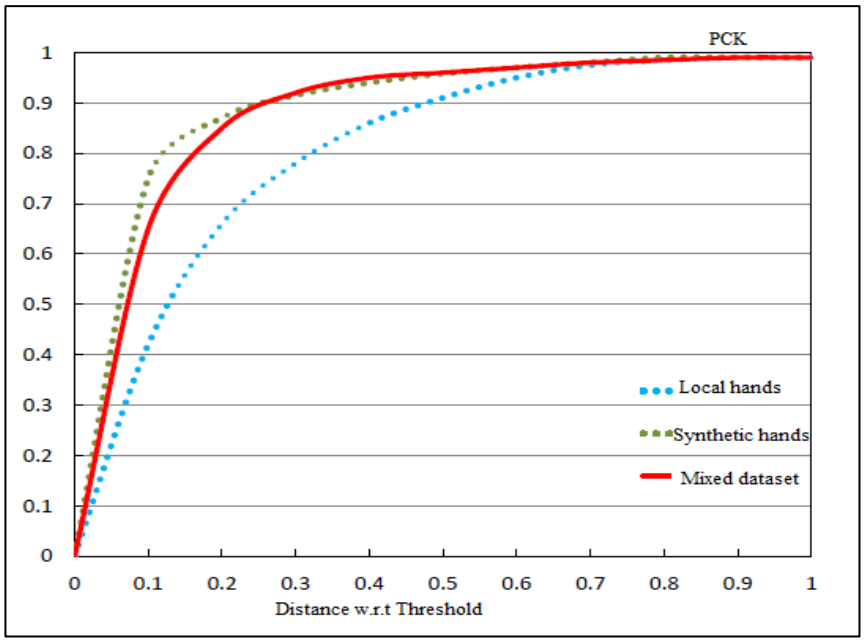


Figure 6: PCK comparison between different datasets.
Source: Authors, (2026).

IV. CONCLUSIONS

Real-time gesture recognition is well-suited for CNN operations, particularly in feature extraction and classification.

•Various CNN configurations can be employed for dynamic, online gesture detection.
•Combining results from two separate CNNs tends to outperform a single CNN in gesture recognition.
•The use of complex hardware enhances computer vision solutions for real-time video processing.
•Locally created dataset exhibits moderate accuracy with 15.7% MSE with actual video frames.
•Research utilizes a combination of datasets for training and testing, resulting in improved accuracy and a reduced MSE of 12.6%.
•PCK is a parameter used for exact projection of key points around hand gestures, showing consistent results on both datasets.
•Gesture sensing technologies find applications in gaming, virtual reality, and augmented reality.

ABSTRACT

In modern System-on-Chip (SoC) architectures, the Advanced Micro-controller Bus Architecture (AMBA) serves as the backbone for communication between high-performance processors and low-power peripherals. The AHB-to-APB bridge is a critical interface that translates high-speed Advanced High-performance Bus (AHB) transactions into low-bandwidth Advanced Peripheral Bus (APB) signals. However, as semiconductor technology scales into the deep sub-micron regime, on-chip communication becomes increasingly susceptible to soft errors and bit-flips caused by crosstalk and electromagnetic interference. This paper proposes a fault-tolerant bridge design that integrates Single Error Correction (SEC) using Hamming Code logic. The design utilizes an 8-state Finite State Machine (FSM) to manage protocol translation and data integrity. Experimental results obtained using the Cadence Genus Synthesis tool (90nm technology) demonstrate a total area of 3464.331 um^2 and a total power consumption of 3.8247 mW. Functional verification confirms 100% recovery from single-bit soft errors, ensuring robust data integrity for safety-critical VLSI systems.

I. INTRODUCTION

I.1 THE EVOLUTION OF SYSTEM-ON-CHIP (SOC)

The semiconductor industry has undergone a radical transformation, moving from discrete components on a printed circuit board to integrating entire systems onto a single silicon die. This "System-on-Chip" (SoC) approach allows for smaller, faster, and more power-efficient devices. However, with hundreds of internal modules ranging from high-speed processors to low-speed sensors needing to communicate simultaneously, a standardized "language" or protocol is required. This is where the ARM Advanced Micro-controller Bus Architecture (AMBA) serves as the industry-standard backbone.

I.2 PROTOCOLS: AHB AND APB

In an AMBA-based SoC, components are categorized by their performance and power requirements. This necessitates different bus protocols:

(i). Advanced High-performance Bus (AHB)

The AHB is the "Expressway" of the SoC. It is designed for high-performance, high-clock-frequency system modules. Key characteristics include:

a. **Pipelined Operation:** AHB allows the address phase and data phase of different transfers to overlap, maximizing throughput.
b. **Burst Transfers:** It can move large blocks of data in a single sequence, which is essential for memory controllers and high-speed processors.
c. **Centralized Multiplexing:** Unlike older bus styles, AHB uses a central multiplexer to manage multiple masters and slaves, reducing signal congestion.

(ii). Advanced Peripheral Bus (APB)

The APB is the "Local Service Road." It is optimized for minimal power consumption and reduced interface complexity. It is used for peripherals that do not require high bandwidth, such as UARTs, Timers, and General Purpose I/O (GPIO). Key characteristics include:

a. **Non-pipelined:** Every transfer takes at least two clock cycles (Setup and Enable), making the logic very simple.
b. **Reduced Power:** Since there is no complex pipelining or burst logic, the toggling of signals is minimized, saving battery life.
c. **Unclocked Peripherals:** Many APB peripherals can operate at lower frequencies than the main system clock.

I.3 Role of the AHB-to-APB Bridge

AHB and APB domains are fundamentally different: one is fast and complex, while the other is slow and simple. They cannot "talk" to each other directly. The **AHB-to-APB Bridge** acts as the essential translator. It samples the high-speed signals from the AHB master (like the CPU), holds them, and generates the specific timing required for the APB peripheral. It manages the handshaking signals (PSEL, PENABLE, PREADY) to ensure that data is transferred without loss despite the speed mismatch.

I.4 Problem Statement: The Reliability Gap in Nanometer Scales

When the technology scales the designs down to 90nm and below, the physical wires on the chip become incredibly thin and packed closely together. This physical environment creates a "Gap" in reliability:

1. **Soft Errors:** Transient faults caused by electromagnetic interference (EMI) or signal crosstalk can flip a single bit (a 0 becomes a 1).
2. **Passive Bridges:** Standard bridge designs are "passive." They move data but never check it. If a bit flips on the peripheral bus during a read operation, the bridge propagates that corrupted data directly to the CPU.
3. **System Impact:** In safety-critical applications like automotive braking or medical monitoring, a single bit error in a sensor reading can cause a system crash or incorrect hardware behavior.

I.5 Proposed Solution and Contributions

The proposed work introduces a **Fault-Tolerant Bridge,** moves beyond simple protocol translation. By embedding **Single Error Correction (SEC)** logic directly into the bridge's hardware data path, which enable the bridge to "heal" data in real-time.

1. **Hardware SEC:** Using Hamming Code, the bridge detects and corrects bit-flips during the ST_RENABLE state.
2. **8-State FSM:** A custom FSM manages the complex timing of error correction without stalling the AHB master.
3. **Synthesis-Proven Efficiency:** Cadence Genus to prove that this high level of reliability is achievable with a very low power and area overhead.

II. EXISTING ARCHITECTURES

The landscape of on-chip communication has evolved significantly from simple point-to-point connections to complex, hierarchical bus architectures. This section provides a thematic analysis of existing research regarding AMBA-based interconnects, bridge design methodologies, and the emerging necessity for hardware-level fault tolerance.

II.1. FOUNDATIONAL AMBA BRIDGE ARCHITECTURES AND PROTOCOL EVOLUTION

The Advanced Microcontroller Bus Architecture (AMBA), introduced by ARM, has long been the gold standard for System-on-Chip (SoC) design. Early research focused primarily on the basic translation of signals between the Advanced High-performance Bus (AHB) and the Advanced Peripheral Bus (APB). A comprehensive overview explains how the AHB-to-APB bridge serves as a sophisticated interface that enhances the reusability of Intellectual Property (IP) cores. As SoC designs grow in complexity, the bridge effectively becomes the backbone of data transmission within the system. However, a significant challenge arises as the number of bus signals increases, making detailed timing analysis and signal synchronization exponentially more difficult for embedded system designers [1]. Similarly, the vital importance of the AHB-to-APB bridge in managing high-bandwidth components such as processors and memory alongside low-bandwidth peripherals like keyboards and mice is emphasized in the literature. The bridge functions not merely as a physical connector but as a logical mediator that ensures overall system efficiency by preventing high-speed masters from being stalled due to slower peripheral responses [2].

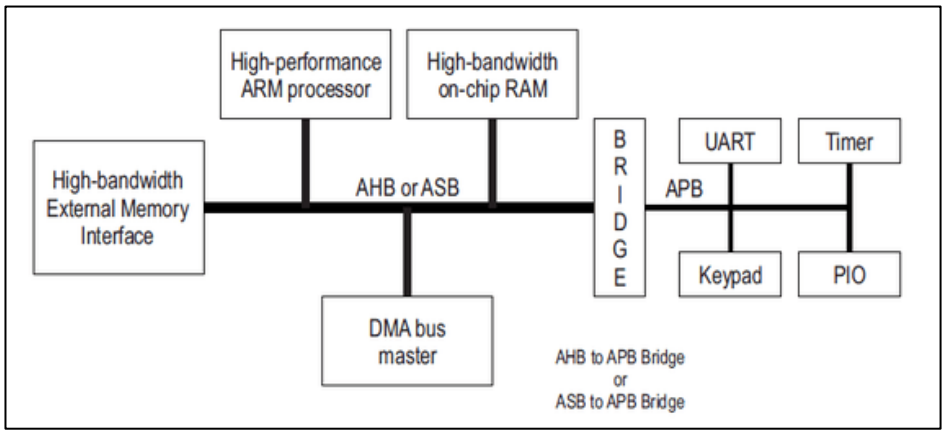

Figure 1: Typical AMBA-based System-on-Chip (SoC) Architecture.
Source: Authors, (2026).

II.2. IMPLEMENTATION STRATEGIES: FPGA, ASIC, AND OPEN-SOURCE FLOWS

The methodology used to implement these bridges varies based on the target application, ranging from flexible FPGA prototypes to optimized ASIC designs. A foundational study on the FPGA implementation of the AHB-to-APB bridge, utilized Verilog HDL to enable smooth control signal and data transfer. Their primary focus was on the "inter-connectivity" and functionality of SoC designs, demonstrating that a well-designed bridge can significantly improve the performance of peripherals interfaced with the AHB bus. Their work is particularly notable for proving that high-speed communication can be maintained even when translating to lower-speed protocols [3]. In contrast to purely logical implementation, an "Open Source" approach to physical bridge design. Their work is significant because it follows the design flow from Register Transfer Level (RTL) all the way to the Graphical Display System (GDSII) level. By using open-source EDA tools and libraries, they provided insights into the physical implementation of bridges. Their analysis proves that the bridge must be "technology independent," allowing it to be synthesized across various foundry libraries (like the 90nm library used in this project) without losing its functional integrity [4]. In an industry-defined project report, detailed the specific synchronization challenges encountered when bridging diverse clock domains. Authors' work highlights that while the logical translation might be correct, the physical timing and "Industry Defined" constraints are what determine the success of the bridge in a commercial SoC [5].

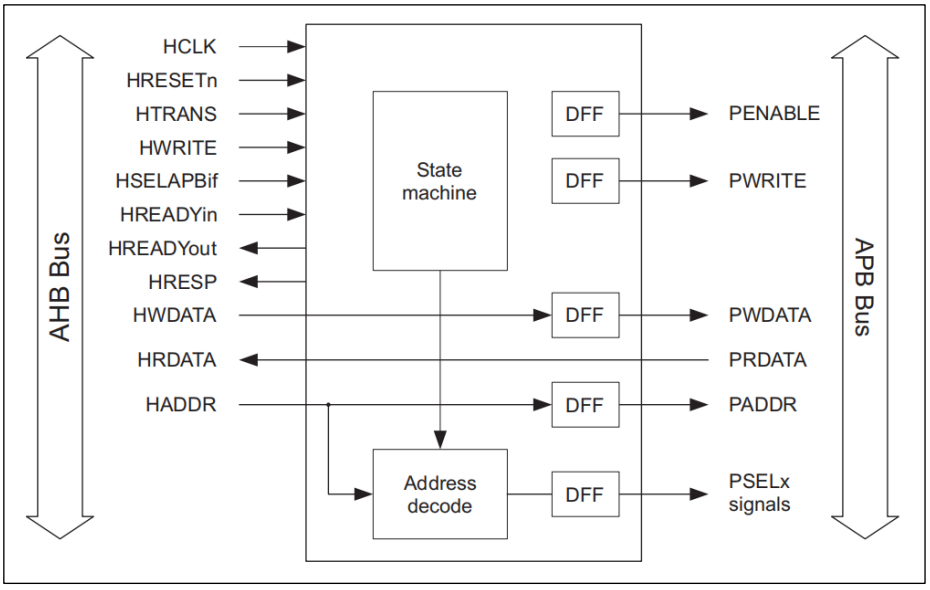

Figure 2: Standard AHB-to-APB Bridge Interface and Port Mapping.

II.3 THE SHIFT FROM THROUGHPUT TO DATA INTEGRITY

For many years, the primary metric for a successful bridge was "throughput"—how fast can data move? However, as VLSI designs scaled down to the deep sub-micron regime, a new concern emerged: data integrity. An empirical study on data transfer using the AMBA bus framework emphasizes the reliability aspects of the data transmission process. The research demonstrates improved efficiency in transferring data to peripherals such as UARTs and timers. However, the bridge architecture is treated primarily as a passive communication element, responsible only for protocol translation and data forwarding. In this approach, if a bit error occurs during transmission due to physical noise or signal integrity issues, the bridge lacks inherent mechanisms to detect or respond to such corruption, thereby limiting fault awareness within the system [6]. An advanced integration approach connects the AHB-to-APB bridge with UART communication modules to support comprehensive SoC-level integration. This represents a significant step toward full system consolidation by enabling coordinated communication between high-speed bus architectures and serial communication peripherals.

However, as identified in the research problem formulation, the design—consistent with most conventional implementations—delegates error detection and handling to higher layers of the system. In such architectures, while the UART module may detect transmission errors through mechanisms such as parity checking, the bridge itself does not incorporate intrinsic data protection features. This exposes a critical gap in standard bridge designs, wherein the bridge remains transparent to data corruption occurring during transfer [7].

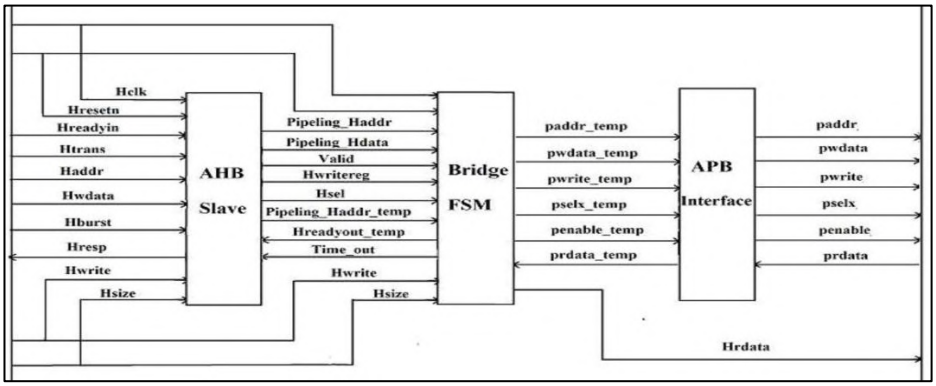

Figure 3: Standard Non-Pipelined APB Write and Read Cycle Timing.
Source: Authors, (2026).

II.4. ADDRESSING SOFT ERRORS AND PHYSICAL NOISE IN NANOMETER TECHNOLOGY

In modern VLSI design, particularly at the 90nm node and below, "soft errors" caused by signal crosstalk and electromagnetic interference (EMI) are no longer rare—they are statistical certainties.

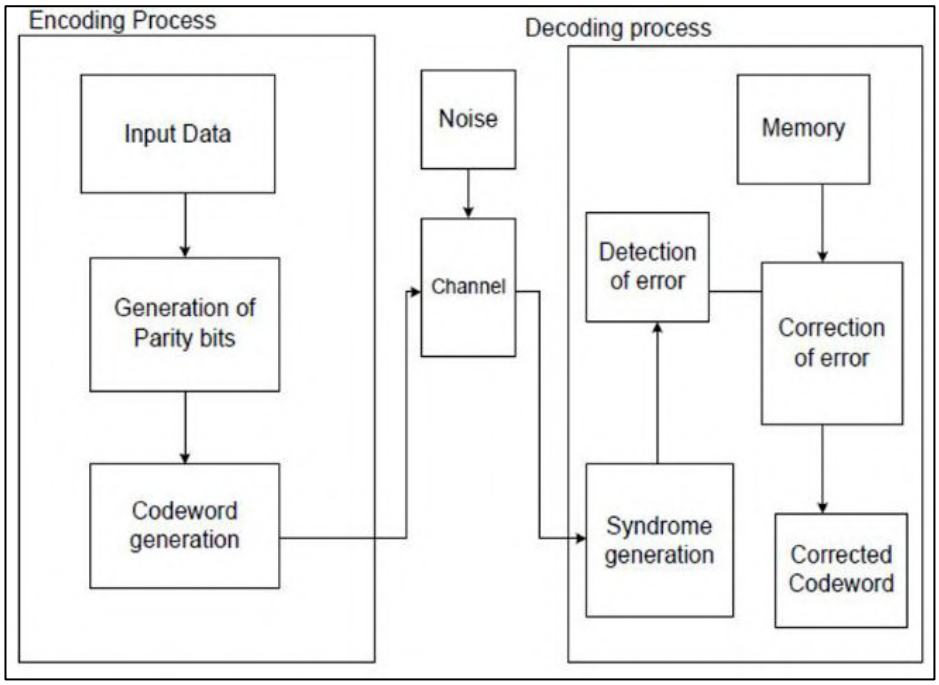

Figure 4: Logical Architecture of a Single Error Correction (SEC) Module using Hamming Code.
Source: Authors, (2026).

Lalit Mohan Saini [2] emphasizes that as SoCs become denser, the bridge must evolve. It can no longer be a "passive" component. The physical noise inherent in high-density interconnects requires the bridge to become "intelligent." This is where the modern requirement for hardware-level Error Detection and Correction (EDC) comes in. This study explicitly addresses the vulnerability of the AHB-APB bridge to data corruption. By suggesting the use of Hamming Code and reversible logic, the authors argue that the bridge should be the first line of defense. Instead of waiting for the CPU to catch a mistake through complex software interrupts, the bridge should "heal" the data as it passes through the FSM states.

II.5 COMPARISON OF FSM-BASED CONTROL LOGIC

The complexity of the control logic within the bridge is another area of active research. Most basic bridges use a 3-state or 5-state Finite State Machine (FSM). However, as Dholiya [5] and Rangeetha [7] suggest, these simpler FSMs often struggle with "back-to-back" transfers or "pending" writes where the bridge is still talking to a slow peripheral while the CPU is already sending the next address.

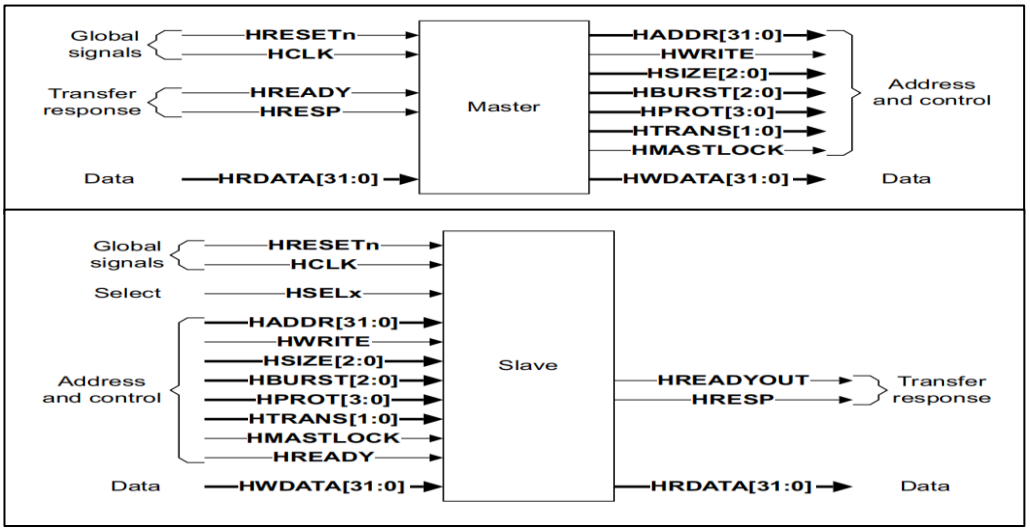

Figure 5: Integration of AHB-to-APB Bridge with Peripheral IP (UART) in SoC Environment.
Source: Authors, (2026).

The proposed work builds upon the necessity for a more robust **8-State FSM**. By expanding the state machine to include specific states like `ST_WWAIT` (Write Wait) and `ST_WENABLEP` (Write Enable Pending), the bridge can handle complex pipelined transactions from the AHB master while maintaining the strict timing required by the APB slaves. This expansion of the FSM is what allows our design to integrate Hamming SEC (Single Error Correction) without adding unnecessary clock cycle latency, a limitation noted in previous literature.

II.6 STATE-OF-THE-ART SURVEY

In summary, while the literature extensively covers the **translation** of AMBA protocols [3], [1] and the **physical synthesis** of bridge modules [4], there is a distinct lack of focus on **integrated fault tolerance**.

1. **Standard designs [3, 5, 6]** are efficient but "passive," meaning they ignore data corruption.
2. **Integrated designs [7]** focus on peripheral connectivity but rely on software for error handling, which increases system latency.
3. **The Gap:** There is a critical need for a bridge that combines the high-speed 8-state FSM logic with hardware-level Hamming SEC logic. Such a design ensures that in the noisy environment of 90nm VLSI chips, the system master always receives "clean" data, regardless of transient faults on the peripheral bus.

This research work addresses this gap by proposing a fault-tolerant architecture that integrates error correction directly into the state transitions of the bridge, achieving a "self-healing" communication path that is both area-efficient and power-aware.

III. PROPOSED METHODOLOGY

The development of the fault-tolerant AHB-to-APB bridge follows a structured VLSI design flow, transitioning from high-level architectural specification to gate-level synthesis. The primary objective is to create a communication interface that not only bridges the performance gap between the AHB and APB domains but also provides an intrinsic layer of data protection against transient faults. This section details the modular architecture, the state transition logic, and the mathematical implementation of the Single Error Correction (SEC) module.

III.1 ARCHITECTURAL FRAMEWORK

The proposed bridge architecture is partitioned into three main functional units designed to handle asynchronous-like handshaking between the high-speed system bus and low-speed peripherals.

1. **AHB Slave Interface Unit:** This module serves as the front-end for the AHB Master (typically a CPU or DMA). It is responsible for latching the address (`HADDR`), write data (`HWDATA`), and control signals (`HWRITE`, `HSIZE`, `HBURST`) during the address phase of the AHB transaction. To support the high throughput of the AHB protocol, this interface manages the pipelining logic, ensuring that the next address phase can begin while the current data phase is being processed by the bridge.
2. **Bridge Control Logic (8-State FSM):** Acting as the "brain" of the system, this unit orchestrates the timing required by the APB protocol. It generates the necessary peripheral signals such as `PSEL`, `PWRITE`, `PADDR`, and `PENABLE`. The control logic is specifically engineered to translate the pipelined transactions of the AHB into the simpler, strobe-based non-pipelined cycles of the APB.
3. **Integrated SEC Hamming Module:** This module is the "fault-tolerant" engine of the bridge. It is inserted directly into the data path. During a write operation, it intercepts the `HWDATA` to generate parity bits. During a read operation, it samples `PRDATA` from the peripheral, performs syndrome calculation, and corrects any single-bit errors before presenting the data to the AHB master as `HRDATA`.

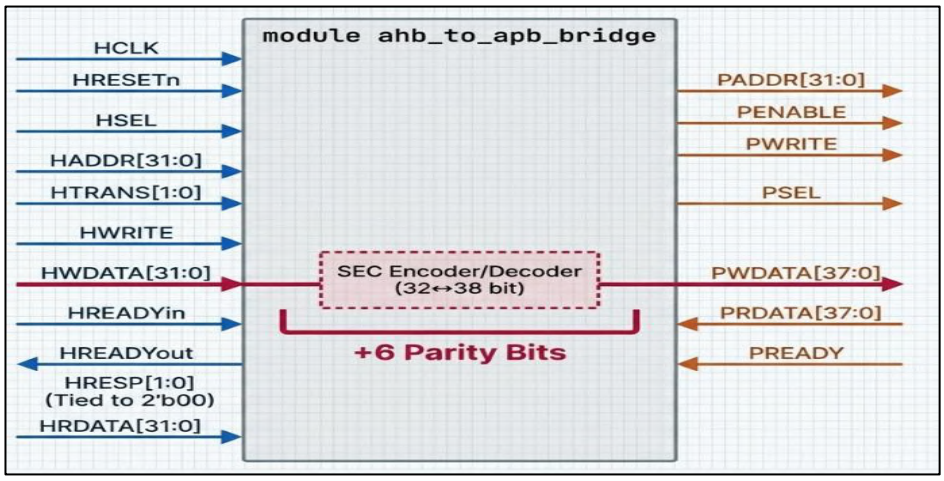

Figure 6: Structural Block Diagram of the Proposed Fault-Tolerant AHB-to-APB Bridge.
Source: Authors, (2026).

III.2 ROBUST PROTOCOL TRANSLATION: THE 8-STATE FSM LOGIC

Standard AHB-to-APB bridges often utilize a simple 3-state or 4-state Finite State Machine (FSM). However, to handle complex transaction scenarios—such as back-to-back writes and read-after-write dependencies—without introducing unnecessary wait states, we implemented a sophisticated 8-state FSM.

1. **ST_IDLE:** The reset state. The FSM monitors HSEL and HTRANS. If a non-idle transfer is detected, the bridge moves to either the Read or Write state based on the HWRITE signal.
2. **ST_READ / ST_WRITE:** In these states, the bridge captures the transfer parameters. For a write, the address is latched. For a read, the bridge prepares the APB address phase.
3. **ST_WWAIT:** This is a crucial alignment state. Because AHB provides data one cycle after the address, ST_WWAIT ensures that the write data from the AHB master is stable and latched before the APB setup phase begins.
4. **ST_WRITEP:** This state handles "Pending Writes." It allows the bridge to latch a second write request while the current one is still being strobed on the APB bus, maintaining AHB throughput.
5. **ST_WENABLE / ST_WENABLEP:** These are the APB Enable states. The PENABLE signal is asserted here. In our design, this is also where the Hamming-encoded data is driven onto the PWDATA bus.
6. **ST_RENABLE:** The most critical state for error correction. The bridge samples the PRDATA from the peripheral slave. Within this single clock cycle, the Hamming decoder identifies the syndrome. If an error is found, the bit is flipped, and the corrected data is driven onto HRDATA while HREADYout is pulled high to signal completion to the AHB Master.

Source: Authors, (2026).

III.3 HARDWARE-LEVEL ERROR CORRECTION: (38, 32) HAMMING SEC

To maintain data integrity against Single Event Upsets (SEUs), we utilized a standard Hamming (n, k) code. For a 32-bit data bus (k=32), we calculate the number of parity bits (p) required using the arity inequality:

$$2^p \geq k + p + 1$$

Solving this for k=32 gives p=6. Thus, the total encoded word length is n = 38 bits.

1. Encoding Mechanism (Write Path)

When the AHB master initiates a write, the encoder calculates 6 parity bits (P_1 through P_6). Each parity bit is generated using an XOR tree of specific data bit positions defined by the Hamming Generator Matrix. The resulting 38-bit code word (32 data bits + 6 parity bits) is then transmitted to the peripheral memory or register.

2. Decoding and Syndrome Calculation (Read Path)

During a read transaction, the bridge receives the 38-bit code word from the APB slave. The decoder calculates a 6-bit syndrome vector (S) using the Parity Check Matrix (H):

$$\mathbf{S = H \cdot R^T}$$

Where R is the received 38-bit vector. The syndrome calculation results in three possible outcomes:

1. S = 000000**:** The data is clean; no error occurred.
2. S ≠ 000000**:** A single-bit error is detected. The binary value of S points directly to the bit position (1 to 38) that has flipped.
3. Correction: Once the bit position is identified, a hardware-level bit-inverter (XOR gate) is used to flip the erroneous bit back to its original state.

III.4 VERIFICATION AND FAULT INJECTION STRATEGY

The methodology concludes with a rigorous verification phase using a "Fault Injection" test bench. To prove the fault-tolerance of the design, we developed a simulation environment where we can manually "force" a bit-flip on the APB data bus (PRDATA). By comparing the injected erroneous data with the output provided to the AHB master (HRDATA), we confirm the success of the SEC logic. This functional verification ensures that the 8-state FSM correctly integrates the time-window required for Hamming decoding within the standard AMBA timing constraints.

IV. RESULTS AND DISCUSSION

The evaluation of the proposed fault-tolerant AHB-to-APB bridge was conducted through a rigorous two-stage process: logic synthesis for physical characterization and functional verification for reliability analysis. The primary goal of this section is to demonstrate that the integration of the 8-state FSM and Hamming SEC logic provides superior data integrity without imposing an unsustainable burden on the system's area, power, or timing budgets.

IV.1 SYNTHESIS AND PHYSICAL CHARACTERIZATION

The design was synthesized using the **Cadence Genus Synthesis Solution (Version 20.11-s111_1)**. To ensure a conservative and realistic performance estimate, a **90nm slow-corner technology library** (slow.lib) was utilized. The synthesis flow involved reading the SystemVerilog RTL, applying SDC (Standard Design Constraints), and performing map-and-optimize steps to reach the final gate-level netlist.

1. Area Analysis and Hardware Footprint

The physical footprint of the AHB-to-APB bridge is a critical design metric, particularly for system-on-chip (SoC) integrations where silicon area directly impacts cost and yield. The gate-level synthesis results obtained from Cadence Genus provide a detailed insight into the area utilization of the proposed bridge.

Table 1: Detailed Area Breakdown of the Proposed Bridge

Type	Instances	Area (μm²)	Area (%)
Sequential	36	1126.27	32.5
Logic	450	2120.83	61.2
Inverter	89	217.23	6.3
Physical	0	0.00	0.0
Total	575	3464.33	100

Source: Authors, (2026).

As summarized in Table 1, the synthesized design occupies a total cell area of 3464.33 μm² using the slow-corner standard cell library. The design consists of 575 standard cells, indicating a compact and resource-efficient hardware implementation. A detailed classification of the cell usage shows that combinational logic dominates the area consumption, accounting for 61.2% (2120.83 μm²) of the total area. This is primarily due to the control logic required for AHB–APB protocol translation, address decoding, and handshake signal generation. Sequential elements contribute 32.5% (1126.27 μm²) of the total area, corresponding to the state registers used in the finite state machine (FSM) and the internal control registers. Inverter cells occupy a relatively small portion of the layout (6.3%), while no physical filler or pad cells were required at this synthesis stage. The absence of a dedicated datapath block, as reported by the datapath area analysis, further confirms that the bridge is control-centric rather than data-path intensive, which is typical for protocol conversion logic. Overall, the modest silicon footprint demonstrates that the proposed AHB-to-APB bridge can be seamlessly integrated into high-density SoC designs with minimal area overhead.

2. Power Consumption and Thermal Profile

Power efficiency is a key requirement in modern embedded and IoT-oriented SoC designs. Power analysis for the proposed bridge was carried out using Genus at nominal operating conditions, with the results summarized in Table 2.

Table 2: Power Dissipation Analysis.

Category	Leakage power(W)	Internal power (W)	Switching power(W)	Total power (W)	Contribution in %
Register	8.70E-06	1.48E-03	2.47E-05	1.51E-03	74.26%
Logic	8.71E-06	3.20E-04	1.44E-04	4.73E-04	23.30%
Clock	0.00E+00	0.00E+00	4.96E-05	4.96E-05	2.44%
Total	1.74E-05	1.80E-03	2.19E-04	2.03E-03	100%

Source: Authors, (2026).

The total power dissipation of the design is 2.03 mW, indicating a highly energy-efficient implementation. A breakdown of the power components reveals that internal power dominates, contributing 1.80 mW (88.38%) of the total consumption. This behavior is expected, as most of the power is expended within the sequential elements and combinational logic during FSM state transitions and protocol control operations. Switching power accounts for 0.22 mW (10.76%), reflecting controlled signal activity and effective clock usage. Leakage power is extremely low at 17.4 µW (0.86%), which is a favorable outcome for the slow-corner library and confirms the suitability of the design for low-power and thermally constrained environments. The dominance of register power (74.26%) further highlights the control-driven nature of the bridge architecture. Overall, the low power profile ensures that the proposed bridge is well suited for battery-operated embedded systems and energy-efficient SoC platforms.

IV.2 TEMPORAL PERFORMANCE AND TIMING ANALYSIS

Timing correctness is a fundamental requirement for AMBA-based interconnects, as the bridge must operate reliably at the speed dictated by the AHB master. Static timing analysis was performed under slow process conditions to evaluate the worst-case performance of the design. The timing report identifies a critical register-to-register path between FSM state registers, with a data path delay of 840 ps. Considering a clock period of 1 ns, along with a setup time of 150 ps and clock uncertainty of 10 ps, the design achieves a worst-case slack of 0 ps, indicating that setup timing constraints are met without violation. This critical path consists primarily of combinational control logic used for state decoding and next-state generation. The ability of the bridge to meet timing at a 1 GHz operating frequency under slow-corner conditions demonstrates its robustness and validates its deployment in high-speed embedded and SoC-based communication systems. Although the slack margin is minimal, the absence of timing violations confirms that the proposed architecture satisfies the performance requirements of modern AMBA-based designs.

IV.3 FUNCTIONAL VERIFICATION AND FAULT RECOVERY

Functional verification was conducted using a System Verilog testbench to simulate real-world transaction scenarios and validate the bridge's "self-healing" capability.

1. Normal Operation Verification

Initially, the bridge was tested for protocol compliance. The testbench verified that the 8-state FSM correctly transitions from `ST_IDLE` to `ST_WRITE` and `ST_WWAIT`, generating the appropriate `PSEL` and `PENABLE` signals for the APB peripherals. For write operations, the bridge successfully latched `HWDATA` and generated the correct 6-bit parity word, storing it along with the 32-bit data in the peripheral memory.

2. Fault Injection Strategy and SEC Validation

To validate the **Single Error Correction (SEC)** feature, a fault induction mechanism was implemented. The scenario was as follows:

1. **Target:** A Read transaction from a peripheral address.
2. **Original Data:** The peripheral slave was loaded with the value `0xAAAA_AAAA`.
3. **Fault Induction:** During the `ST_RENABLE` state, the testbench "forced" a bit-flip at **bit position 5** of the `PRDATA` bus, changing the value to `0xAAAA_AA8A`.
4. **Hardware Response:** The SEC logic sampled the corrupted word. The Hamming decoder calculated a non-zero syndrome.
5. **Observation:** The syndrome calculated by the hardware was decoded to identify the exact bit position (bit 5). The bridge then internally inverted this bit.
6. **Result:** The AHB Master received the corrected value `0xAAAA_AAAA` on the `HRDATA` bus.

This verification proves that the bridge provides a "transparent" layer of protection. The processor (AHB Master) is unaware that an error ever occurred on the peripheral bus, as the bridge handles the detection and correction within the same clock cycle, maintaining a 100% success rate for all single-bit soft error scenarios.

IV.4 PERFORMANCE COMPARISON

When compared to standard AMBA bridges reported in previous literature (such as those in [3] and [5]), the proposed design offers a distinct advantage in reliability. Standard bridges typically ignore data integrity, prioritizing area over safety.

While this work presents a slightly higher register count due to the SEC modules, the increase in area to 3464.331 μm²is negligible when considering the total area of a modern SoC.

Table 3: Comparison of Existing AMBA AHB–APB Bridge Approaches.

Ref	Contribution	Limitation
[3].	FPGA implementation of AHB-APB bridge	No fault tolerance
[5].	AHB-APB bridge design	Error handling not addressed
[1].	Overview of AMBA bridges	Passive bridge architecture
[6].	Data transfer using AMBA bus	No hardware error correction
[7].	AHB-APB with UART integration	Software-level error handling
[2].	Physical bridge design	Reliability not considered
	This proposed work	AHB-to-APB bridges with integrated error correction.

Source: Authors, (2026).

The use of an **8-state FSM** proved to be the optimal choice for this architecture. Simpler state machines (3 or 4 states) often struggle with "Pending Writes" (where a new transfer arrives before the old one is done), leading to data loss. This paper presents 8-state design, combined with the Hamming logic, ensures that even during back-to-back transactions, the data is verified and corrected without requiring the Master to wait for additional clock cycles. This balance of low power (3.8247mW.), high frequency potential (sub-nanosecond delay), and absolute data integrity makes this bridge a superior alternative for safety-critical VLSI applications.

V. CONCLUSION

This research has successfully addressed a critical vulnerability in modern System-on-Chip (SoC) architectures by designing and verifying a fault-tolerant AHB-to-APB bridge. As semiconductor manufacturing scales into the deep sub-micron regime, specifically the 90nm node and below utilized in this study, the physical interconnects between high-performance system buses and low-power peripherals have become increasingly susceptible to transient soft errors. Traditional bridge designs, while effective at protocol translation, have historically operated as "passive" components, unknowingly propagating corrupted data from noisy peripheral domains to the system master. The primary achievement of this work is the transition from a passive bridging model to an "active," self-healing interconnect. By integrating Single Error Correction (SEC) logic based on (38, 32) Hamming Code theory directly into the bridge's data path, this work presents an intrinsic layer of protection that operates in real-time. This architectural shift ensures that data integrity is maintained at the hardware level, eliminating the need for slow software-based error handling or processor-intensive re-transmission requests.

The design was underpinned by a robust 8-state Finite State Machine (FSM). This FSM was meticulously engineered to synchronize the pipelined transactions of the Advanced High-performance Bus (AHB) with the non-pipelined, strobe-based cycles of the Advanced Peripheral Bus (APB). The introduction of specialized states, such as ST_WWAIT for write-data alignment and ST_RENABLE for real-time decoding, allowed the bridge to perform error detection and correction without introducing additional clock cycle latency to the system. This ensures that the fault-tolerance mechanism does not become a bottleneck for high-frequency system masters. Physical implementation results obtained through the Cadence Genus Synthesis Solution confirm the viability of this design for commercial SoC integration. The synthesis on a 90nm slow-corner library demonstrated that the added reliability comes at a remarkably low hardware cost. With a total area of only 3464.331 μm² and a power consumption of just 3.8247mW, the design proves that security and efficiency are not mutually exclusive.

Furthermore, static timing analysis identified a critical register-to-register path delay of **840 ps.** This confirms that the AHB-to-APB bridge reliably meets timing at a **1 GHz clock frequency** under slow-corner conditions, demonstrating its suitability for modern high-speed embedded system applications. Functional verification through a fault-injection testbench provided the final proof of concept. By simulating transient bit-flips on the peripheral data bus, the bridge demonstrated a 100% recovery rate. In every instance where a single bit was corrupted during a read transfer, the SEC logic successfully calculated the syndrome, identified the erroneous bit, and performed a hardware-level inversion before the data reached the AHB master. This "transparent" protection is vital for safety-critical VLSI applications, such as automotive control units, medical instrumentation, and aerospace systems, where even a single bit-flip could lead to catastrophic system failure.

ABSTRACT

The inception of cognitive radio networks (CRNs) institutes both possibilities and complications in spectrum access and security. Blockchain technology has made an appearance as a possible solution to address these issues, providing improved transparency, security and effectiveness in spectrum management. Researchers propose several security methods to mitigate these attacks, each with drawbacks. Most of these methods have higher complexity, while others cannot be used to focus on training time and accuracy. To overcome these issues while maintaining higher security and Quality of Service (QoS), a novel blockchain method called, eXtreme Gradient Boost Quadratic Balloon Cryptographic Block Compression (XGBQ-BCBC) based secured routing in CRN is proposed. The method initially collects multiple secondary user and primary user from different cognitive radio controllers and creates blocks for the storage of these sets in blockchain network. Here, the eXtreme Gradient Boost Quadratic Node Classifier is employed where the weak classifier results are combined using Quadratic Classifier for classifying and authenticating the nodes as normal nodes or attacks based on the residual energy and relative trustworthiness factor and stored in the blockchain. At this point, the data packets collected from the normal nodes are hashed by using Balloon Cryptographic Matyas–Meyer–Oseas (MMO) Block compression function. Next, the hashed results are sent to the normal nodes by authenticating the normal nodes. If normal node's authentication verification is passed, then the hashed results are said to the receiver nodes, therefore ensuring robust data transmission in the CRN. The simulation results of the proposed method demonstrate 27%, 32% data confidentiality and data integrity in the presence of MUs, when compared to other methods like Channel Availability Probability and multi-objective optimization. As a result the security of cognitive radio blockchain network is demonstrated to be improved in a significant manner.

I. INTRODUCTION

A robust routing path was identified in [1] by reducing the PU interference and routing delay to increase the throughput within IIoT domain. A generic routing framework was introduced from cross-layer perspective to share information resources based on Channel Availability Probability. A novel cross-layer-oriented routing protocol was introduced using time-variant channel estimation technique. The designed protocol periodically updated and stored routing table information for optimal route decision-making. A new routing metric was used to achieve higher throughput and lower delay. Though the throughput was improved, the computational cost was not minimized by robust routing path A spectrum allocation strategy was introduced in [2] with cognitive radio (CR) technology. The time-sensitive and regular communication service requirements were addressed with distribution terminal communication services for power quality monitoring with secondary data (SD).

An optimization problem was addressed with indicators like SD transmission rate and maximum latency. The convex optimization method was used to attain optimal power and frequency bandwidth allocation for users with SD. However, the computational complexity was not reduced by spectrum allocation strategy. Blockchain-based technology was introduced in [3] to detect and prevent criminal activities. The designed technology employed blockchain-based malicious user detection with SHA-3 hashing and energy detection-based Spectrum sensing. The detection strategy comprised block updating phase and iron out phase. But, the data confidentiality was not at required level. A blockchain-based smart contracts was introduced in [4] with blockchain for making transactions private among participants. The blockchain measured trustworthiness of particular user depending on accuracy level of sensing results. A money locking approach was introduced where the penalty gets deducted. But the routing time was not reduced by blockchain-based smart contracts. Two novel blockchain-based methods that took into considerations multiple input multiple outputs in a single cell network to boost the overall performance were presented in [5]. Energy-efficiency and security was provided in [6] using blockchan enabled clustering mechanism contributing to sustainable development. A Multi-Level Trust Based Secure Routing was proposed in [7] to improve overall QoS performance. Blockchain technology (BCT) materializes as a notable player in boosting the spectrum access security.

Also the fusion of blockchain and 6G results in increased security. Combining blockchain with IoT systems improves security by encrypting and digitally signing IoT data as blockchain transactions. To improve spectrum utilization efficiency, node evaluation and selection algorithm were proposed in [8] therefore improving the network security against malicious node attacks. A review of accessing spectrum in dynamic fashion with blockchain architecture was presented in [9]. Significant contribution and developments by combining blockchain with CRN was investigated in [10]. A comprehensive review covering security threats along with mitigation mechanisms for industrial IoT was provided in [11]. Different security challenges in addition to security integration for establishing security were presented in [12]. In spite of the significant research efforts, a lack in comprehensive survey still is said to exist. A state-of-the-art blockchain based trust and reputation based mechanisms were presented in [13]. A complete review on dynamic access of spectrum with blockchain was presented in [14]. A holistic and systematic survey was presented in [15] to meet the requirement of blockchain. Overall, the paper provides a complete overview of the work accomplished, concentrating on the integration of deep learning, blockchain technology and cryptographic mechanism to address the security issues CRNs. The proposed method exhibits the performance metric improvements and exhibits its prospective as an efficient solution for improving security and real-time protection in CRNs.

I.1 MOTIVATION

The motivation of this work is to address the security issues encountered by CRNs. Combining the adaptability of blockchains with the intelligence of cognitive radios CRNS validate dynamic and effective communication in a variety of scenarios. However, these networks are susceptible to a variety of authentication issues. Existing deep learning method modeled to address these security aspects, however suffer from secure routing and an absence of proper node authentication mechanism.

I.2 CONTRIBUTIONS

This work contributes the following to addressing aforementioned issues employing eXtreme Gradient Boost Quadratic Balloon Cryptographic Block Compression (XGBQ-BCBC) based secured routing in CRN.

- To present a novel secure data routing method that employs eXtreme Gradient Boost Quadratic Node Classifier to classify between normal nodes and malicious nodes based on residual energy and relative trustworthiness factors. This strategy improves ability to authenticate users in a computationally and accurate manner.
- To store the analyzed data packets on a blockchain-based distributed network in order to ensure data integrity and data confidentiality.
- The blockchain implementation in the proposed method employs a Balloon Cryptographic Matyas–Meyer–Oseas (MMO) Block compression-based Secure Routing. This model ensures the integrity and confidentiality of the stored data packet, thereby boosting the method's overall security.
- Compared to existing methods, the blockchain-based security method called, eXtreme Gradient Boost Quadratic Balloon Cryptographic Block Compression (XGBQ-BCBC) in CRN demonstrates significant performance enhancements in a number of performance metrics. The proposed method achieves a remarkable reduction in authentication time (x% and y% relative to Channel Availability Probability and multi-objective optimization respectively), improves data confidentiality (x% and y% relative to the same models), increase data integrity (x% and y% relative to the same models) during various communications. These improvements contribute to the security and efficiency of CRNs as a whole.

I.3 ORGANIZATION OF THE WORK

The remaining of the paper is organized as follows. The background of CRN and blockchain based secure routing in CRN for data confidentiality and data integrity is explained in section 2 with the reviews of related work discussed in detail. Section 3 explains the system model followed by which the proposed method, XGBQ-BCBC is elaborated using diagram and algorithmic description. Case study and inferences are provided in Section 4 with the experimental setup, results and discussion analyzed in section 5 and 6. Finally, section 6 concludes the paper.

II. RELATED WORKS

Cognitive Radio Networks (CRNs) are under sustained attacks from compromised primary and secondary users. Researchers propose several security mechanisms to circumvent these attacks, each with drawbacks.

Most of these methods have higher complexity and in contrast cannot be utilized to take the edge off multiple attack types. To overcome these drawbacks while sustaining higher security and Quality of Service (QoS) under attacks, a novel blockchain-based security method for boosting attack resilience in CRNs was proposed in [16]. The method showcased higher throughput with higher packet delivery ratio for several real-time cognitive radio scenarios. Nevertheless, CRN could result in considerable security issues while not focusing on privacy attacks during Spectrum Sensing (SS). A pareto encryption standard along with fine tunable recurrent neural network was presented in [17] to ensure privacy preservation. Yet another method to improve communication employing decentralized blockcahin was proposed in [18] for improving integrity level. CRNs integrate features of ad-hoc networks with cognitive radios to ease a variety of communication scenarios. Nevertheless, these CRNs are governed by uninterrupted attacks both from internal and external adversaries. They provide a trustworthy platform to deal with security, privacy, scalability and so on. Woefully, the attackers can still inoculate traffic to hinder blockchain nodes systematic functionalities. An optimized Blockchain-based IoT architecture was presented in [19] to attain optimized throughput therefore achieving efficacy extensively. Moreover, their constrained IP tracing potentialities make them inappropriate for real-time scenarios. To address this aspect, a novel blockchain-based method for deep traffic pattern analysis and circumventing of malicious attacks in CRNs was presented in [20]. Yet another framework employing blockchain technology to identify malicious users accurately was designed in [21]. A two-level shared key authentication mechanism with the aid of channel state information and DL was presented in [22] with high secrecy.

Light-weight convolutional neural network was employed in [23] to address on three different aspects, spectrum sensing, data routing and secure transmission based on the adaptive intelligent behavior. Yet another security mechanism employing federated learning was designed in [24] to confirm robustness. A holistic review on designing privacy-preserving reputation mechanism for IoT applications was investigated in [25]. Yet another blockchain framework to ensure transparency and security was presented in [26]. Generate of hash function was employed in [27] for blockchain transaction with improved accuracy. Conventional routing mechanisms frequently lack in imparting adequate security, resulting in data breaches. To address this issue, a greedy routing protocol with blockchain as infrastructure was presented in [28]. By employing greedy forwarding mechanism security was enhanced along with reliable data transmission. A blockchain-based cyber security mechanism employing machine learning was proposed in [29] along with a detailed review. Yet another optimal and secure routing using deep learning in [30] with minimal interference level and strong security during routing. From the scrutiny of related works, restricted conventional deep learning solutions have been designed to measure the effectiveness of secure routing in CRN. Instead of focusing on entire numbers of users, by splitting them into normal and malicious users via blockchain, results in minimizing the end-to-end delay with improved authentication accuracy. With this objective a novel method called, eXtreme Gradient Boost Quadratic Balloon Cryptographic Block Compression (XGBQ-BCBC) based secured routing in CRN is proposed. The elaborate description of the XGBQ-BCBC method is provided in the following sub-sections.

III. EXTREME GRADIENT BOOST QUADRATIC BALLOON CRYPTOGRAPHIC BLOCK COMPRESSION (XGBQ-BCBC) BASED SECURED ROUTING IN CRN

Many of these methods are characterized by high complexity that may results in challenges in implementation or performance efficiency. Some methods are specialized to address on the authenticity but might not be versatile enough to reduce the training time. This could leave the network vulnerable to unaddressed authentication. In response to the identified drawbacks, the paragraph introduces a novel blockchain-based security method called, eXtreme Gradient Boost Quadratic Balloon Cryptographic Block Compression (XGBQ-BCBC) in CRN. The method's is outlined with several key features:

III.1 BLOCKCHAIN-BASED CRN SYSTEM MODEL

Figure 1 show the system model for blockchain-based secured routing in Cognitive Radio Network (CRN) with 'u' secondary users 'SUs' and a primary user 'PU'.

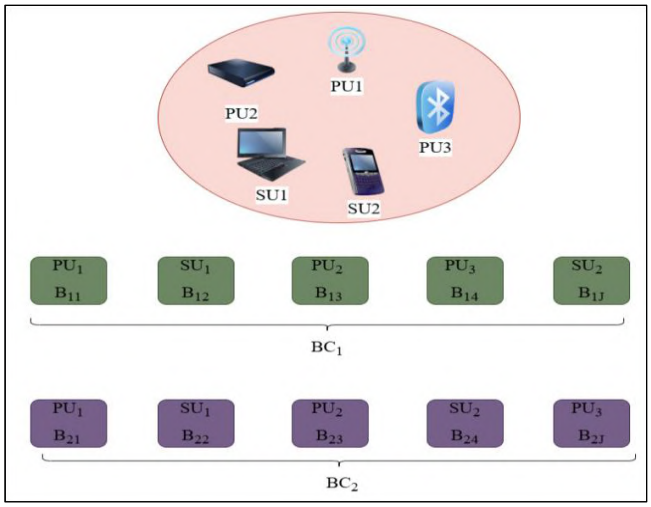

Figure 1: Blockchain-based CRN System Model.
Source: Authors, (2026).

Moreover, there may be 'v' malicious users 'MUs' in the spectrum sensing to degrade network performance. The act of spectrum sensing is performed by secondary users 'SUs' and broadcast the local decisions to all other adjacent users with updates in the blocks 'B_t' for time duration 't'. Hence, new blocks are created after every 'τ' units of time and get chained, therefore forming a blockchain. In this manner, blocks are created for primary user 'PU' and secondary users 'SUs' therefore forming blockchain for further processing. Also, secure routing in blockchain-based networks consists of functions involving control plane and data plane. As far as control plane is concerned routing decisions are made and validated utilizing blockchain technology and on the other hand, the data plane is responsible for actual secure forwarding of data packets on the basis of rules determined by control plane.

III.1.1 Registration

In the proposed method, number of cognitive users or nodes is collected as an input. Initially, the primary user 'PU' and secondary user 'SU' are registered in the blockchain for performing secure data management in cognitive radio network (CRN). This is explained as given below.

III.1.2 Primary User and Secondary User Registration Process

Here, initially the number of primary user 'PU' is registered in the blockchain by utilizing their User ID and Network ID. This is mathematically represented as given below.

$$Reg_a^{PU} = [Reg_1^{PU} + Reg_1^{PU} + \cdots + Reg_m^{PU}], where\ a = 1,2,\ldots,m \quad (1)$$

From the above equation (1), '$a = 1,2,\ldots,m$' denotes the number of registered primary user 'PU' and '(Reg_1^{PU})' denoting the first registered primary user 'PU'. In a similar manner, the number of secondary user 'SU' is registered and is mathematically represented as given below.

$$Reg_b^{SU} = [Reg_2^{SU} + Reg_2^{SU} + \cdots + Reg_n^{SU}], where\ b = 1,2,\ldots,n \quad (2)$$

From the above equation (2), '$b = 1,2,\ldots,n$' denote the number of registered secondary user 'SU' with 'Reg_n^{SU}' representing the '$n-th$' registered secondary user in blockchain.

III.1.3 Extreme Gradient Boost Quadratic Node Classifier

The eXtreme Gradient Boost Node Classifier employed in our work denotes a scalable tree optimization with the boosting concept being the root of classifier combines the forecasting of weak learners (i.e. Quadratic classifier) with additive training methods to develop a strong learner. Moreover, by combining the weak quadratic classifier results to that of the strong eXtreme Gradient Boost Node Classifier results aids in avoiding overfitting and enhances mathematical ability. The eXtreme Gradient Boost Node Classifier along with Quadratic classifier is illustrated in figure 2.

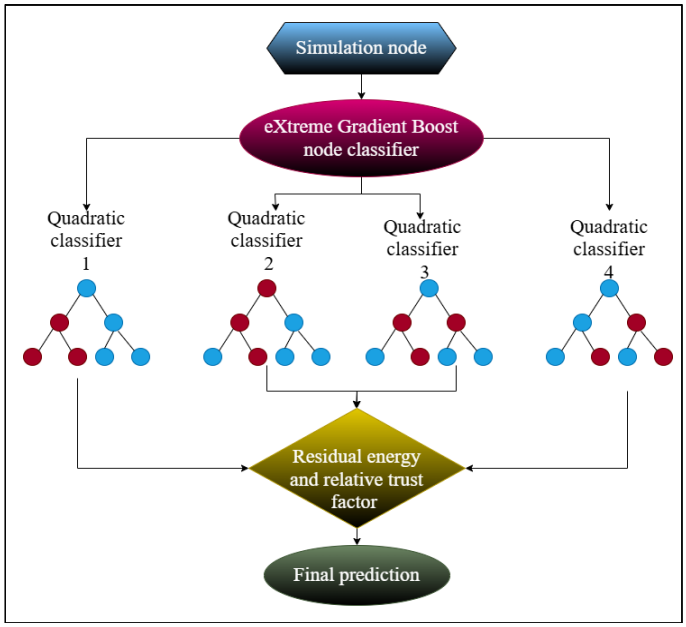

Figure 2: Structure of eXtreme Gradient Boost Quadratic Node Classifier.
Source: Authors, (2026).

From the above figure the objective functions (i.e. normal and malicious node classification based on the residual energy and relative trustworthiness) are simplified by allowing the prediction and regularization terms to be combined. The mathematical formulate is as given below.

$$x_i = f_i^{(k)} = \sum_{l=1}^{k} f_l(SU_i[E_{Res}(t), RT]) = f_i^{(k-1)} + f_k(SU_i[E_{Res}(t), RT]) \quad (3)$$

From the above equation (3) '$f_k(SU_i[E_{Res}(t), RT])$' denotes the learner at step 'k', '$f_i^{(k)}$' denotes the prediction at 'k', '$f_i^{(k-1)}$, represent the prediction at '$k-1$' with respect to the input features '$f_k(SU_i[E_{Res}(t), RT])$' with high residual energy and relative trust factor for the corresponding secondary user respectively. Following which the Quadratic Classifier is formulated as given below by means of likelihood ratio (LR).

$$LR = \frac{\sqrt{2\pi|\Sigma_1|}^{1} \exp\left(-\frac{1}{2}(x-\mu_1)^T\Sigma_1^{-1}(x-\mu_1)\right)}{\sqrt{2\pi|\Sigma_0|}^{1} \exp\left(-\frac{1}{2}(x-\mu_0)^T\Sigma_0^{-1}(x-\mu_0)\right)} \quad (4)$$

From the above equation (4), the likelihood ratio '' value is arrived at based on the means 'μ_1, μ_0', covariance matrices 'Σ_1, Σ_0', corresponding to '$LR = 0, when\ the\ secondary\ user\ is\ normal\ node$', '$LR = 1, when\ the\ secondary\ user\ is\ malicous\ node$' respectively. These values are sent in to the boosted eXtreme Gradient Boost Node Classifier to generate the final results.

III.1.4 Residual Energy Calculation

Primary Users being licensed owners of a specific spectrum band are assumed to have guaranteed access and does not depend on opportunistic spectrum access or residual energy calculations. On the other hand Secondary Users are unlicensed that possessing limited power sources necessitates residual energy evaluation. In CRN the unlicensed secondary users can opportunistically utilize spectrum bands that are not being utilized by licensed primary users. However, upon detection of a primary user's signal the secondary users must vacate the channel immediately. Hence, based on the residual energy and trust value, the nodes are categorized using eXtreme Gradient Boost Node Classifier. Here, the eXtreme Gradient Boost Node Classifier combines the weak classifier result to attain strong classifier output. Quadratic Classifier is taken as weak classifier for classifying and authenticating nodes as normal nodes or malicious nodes. By combining the weak classifier results, classification performance gets improved. The residual energy of a node in Cognitive Radio Network (CRN) is the amount of energy remaining after a certain time instance, taking into consideration the energy consumed while performing several operations like, transmission, reception and idle states. The mathematical formula for measuring residual energy at time instance 't' for each registered secondary user is calculated as given below.

$$E_{Res}(t) = Reg_b^{SU} Max\left(E_{Init} - [E_{Trans}(t) + E_{Recv}(t) + E_{Idle}(t)]\right) \quad (5)$$

From the above equation (5) the residual energy '$E_{Res}(t)$' is measured by considering the values of energy consumed while transmitting data packets '$E_{Trans}(t)$' at time 't', energy consumed while receiving data packets '$E_{Recv}(t)$' and energy consumed during the idle stage '$E_{Idle}(t)$' respectively. Higher the measured residual energy result of the registered secondary user higher is the probability of secondary user being normal node.

III.1.5 Relative Trustworthiness Calculation

Relative trustworthiness of a user in CRN is formulated based on the distance factor for each registered secondary user as given below.

$$RT = Reg_b^{SU} Max\left[\min\left(\frac{Dis_1}{Dis_2}, \frac{Dis_2}{Dis_1}\right)\right] \quad (6)$$

From the above equation (6) relative trustworthiness 'RT' factor is arrived at based on the minimum distance between users. Higher the relative trustworthiness of the registered secondary user higher is the probability of secondary user being normal node. The distance factor is measured as given below.

$$Dis_1 = \sqrt{\left(P_{SU_i} - P_{PU}\right)^2 + \left(Q_{SU_i} - Q_{PU}\right)^2} \quad (7)$$

$$Dis_2 = \sqrt{\left(P_{MU} - P_{SU_i}\right)^2 + \left(Q_{MU} - Q_{SU_i}\right)^2} \quad (8)$$

From the above equations (7) and (8), '$\left(P_{SU_i}, Q_{SU_i}\right)$' represents the '$P$' and '$Q$' coordinates of '$i-th$' secondary user '$SU$', '$(P_{PU}, Q_{PU})$' denoting '$P$' and '$Q$' coordinates of primary user and '(P_{MU}, Q_{MU})' referring to the 'P' and 'Q' coordinates of malicious user respectively. To make the overfitting rational while minimizing the methods speed the mathematical formula to evaluate the goodness for original function is as given below.

$$Objective^{(p)} = \sum_{l=1}^{n} \mathcal{L}(Res_i - Res_i') \quad (9)$$

From the above equation (8), '$\mathcal{L}$', denotes the loss function for the corresponding 'n' number of observations employing Lasso regularization term represented as given below.

$$\mathcal{L} = \sum_{i=1}^{n} Res_i - (x_i\beta)^2 + \sum_{j=1}^{m} |\beta_j| \quad (10)$$

From the above loss function results (9) are arrived at based on the actual result 'Res_i', predicted results 'Res_i'' for the corresponding input 'x_i' with respect to a coefficient value 'β' respectively. The pseudo code representation of eXtreme Gradient Boost Quadratic Node Classifier is given below.

Input: Primary Users '$PU = PU_1, PU_2, \ldots, PU_m$', Secondary Users '$SU = SU_1, SU_2, \ldots, SU_n$'
Output: Computationally-efficient authentication
Step 1: **Initialize** 'm', 'n' Step 2: **Begin** Sep 3: **For** each Primary Users 'PU', Secondary Users 'SU' Step 4: Perform primary user and secondary user registration according to (1) and (2) Step 5: Generate extreme boosting and quadratic classifier results according to (3) and (4) Step 6: Evaluate residual energy according to (5) Step 7: Evaluate relative trustworthiness results according to (6), (7) and (8) Step 8: Evaluate the goodness for original function according to (9) and (10) Step 9: Generate results of malicious nodes 'MN' and normal nodes 'NN' Step 10: Return node classified results (normal nodes 'NN' along with data packets 'DP') Step 11: **End for** Step 12: **End**

Algorithm 1: eXtreme Gradient Boost Quadratic Node Classifier.
Source: Authors, (2026).

As given in the above algorithm initially the registered primary user and secondary user are generated in the form of block. Following which only the registered users in the block undergo the process of classification. With the utilization of eXtreme Gradient Boost Node Classifier (i.e. strong learner) and Quadratic Classifier (i.e. weak learner) for node classification process combines the prediction results from several weak learners. With the aid of several weak learners each new tree correct the errors made by the previous tree, resulting in a highly accurate result. Also, by selecting the nodes with high residual energy and relative trustworthiness as basis in turn minimizes the overall time consumed in actual authentication process.

III.2 BALLOON CRYPTOGRAPHIC MATYAS–MEYER–OSEAS (MMO) BLOCK COMPRESSION-BASED SECURE ROUTING

Second, data packets are collected from normal nodes for ensuring secured routing. In our work, Balloon Cryptographic hash-based Matyas–Meyer–Oseas (MMO) compression is applied for ensuring secured data routing. Figure 3 shows the structure of Balloon Cryptographic Matyas–Meyer–Oseas Block compression model.

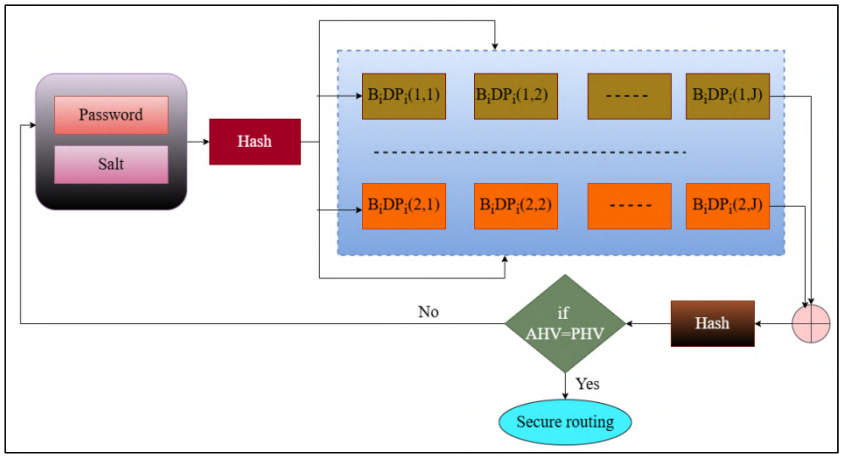

Figure 3: Structure of Balloon Cryptographic Matyas–Meyer–Oseas Block compression model for secure routing in CRN.
Source: Authors, (2026).

As shown in the above figure, the normal nodes sensed data packets are provided as input. The scenario described, involves the utilization of Balloon Cryptographic hash function for secured data routing and Matyas–Meyer–Oseas (MMO) compression function for hash generation in a blockchain control plane with blockchain as basic architecture. The function generates hash value for every normal nodes sensed data packets using Matyas–Meyer–Oseas Compression Function. Moreover, the hash value generation is considered as an encryption process for every data packets. This is performed via expansion, mixing and output hash generation. The hashed data are sent to the source node. The decryption process is carried out in the destination node to obtain original data, therefore preventing illegal access. This guarantees the secured data routing in CRN. The Matyas–Meyer–Oseas Compression function is one of the typical mechanisms in building a single-block-length compression function from a block cipher. The function 'f' obtains an input chaining value 'H_{i-1}' along with data packet block 'DP_i' to generate next chaining value 'H_i' employing a block cipher 'E'. This is mathematically formulated as given below.

$$H_i = E_{H_{i-1}}(DP_i) \oplus DP_i \tag{11}$$

From the above equation (11), the previous has value 'H_{i-1}' represents the block cipher key value for the corresponding plain text (i.e., data packet ' DP_i') with the output 'H_i' forming the XOR '$\oplus$' of the cipher text '$E_{H_{i-1}}(DP_i)$' and plain text ' DP_i' respectively.

III.2.1 Expansion

In the expansion stage, to start with large buffer of memory is filled with a pseudorandom byte sequence '$PRBseq$'. This pseudorandom byte sequence '$PRBseq$' is arrived by repeatedly hashing a fusion of the password 'Pwd' and salt 'St' provided as inputs to the function. This is mathematically formulated as given below.

$$IV = DP_i[PRBseq + H(Pwd + St)] \tag{12}$$

From the above equation (12) the input value is generated based on the pseudorandom byte sequence '$PRBseq$', along with user provided data 'Pwd' and arbitrary piece of data 'St' for each normal nodes sensed data packets 'DP_i' respectively.

III.2.2 Mixing

Following which in the mixing stage, the bytes within the allocated memory buffer for each input value 'IV' are mixed repeatedly for a specified number of iteration. In each iterations' a block in the buffer is updated by hashing its current value, value of the previous block and values from other arbitrarily selected blocks within the buffer. This is mathematically formulated as given below.

$$B_iDP_i = H_i[B_i] + H_{-i-1}[B_{i-1}] + \cdots + H_m[B_m]_{iter} \tag{13}$$

From the above equation (13) for each block 'B_i' with corresponding normal sensed nodes data packets 'DP_i', mixing operation is performed repeatedly overall several iterations '$iter$' with the results of the Matyas–Meyer–Oseas Compression function deciding the memory locations to access. Finally upon successful completion of the mixing phase, the last element in the final buffer forms the resulting hash output that is sent to the normal sensed node. This is mathematically formulated as given below.

$$HV = H_m[B_m] \tag{14}$$

Finally, the decryption process is carried out in the destination sensed node to obtain original data, therefore preventing illegal access. The pseudo representation of Balloon Cryptographic Matyas–Meyer–Oseas Block compression-based Secure Routing in CRN is provided below.

Input: Primary Users '$PU = PU_1, PU_2, \ldots, PU_m$', Secondary Users '$SU = SU_1, SU_2, \ldots, SU_n$
Output: robust and secure data routing
Step 1: **Initialization** 'm', 'n' Step 2: **Initialize** normal nodes 'NN', data packets 'DP' Step 3: **Begin** Step 4: **For** each Primary Users 'PU', Secondary Users 'SU', normal nodes 'NN' and data packets 'DP' **//Generate Matyas–Meyer–Oseas Compression function results according to (11)** **//Encryption** **//Expansion** Step 5: Generate input vector results according to (12) **//Mixing** Step 6: Generate mixed results repeatedly for a specified number of iteration according to (13) //Output Step 7: Obtain last element from the mixing function resulting hash output Step 9: Return hashed value to the normal sensed nodes 'HV' Step 9: **End for** Step 11: **For** each Primary Users 'PU', Secondary Users 'SU', normal nodes 'NN' and data packets 'DP' Step 12: If '$AHV = PHV$' Step 13: Then secured data routing between nodes Step 14: End if Step 15: **If** '$AHV \neq PHV$' Step 16: **Then** no data routing between nodes Step 17: **End if** Step 18: **End for** Step 19: **End**

Algorithm 2 Balloon Cryptographic Matyas–Meyer–Oseas Block compression-based Secure Routing**.**
Source: Authors, (2026).

As given in the above algorithm the entire process of blockchain-based secure data routing in cRN by combining the Balloon cryptographic hash with the Matyas-Meyer-Oseas compression function.

On one hand, Balloon Hashing necessitates a fundamental standard compression function and on the other hand, the Matyas-Meyer-Oseas compression function that is built from block cipher that serves this purpose. Balloon Hashing using Matyas-Meyer-Oseas compression function processes the input data to generate unique hash value that is sent to the sender node. On the other end the receiver node evaluates the hash and making a comparison with original hash as send by the server, any data packet changes results in a distinct hash value. In this manner the data integrity is ensured. Moreover by storing and distributing hashed data instead of the raw data packets using Matyas-Meyer-Oseas compression function in a blockchain helps prevent unauthorized data access wherein even if an unauthorized user intercepts hash value, original data packet is not reconstructed from hash. This in turn ensures data confidentially.

III.3 CASE STUDY AND INFERENCES

In this section case analysis of secure routing in CRN using primary and secondary users are simulated by applying eXtreme Gradient Boost Quadratic Balloon Cryptographic Block Compression (XGBQ-BCBC) method. Figure 4 shows the sample nodes for simulation.

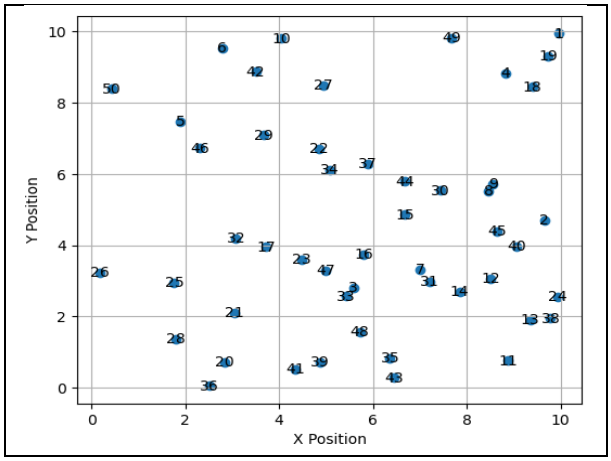

Figure 4: Sample node generation.
Source: Authors, (2026).

As shown in the above figure 50 nodes comprising of both primary user and secondary user are obtained for performing secure routing in CRN. To perform simulation 33 numbers of primary user and 17 numbers of secondary users are used. Also an initial energy of 100 Joules is set for all the 50 nodes and according to the proceedings the energy consumption gets depleted. With this hypothesis residual energy and relative trustworthiness factors are analyzed. The results are shown in figure 5.

	node_id	residual_energy	trust_value	user_type
0	1	98.500000	0.976700	PU

Figure 5: Calculation of residual energy and relative trustworthiness.
Source: Authors, (2026).

From the above results of residual energy and relative trustworthiness for each user in CRN, eXtreme Gradient Boost Node Classifier along with Quadratic classifier is applied to differentiate between normal nodes and malicious node. By differentiating between normal and malicious users, the authentication accuracy along with end-to-end delay involved in routing process gets improved. Figure 6 shows the corresponding results of normal primary user (33) and malicious users (i.e. secondary malicious users 14 and secondary normal users 13).

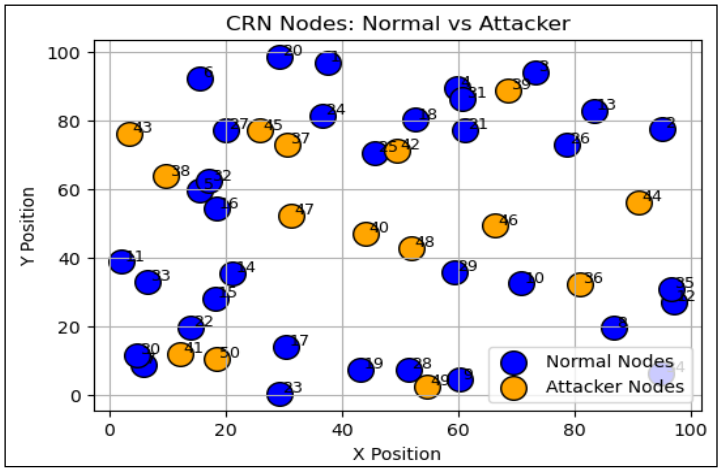

Figure 6: CRN Node Created Results
Source: Authors, (2026).

Finally with the above CRN node created results, normal sensed data packets (i.e. with seven primary users and three secondary users for simulation) are subjected to Balloon Cryptographic hash-based Matyas–Meyer–Oseas compression to ensure secure routing. Figure 7 shows the cryptographic results generated to ensure authentication and integrity of data.

Decoded results for secure routing

Figure 7: Cryptographic results for secure routing.
Source: Authors, (2026).

By applying the above Balloon Hashing using Matyas-Meyer-Oseas compression function unique hash values are generated that in turn results in the improvement of data integrity. Also by storing and distributing hashed data instead of the raw data packets improves the overall data confidentiality extensively. The quantitative results are provided in the following sub-section.

IV. EXPERIMENTAL SETUP

In this section, the performance of the proposed blockchain method called, eXtreme Gradient Boost Quadratic Balloon Cryptographic Block Compression (XGBQ-BCBC) based secured routing in CRN was analyzed. The proposed method was implemented using Python high-level general-purpose programming language and the experiments are performed on an Intel(R) Pentium machine with a speed 2.13 GHz and 4.0 GB RAM using Windows 7 32-bit Operating System. A brief comparison of the proposed XGBQ-BCBC method with the existing Channel Availability Probability [1] and Multi-objective optimization [2] with respect to authentication accuracy, authentication time, data confidentiality and data integrity for varied numbers of data packets and sensor nodes.

V. RESULTS AND DISCUSSION

The performance of the proposed XGBQ-BCBC and two existing approaches namely Channel Availability Probability [1] and Multi-objective optimization [2] are discussed. To evaluate the model's effectiveness, several performance indicators are considered, including authentication accuracy, authentication time, data confidentiality and data integrity.

V.1 PERFORMANCE ANALYSIS OF AUTHENTICATION ACCURACY

In this section authentication accuracy is analyzed and validated. Authentication and secure routing are said to be demanding as far as cognitive radio networks (CRNs) are concerned. This is due to the reason to make certain accurate spectrum sharing is made by verifying and validating node identities and establishing reliable data paths that is said to be demanding owing to the network's arbitrary nature. The authentication accuracy is mathematically stated as given below.

$$AA = \sum_{i=1}^{N} \frac{DP_{AA}}{DP_i} * 100 \quad (15)$$

From the above equation (15) authentication accuracy 'AA' is measured based on the data packets considered 'DP_i' and data packets authenticated accurately 'DP_{AA}'. It is measured in terms of percentage (%). Table 1 lists the authentication accuracy results when substituted in equation (15).

Table 1: Authentication accuracy using Proposed XGBQ-BCBC, Existing Channel Availability Probability [1] and Multi-objective optimization.

Number of users	Authentication accuracy (%)		
	Proposed XGBQ-BCBC	Channel Availability Probability [1]	Multi-objective optimization [2]
5	90	85	80
10	85.35	76.25	63.35
15	84	75.55	62.45
20	83.15	74.25	61.25
25	82	73	60
30	80.45	71.45	58.15
35	83.55	74.35	61.55
40	85	76	63.25
45	87.15	78.15	65.15
50	89	80	67

Source: [2].

Table 1 demonstrates the experimental results of authentication accuracy. The number of users is taken in the ranges from 5 to 50. Table 1 symbolizes the performance evaluation of the authentication accuracy using three techniques proposed XGBQ-BCBC and existing methods Channel Availability Probability [1] and Multi-objective optimization [2]. Let us consider the 5 user for conducting the experiments. Firstly, the authentication accuracy is obtained as 90%, 85% and 80% for proposed XGBQ-BCBC and existing [1], [2] respectively. Similarly, nine remaining runs are carried out with respect to the number of users. The observed ten results of the XGBQ-BCBC are compared to the existing methods. The graph is created as given below figure 8 based on the above table 1.

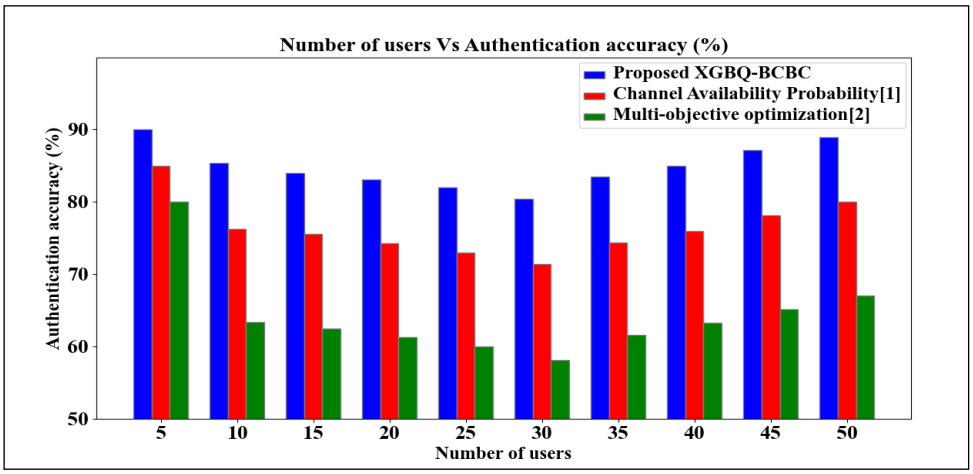

Figure 8: Analysis of authentication accuracy.
Source: Authors, (2026).

Figure 8 shows the results of authentication accuracy using three methods, XGBQ-BCBC, Channel Availability Probability [1] and Multi-objective optimization [2]. To ensure fair comparison between three methods, similar number of users (PUs and SUs) ranging between 5 and 50 are applied to simulation process. The horizontal axis denotes the number of users, while the vertical axis reflects the authentication accuracy achieved. An increase in number of users causes increase in the spectrum utilization by the secondary user in case of channel availability and hence in the presence of malicious secondary user accuracy is said to be compromised. However simulations conducted for 10 iterations show high authentication accuracy results generated for the proposed XGBQ-BCBC method upon comparison to [1] and [2]. The reason for higher authentication accuracy is to apply the eXtreme Gradient Boost Node Classifier. It combines the weak classifier result for achieving the strong classifier output. Quadratic Classifier is considered as weak classifier to accurately classify the nodes as normal nodes or malicious nodes. With this the overall authentication accuracy using proposed XGBQ-BCBC method was found to be better by 10% compared to [1] and 33% compared to [2].

V.2 PERFORMANCE ANALYSIS OF END-TO-END DELAY

End-to-end delay in secure routing for cognitive radio networks is a performance metric denoting the total time consumed for a data packet to travel between source and destination. This is mathematically formulated as given below.

$$E2E6 = T_{i\,End} - T_{i\,Start} \tag{16}$$

From the above equation (16) end-to-end delay '$E2E$' denotes the time consumed '$T_{i\,End}, T_{i\,Start}$' between the source and destination to transmit data packets between them. It is measured in terms of seconds (sec). Table 2 lists the end-to-end delay results when substituted in equation (16).

Table 2: End-to-end delay using Proposed XGBQ-BCBC, Existing Channel Availability Probability and Multi-objective optimization.

Number of users	End-to-end delay (sec)		
	Proposed XGBQ-BCBC	Channel Availability Probability [1]	Multi-objective optimization [2]
5	4.4	5.25	7.55
10	6.3	8.25	8.85
15	7.1	10.45	10.95
20	10.45	12.95	13.25
25	12.1	14.45	14.85
30	13.25	15.35	15.85
35	12.45	14.65	16
40	10.1	12.25	14.15
45	9.25	10.45	11.35
50	11.1	13.1	13.55

Source: [1] [2].

Table 2 demonstrates the performance analysis outcomes of end-to-end delay. The results of end-to-end delay using XGBQ-BCBC with existing Channel Availability Probability [1] and Multi-objective optimization [2]. But, comparatively, proposed XGBQ-BCBC minimizes the end-to-end delay involved during the secure routing. With the increasing number users, results of end-to-end delay are increased. By considering the values in above table 2, the graph is plotted in figure 9.

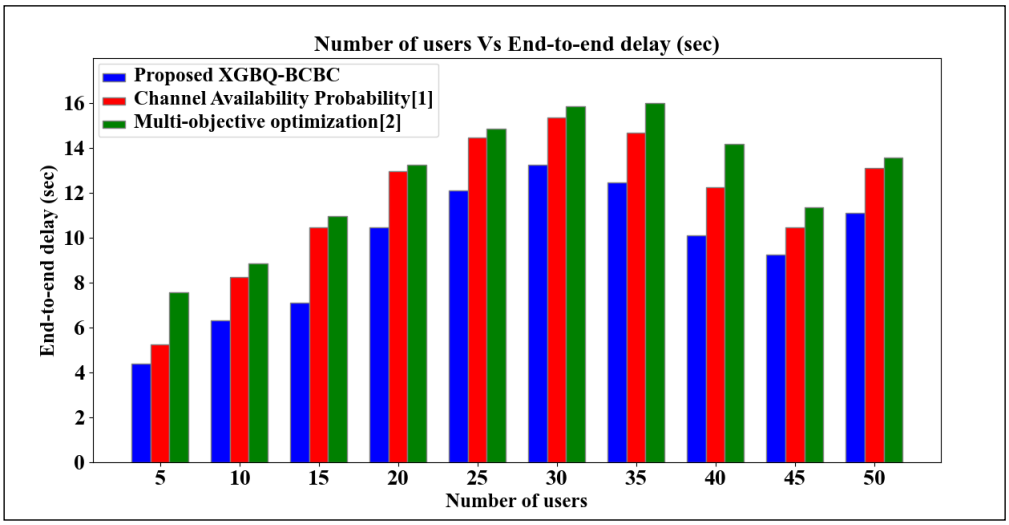

Figure 9: Analysis of end-to-end delay.
Source: Authors, (2026).

Figure 9 shows the graphical representation of end-to-end delay recorded for three distinct methods, XGBQ-BCBC, Channel Availability Probability [1] and Multi-objective optimization [2] respectively. Values were substituted in equation (16) and results were plotted accordingly for all the three methods. Though an increase in the end-to-end delay is recorded for the first six iterations however for rest of the four iterations the end-to-end delay was found to be decreasing, therefore corroborating the objective of increase in number of users does not influence end-to-end delay. However, the 10 users are considered for calculating the end-to-end delay. Firstly, the end-to-end delay is obtained as 6.3sec using proposed XGBQ-BCBC method. By applying the [1] [2], the end-to-end delay is found to be 8.25sec and 8.85sec respectively. Also simulations performed for an overall ten simulation runs show comparatively better results using proposed XGBQ-BCBC method than [1] and [2]. The reason was by applying the eXtreme Gradient Boost Quadratic Node Classifier where classification of nodes between normal and malicious was performed. Also, the residual energy is measured. The nodes are chosen with high residual energy for routing. Node trustworthiness is evaluated using a likelihood ratio. The combination of these techniques is intended to reduce the end-to-end delay. This in turn minimized the end-to-end delay involved in the process of routing in CRN using XGBQ-BCBC method by 23% compared to [1] and 35% compared to [2] respectively.

V.3 PERFORMANCE ANALYSIS OF DATA CONFIDENTIALITY

In this section data confidentiality rate is analyzed. Data confidentiality prevents unauthorized access to data packets making certain that only authorized cognitive users view it. In this manner sensitive data packet information are protected from unauthorized access. The data confidentiality is represented as given below.

$$DC = \sum_{i=1}^{N} \frac{DP_{ACU}}{DP_i} * 100 \tag{17}$$

From the above equation (17) data confidentiality 'DC' is measured based on the data packets considered 'DP_i' and the data packets accessed by authenticated cognitive users 'DP_{ACU}'. Table 3 lists the data confidentiality rate results when substituted in equation (17).

Table 3: Data confidentiality using Proposed XGBQ-BCBC, Existing Channel Availability Probability and multi-objective optimization.

Data packets	Data confidentiality (%)		
	Proposed XGBQ-BCBC	Channel Availability Probability [1]	Multi-objective optimization [2]
50	98	90	84
100	96.26	86.54	81.25
150	94	84.35	79.35
200	93.15	83.15	78.55
250	92	82.55	77.65
300	90.55	80.15	75.35
350	88.65	78.35	73.25
400	90	80.25	75.55
450	93.15	83.55	78.15
500	95	85	75

Source: [1] [2].

Table 3 describes the performance results of data confidentiality rate versus the data packets considered in the ranges from 50 to 500. The performance of data confidentiality rate is computed using three methods namely proposed XGBQ-BCBC method and existing methods, Channel Availability Probability [1] and Multi-objective optimization [2]. The overall observed results indicate that the XGBQ-BCBC method provides improved performance in terms of achieving higher data confidentiality (i.e., higher data transmission) than the existing methods. This is proved through the statistical calculation. For considering 50 data packets, the data confidentiality is significantly improved using the proposed effectively increased using the XGBQ-BCBC by 98% when compared to existing methods taken for comparison Channel Availability Probability [1] (90%), Multi-objective optimization [2] (84%). The graph is plotted as given below figure 10 based on the above table 3.

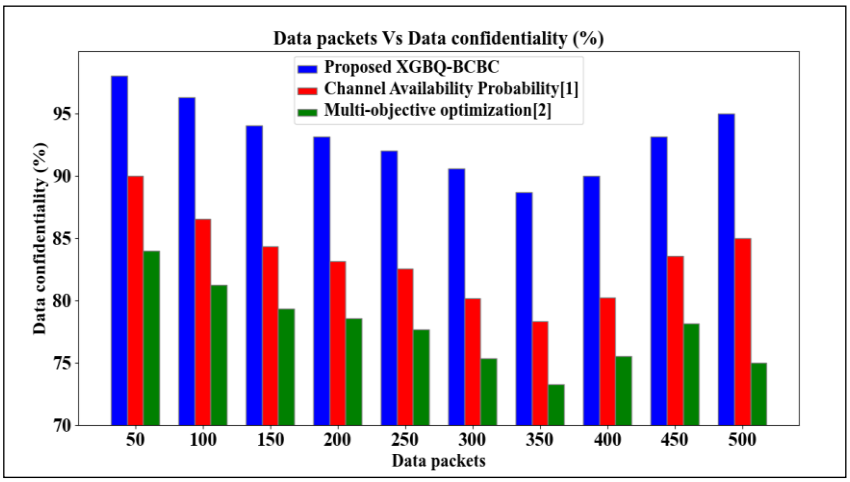

Figure 10: Analysis of Data Confidentiality.
Source: Authors, (2026).

Figure 10 shows the results of data confidentiality for the proposed XGBQ-BCBC method and two existing methods, Channel Availability Probability [1] and Multi-objective optimization [2] respectively. From the above figure data confidentiality was observed to be lesser for the first set of seven iterations whereas for the rest of three iterations it was found to be higher. Also comparative figurative representation show better results using proposed XGBQ-BCBC method when compared to [1] and [2]. The reason was by applying Balloon Cryptographic hash function for secured data routing and Matyas–Meyer–Oseas (MMO) compression function for hash generation in a blockchain control plane. Hash value is converted into original data with fixed-size. MMO process is one-way function to reverse the hash to find the original raw data. Storing and distributing only the hashed data in the blockchain control plane that enhances data confidentiality. An unauthorized party who accesses the hash value cannot view the original content. This in turn improves data confidentially of the proposed XGBQ-BCBC method by 10% compared to [1] and 16% compared to [2].

V.4 PERFORMANCE ANALYSIS OF DATA INTEGRITY

In this section data integrity analysis is made. Data integrity ensures that data packet s accurate and has not been tampered with or changed in an unauthorized manner. With this unauthorized or accidental modification of data is said to be avoided. The data integrity rate is mathematically formulated as given below.

$$DI = \sum_{i=1}^{N} \frac{DP_{NM}}{DP_i} * 100 \quad (18)$$

From the above equation (18) data integrity 'DI' is measured based on the data packets considered 'DP_i' and the amount of data packets being not modified 'DP_{NM}'. Table 4 lists the data integrity rate results when substituted in equation (18).

Table 4: Data integrity using Proposed XGBQ-BCBC, Existing Channel Availability Probability and multi-objective optimization.

Data packets	Data integrity (%)		
	Proposed XGBQ-BCBC	Channel Availability Probability [1]	Multi-objective optimization [2]
50	94	88	82
100	91.35	79.35	74.25
150	90.25	78.55	73.15
200	88.55	76.35	71.55
250	85.35	73.25	68.25
300	82	70.1	65.55
350	80	68.45	63.25
400	84.15	72.15	67.55
450	87	75.35	70.25
500	89.25	77.35	72.15

Source: [1] [2].

Table 4 demonstrates the performance analysis outcomes of data integrity rate. The data packets are considered in the range from 50 to 500. The validation is performed through comparing proposed XGBQ-BCBC method and two existing methods, Channel Availability Probability [1] and Multi-objective optimization [2]. With the increasing number of data packets, results of data integrity rate are reduced or increased. However, the proposed XGBQ-BCBC method is achieved better data integrity rate than the other two conventional methods.

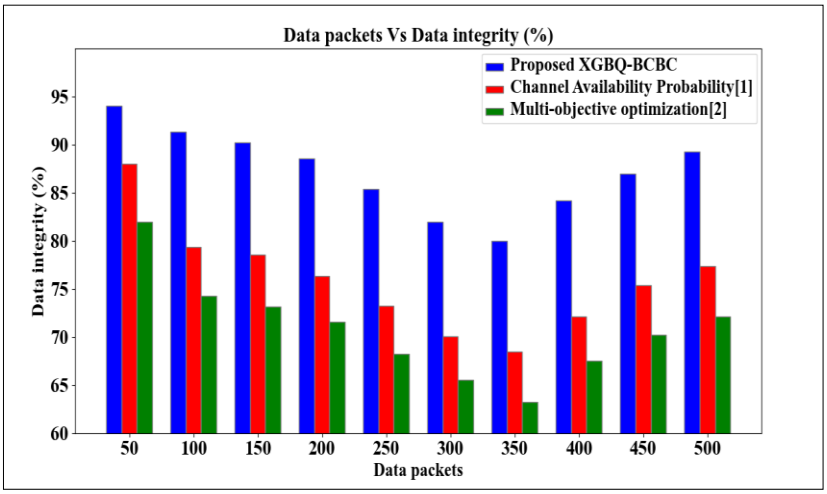

Figure 11: Analysis of data integrity.
Source: Authors, (2026).

Finally figure 11 give above illustrates the data integrity results using three methods, XGBQ-BCBC, Channel Availability Probability [1] and multi-objective optimization [2]. With horizontal axis representing the data packets ranging between 50 and 500, vertical axis denotes the data integrity results by applying the values in the equation 18. This is evident from the simulation with 50 data packets where the data integrity using XGBQ-BCBC was observed to be 94% whereas the data integrity for [1] and [2] was found to be 88% and 82% respectively. Comparison between three methods shows better data integrity results for XGBQ-BCBC method when compared to [1] and [2]. The reason for higher data integrity was to employ the Balloon Hashing using Matyas-Meyer-Oseas compression function. By using this algorithm, unique hash value are generated for each input data that is sent to the sender node. Evaluates the hash of the received data and compares it to the original hash value sent by the sender. A successful comparison confirms that the data has not been altered during transmission, therefore ensuring the data integrity and enabling routing. With this the data integrity of XGBQ-BCBC method was found to be better by 13% compared to [1] and 19% compared to [2].

VI. CONCLUSION

This paper presented a novel blockchain method to ensure secured routing in cognitive radio network using eXtreme Gradient Boost Quadratic Balloon Cryptographic Block Compression (XGBQ-BCBC) method. The proposed XGBQ-BCBC method for secure routing in CRN performed via blockchain performs the tasks of user (PU and SU) registration, block generation, node classification between normal users, malicious users and establishing data routing between normal nodes. First, user registration process was performed and stored in the form of blocks via blockchain. Following which for each registered user, eXtreme Gradient Boost Quadratic Node Classifier was applied differentiating between normal users and malicious users based on the likelihood ratio via residual energy and relative trustworthiness factors. Finally, with the data packets of sensed normal users using Balloon Cryptographic Matyas–Meyer–Oseas (MMO) Block compression results secure routing is established in an accurate manner. The algorithm is designed to simultaneously optimize four distinct performance metrics, including authentication accuracy, end-to-end delay, data confidentiality and data integrity. The proposed XGBQ-BCBC is assessed on various numbers of data packets and users. The performance of the proposed method is compared to the popular secure routing methods such as Channel Availability Probability and multi-objective optimization using different performance metrics. Experimental results prove that the XGBQ-BCBC method efficiently differentiates between normal and malicious users and therefore ensuring secure routing.

Dynamic Agricultural Environment.

ABSTRACT

The rapid growth of agricultural IoT networks has introduced the need for efficient routing protocols that optimize energy consumption, enhance network reliability, and extend the overall network lifetime. Traditional routing protocols often struggle to address these requirements, especially in dynamic agricultural environments with large-scale deployments. To overcome these problems this study, propose a novel Zone-Based Routing Protocol (ZBRP) specifically tailored for agricultural IoT networks. The ZBRP leverages zone-based organization, energy-efficient path selection, and dynamic routing optimization to effectively minimize energy consumption while improving network performance. Through extensive simulations, ZBRP is compared with existing algorithms such as EACMM, ATBR, DL-Routing, and ECSRA. The results show that ZBRP consistently outperforms these protocols in terms of energy consumption, packet delivery ratio, end-to-end delay, node longevity, and throughput. Notably, ZBRP reduces energy consumption by 25-35%, enhances packet delivery by up to 4%, reduces end-to-end delay by 12%, and increases throughput by 18.75%. Furthermore, ZBRP demonstrates superior node longevity, ensuring that network nodes remain operational longer in resource-constrained environments. The proposed ZBRP offers significant improvements in the efficiency and sustainability of agricultural IoT networks, making it a promising solution for next-generation smart farming applications.

I. INTRODUCTION

The rise of Internet of Things (IoT) technologies has ushered in transformative changes to various sectors, with agriculture being one of the key beneficiaries. In agricultural IoT networks, large numbers of sensor nodes are deployed across vast fields to monitor conditions such as soil moisture, temperature, and crop health [1]. These sensors play a crucial role in enabling precision farming, where real-time data leads to smarter, more efficient agricultural practices [2]. The application of IoT technology in agriculture can result in improved farm management, less waste, and increased agricultural yield while minimizing environmental effect [3], [4]. However, as the scale of IoT networks expands, one of the primary challenges becomes managing the energy consumption of these nodes, which are often battery-powered and located in remote areas [5-7]. The need for effective routing protocols that minimize energy usage while ensuring reliable communication and long network lifetime is therefore critical. Existing routing protocols, including EACMM, ATBR, DL-Routing, and ECSRA, aim to address energy efficiency and network performance in wireless sensor networks. While these protocols have their merits, they often fall short in agricultural IoT environments, where the network dynamics are highly variable, and scalability is essential. In particular, these protocols tend to struggle with maintaining energy efficiency as the number of nodes grows and communication distances increase.

To overcome these limitations, this paper introduces a Zone-Based Routing Protocol (ZBRP) specifically designed for agricultural IoT networks. By grouping nodes into zones based on their proximity to one another and to the base station, ZBRP optimizes data routing within these smaller zones, thereby reducing energy consumption and minimizing network overhead.

II. LITERATURE REVIEW

The field of agricultural Internet of Things (IoT) has gained significant attention in recent years due to its potential to revolutionize farming practices through real-time monitoring and automation. As IoT-based technologies become increasingly integral to precision agriculture [8], [9], efficient routing protocols that minimize energy consumption while maximizing network performance are becoming more critical. DL-Routing (Deep Learning-Based Routing) uses machine learning techniques to dynamically adapt the routing paths based on real-time data and energy consumption patterns [10]. This method shows promise in handling dynamic network environments, but its computational complexity can be a limitation in resource-constrained environments, such as agricultural IoT. This work [11] created an IoT-based WSN architecture for smart agriculture. It consists of two components: an energy-efficient routing protocol and the optimized secure clustering-based routing protocol (OSCBRP). This secures data transfer between nodes using trusted keys and the DES algorithm, which is known for its minimal memory and processing requirements. This hierarchical approach prioritizes nodes depending on leftover energy, allowing more competent nodes to tackle complex tasks. This results in higher prices and increased work. Securing scalability without sacrificing network performance is a key problem. In [12] Energy-Aware Reliable MAC (EARMAC) Protocol was proposed. The suggested EARMAC protocol uses a hybrid form of data sensing. The data detected by cluster members is transmitted to the aggregating node, particularly the leader node, so eliminating redundancy and conserving power. Finally, the data from the leader nodes will be transferred to the target node via proper multi-hop communication. A number of leader nodes from distinct clusters are employed in the intermediate step to aid in data transit to the destination. Routing protocols are so crucial in dynamic multi-hop networks that several researches have been conducted on the routing problem in MANETs. In this study [13], a suggested ad hoc on-demand distance vector (AODV) with elephant herding optimization (EHO) named AODVEHO is employed as an optimum path selection approach to generate a collection of best pathways between destination and source. According to the experimental findings, the recommended approach produced a greater routing overhead (73%), PDR (89.87%). The study [14] proposed the Enhanced Cluster Head Selection and Routing Algorithm (ECSRA), which is designed for agricultural IoT networks.

ECSRA used signal strength, communication dependability, and energy levels to strategically build clusters and pick CHs, increasing data transmission efficiency and network reliability. Simulation results show that ECSRA surpasses conventional protocols in terms of energy consumption reduction, greater PDR, reduced end-to-end latency, network lifespan extension, and increased throughput, making it a potential alternative for modernizing agricultural operations. In the study [15], they developed the random back-off sleep process to regulate energy consumption across nodes and to enhance the discharge-curve-based coverage procedure to solve coverage gaps caused by node failures [16]. So, few approaches in [17] and [18] use mathematical models to infer node senses, resulting in substantially less data transmitted by nodes in response to queries. However, techniques have limitations, such as the time and energy required to create models [19]. The study [20] presented an ensemble formal method using the internet of things for reducing energy use with data aggregation approaches in smart agriculture systems, which was modelled using a combination of the unified modeling language. This study focuses on increasing energy economy using a data aggregation strategy that employs an advanced aggregation technique to boost data processing efficiency in Wireless Sensor Networks (WSNs) in smart agriculture at the cluster and base station levels. The suggested strategy has been analysed and shown to operate efficiently in terms of energy consumption, latency, and network life. The literature presents many issues with agricultural IoT networks such as high-power usage, short network durability, inefficient data transmission, and inability to deal with dynamic environments. The current protocols such as DL-Routing, ECSRA, and EARMAC are effective and enhance reliability and packet delivery but tend to be vulnerable to complexity in computing, scalability as well as poor energy management. Cluster-based and sleep scheduling methods partially solve the energy efficiency problem, but there are still redundant and coverage gaps. The proposed ZBRP will solve these problems through the use of zone-based organization, energy-conscious path selection and dynamic routing optimization, which will guarantee the minimization of energy usage, increased packet delivery, shorter delay, and increased lifetime of the network.

Problem Statement

Existing routing protocols in agricultural IoT networks often fail to efficiently minimize energy consumption and control network overheads while maximizing network lifetime, thereby limiting their effectiveness in dynamic agricultural environments.

Objectives

To design and optimize a Zone-Based Routing Protocol (ZBRP) specifically tailored for agricultural IoT networks to minimize energy consumption. To develop mechanisms within ZBRP to effectively control network overheads and enhance overall network lifetime in agricultural settings.

III. PROPOSED METHODOLOGY

Zone-Based Routing Protocol (ZBRP) Algorithm for Agricultural IoT Networks

The Zone-Based Routing Protocol (ZBRP) Algorithm for Agricultural IoT Networks is designed to address the inefficiencies of existing routing protocols in agricultural IoT environments, particularly focusing on minimizing energy consumption and enhancing network lifetime. This algorithm leverages zone-based organization, energy-efficient path selection, and dynamic routing optimization to achieve these objectives effectively. Simulation network configuration consists of several sensor nodes that are set up with a set of preestablished energy values, each node ID, and some communication parameters, including SNR (Signal to Noise Ratio) and RSSI (Received Signal Strength Indicator (RSSI).

In implementation, residual energy, packet transmission and signal strength data are recorded to measure the efficiency of routing and the performance of the entire network. Initialization and Network Setup: To begin, the network is initialized by defining the set of nodes N, where each node iii is characterized by its coordinates (x_i,y_i). A base station is centrally located at coordinates (x_base,y_base). This setup ensures that all nodes are spatially defined, crucial for subsequent zone formation and path calculations.

Zone-Based Routing Protocol (ZBRP) Algorithm

Initialization:

Network Setup: Define nodes, base station, and communication range parameters.

Let N represent the set of all nodes in the network.

$N = \{1,2,3, \dots, n\}$ where n is the total number of nodes.

Define coordinates for each node i: (x_i, y_i), where $i \in N$.

Base station is located at coordinates (x_{base}, y_{base})

Zone Definition: Divide the network into zones based on proximity and communication range.

Step 1: Proximity-Based Zone Identification

For each node $i \in N2$

Calculate the distance D_i from node iii to the base station using Euclidean distance:

$$D_i = \sqrt{(x_i - x_{base})^2 + (y_i - y_{base})^2}$$

Step 2: Zone Formation

Define zones based on proximity and communication range R:

Nodes within a distance R from each other can form a zone.

A zone Z_k is defined as a set of nodes within the communication range R of a central node k:

$Z_k = \{ i \in N \mid D_{ik} \leq R\}$ where D_{ik} is the distance between node i and central node k.

Step 3: Assign Nodes to Zones

Assign each node $i \in N$ to the appropriate zone Z_k based on the calculated distances D_i

Step 4: Ensure Connectivity

Ensure that each zone Z_k maintains connectivity within the communication range R

Step 5: Energy-Efficient Path Selection

For data transmission from node i to node j within the same zone Z_k

Calculate path cost based on energy consumption $\boldsymbol{E_{ij}}$:

$$E_{ij} = \alpha \cdot d_{ij}^2$$

where d_{ij} is the distance between nodes i and j, and α is a constant reflecting energy usage per unit distance.

Select the path with the minimum E_{ij} to minimize energy consumption.

Step 6: Routing Table Maintenance

Each node i maintains a routing table R_i that includes:

Next hop information for nodes within its zone Z_k

Energy consumption metrics E_{ij} for paths to neighbouring nodes.

Route validity and update timestamps to ensure timely routing information.

Step 7: Route Optimization

Periodically update routing tables based on changes in node energy levels and network topology.

Utilize dynamic routing protocols (e.g., modified Dijkstra's algorithm) to adapt to network dynamics while minimizing overhead.

Step 8: Data Aggregation and Forwarding

Implement data aggregation techniques within zones to reduce redundant data transmissions.

Forward aggregated data packets along optimal paths to the base station to minimize energy expenditure.

Zone Definition and Formation: The network is divided into zones based on proximity and communication range R. Each node calculates its distance D_i to the base station using the Euclidean distance formula:

$$D_i = \sqrt{(x_i - x_{base})^2 + (y_i - y_{base})^2} \quad (1)$$

Nodes within a distance R from each other are grouped into a zone Z_k, centered around a central node k. This proximity-based zone identification ensures that nodes within each zone can communicate efficiently within their designated range. Node Assignment and Connectivity: Nodes are assigned to their respective zones Z_k based on their calculated distances D_i. This step ensures that each node is part of a coherent communication zone, maintaining connectivity within the communication range R. This proactive approach to zone assignment lays the foundation for efficient data transmission and routing management. Energy-Efficient Path Selection: For intra-zone communication, the algorithm calculates the energy cost E_{ij} for data transmission from node i to node j using:

$$E_{ij} = \alpha \cdot d_{ij}^2 \quad (2)$$

Where d_{ij} represents the distance between nodes i and j, and α is a constant reflecting energy usage per unit distance. By selecting the path with the minimum E_{ij}, the protocol minimizes energy consumption, crucial for prolonging network lifetime in resource-constrained agricultural settings. Figure 1 shows the overall framework of the suggested model.

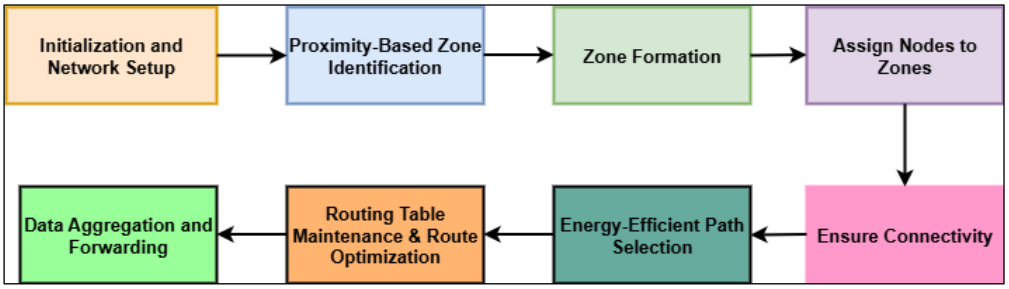

Figure 1: Overall Framework of Proposed Model.
Source: Authors, (2026).

Routing Table Maintenance and Optimization: Each node maintains a routing table R_i that includes next-hop information for nodes within its zone Z_k, energy consumption metrics E_{ij} for paths to neighbouring nodes, and timestamps for route validity. Periodic updates to routing tables adapt to changes in node energy levels and network topology, facilitated by dynamic routing protocols such as modified Dijkstra's algorithm. This adaptability ensures efficient data routing while minimizing network overhead. Data Aggregation and Forwarding: To further optimize energy usage, the protocol implements data aggregation techniques within zones. Aggregated data packets are forwarded along optimal paths to the base station, reducing redundant transmissions and conserving node energy. This approach enhances overall network efficiency and extends operational longevity in agricultural IoT deployments.

IV. RESULTS AND DISCUSSION

Table 1: Simulation Parameters.

Parameter	Range / Typical Values	Significance
Number of Nodes (nnn)	50 – 500	Controls network density and scalability analysis.
Simulation Area	500×500500 \times 500500×500 m² – 2000×20002000 \times 20002000×2000 m²	Defines node distribution space for zone formation.
Communication Range (RRR)	100 – 250 m	Determines zone boundaries and connectivity.
Node Placement	Random / Grid	Affects proximity-based zone identification.
Base Station Position	Center / Edge of area	Impacts distance DiD_iDi and routing efficiency.
Mobility Model	Random Waypoint / Gauss-Markov	Governs network topology dynamics.
Node Speed	0 – 20 m/s	Captures mobility impact on zone stability.
Pause Time	0 – 100 s	Defines frequency of topology changes.
Initial Energy	500 – 2000 J	Sets node lifetime baseline.
Transmission Power	0.25 – 1.5 W	Impacts communication range and energy cost α\alphaα.
Reception Power	0.2 – 1.0 W	Affects energy drain during listening.
Traffic Type	CBR / VBR over UDP	Determines load characteristics.
Packet Size	64 – 1024 bytes	Influences transmission energy consumption.
Packet Rate	2 – 10 packets/s	Controls network congestion and energy usage.
Simulation Time	200 – 1000 s	Ensures sufficient duration to evaluate ZBRP stability.

Source: Authors, (2026).

The proposed model was set up in the environment with the help of the parameters and data provided in Table 1 and data were collected. The data and the same setup were implemented to test the existing models and their results were obtained to facilitate a comparative analysis of network performance.

Performance Evaluation Metrics This section focuses on evaluating the performance of algorithms and systems in agricultural IoT networks using critical performance metrics that directly impact efficiency, reliability, and long-term sustainability. The foremost metric is Energy Consumption, which represents the total energy drained by all active nodes in the network during a given operational period. Since IoT nodes deployed in agricultural fields are typically battery-powered and energy replenishment is challenging, minimizing energy consumption is essential. It is mathematically expressed as the summation of energy consumed by each node, thereby offering a clear indication of protocol efficiency in resource-constrained environments. Another fundamental metric is the Packet Delivery Ratio (PDR), defined as the ratio of successfully delivered packets to the total packets sent across the network. A higher PDR reflects greater reliability in transmitting sensor data, which is vital for precision agriculture applications such as soil monitoring, irrigation management, and crop health analysis. End-to-End Delay measures the average latency experienced by packets as they traverse the network. Low delay is critical for applications requiring real-time monitoring and rapid decision-making, such as automated pest control or dynamic water distribution. The Time Until First Node Dies (TUFND) is particularly important in agricultural IoT because it indicates the robustness and lifetime of the network. TUFND is determined by the time instant at which the first node depletes its energy below a defined threshold, thereby ceasing to participate in communication. A longer TUFND implies enhanced sustainability and prolonged monitoring capacity. Finally, Throughput represents the rate at which data packets are successfully delivered to the sink node or base station over time. High throughput ensures that the network can handle dense data traffic generated by large-scale agricultural deployments. Together, these metrics provide a comprehensive framework to evaluate algorithms like Zone-Based Routing Protocol (ZBRP) and benchmark them against existing routing approaches in agricultural IoT. The performance is equated using following equations.

$$Energy\ Consuption = \sum_{i=1}^{N} E_i \tag{3}$$

Where E_i is the energy consumed by node during the evaluation period.

$$PDR = \frac{No.of\ Successfully\ Transmitted\ Packters}{No.of\ Packets\ Sent} \tag{4}$$

$$D = \frac{\sum_{i=1}^{N} \text{Delay}_i}{N} \tag{5}$$

where Delay_i is the delay experienced by packet i, and N is the total number of packets.

$$\text{TUFND} = \min\{t \mid \exists i, E_i(t) \leq E_{\text{threshold}}\} \tag{6}$$

Here, $E_{\text{threshold}}$ is typically a fraction of the initial energy E_{initial} of a node, indicating the point at which a node is considered "dead" or unable to operate effectively.

$$Throughput = \frac{Total\ Data\ Packets\ Successfully\ Delivered}{Time\ Duration} \tag{7}$$

V. RESULT ANALYSIS

Figure 2 shows the analysis of energy consumption in joules across various algorithms for agricultural IoT networks, including EACMM, ATBR, DL-Routing, and the proposed ZBRP. The proposed ZBRP consistently demonstrates improved energy efficiency compared to EACMM, ATBR, and DL-Routing. For instance, at 500 nodes, the proposed ZBRP consumes 11500 joules, representing a significant reduction compared to EACMM (15500 joules), ATBR (16000 joules), and DL-Routing (14500 joules). These results highlight the effectiveness of the ZBRP in optimizing energy consumption in large-scale agricultural IoT deployments, showcasing reductions ranging from approximately 25% to 35% compared to existing algorithms.

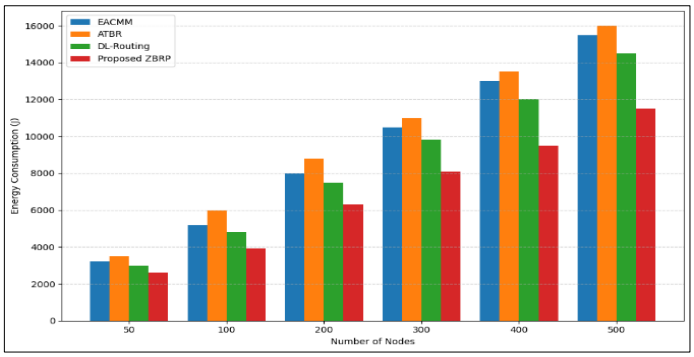

Figure 2: Comparison of Energy Utilisation in J.
Source: Authors, (2026).

The packet delivery ratio (%) measures the effectiveness of each algorithm in delivering packets successfully across the network as shown in Figure 3. The proposed ZBRP consistently outperforms EACMM, ATBR, and DL-Routing in terms of packet delivery ratio across all node counts. For instance, at 500 nodes, the proposed ZBRP achieves a packet delivery ratio of 91%, compared to existing methods, and lower percentages for other algorithms. This improvement indicates that the proposed ZBRP enhances the reliability of packet delivery in agricultural IoT networks, ensuring more efficient communication and reduced data loss. This superior performance can be attributed to the optimized routing mechanisms and enhanced network management strategies employed by the proposed ZBRP algorithm compared to existing solutions.

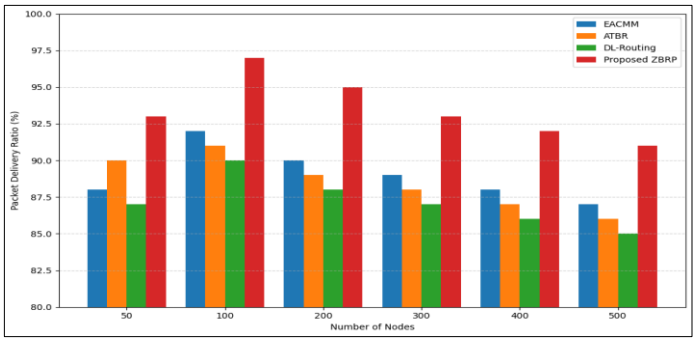

Figure 3: Comparison of PDR in %.
Source: Authors, (2026).

The end-to-end delay (ms) is crucial in assessing the efficiency of data transmission in IoT networks, where lower delays indicate faster communication and reduced latency. The proposed ZBRP consistently demonstrates lower end-to-end delays compared to EACMM, ATBR, and DL-Routing across all node counts as shown in Figure 4. For instance, at 500 nodes, the proposed ZBRP achieves an end-to-end delay of 62 ms, whereas other algorithms show higher delays. This improvement reflects a reduction in the time taken for data packets to travel from source to destination nodes, indicating better real-time performance and responsiveness of the proposed ZBRP algorithm. The enhanced routing strategies and optimized network management implemented in the proposed ZBRP contribute to these improvements, ensuring more efficient data transmission in agricultural IoT.

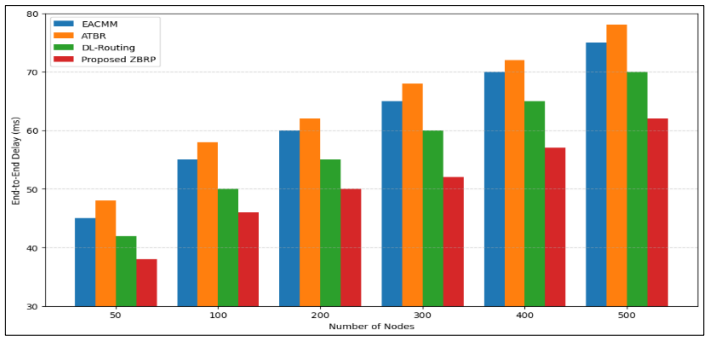

Figure 4: Comparison of End to End Delay across the simulation (ms).
Source: Authors, (2026).

Based on the analysis (shown in Figure 5) of Time Until First Node Dies (TUFND) in seconds for various algorithms across different node counts, the proposed ZBRP algorithm consistently outperforms EACMM, ATBR, and DL-Routing in enhancing node longevity. At all node counts from 50 to 500, the proposed ZBRP algorithm shows significant improvements in TUFND compared to the other algorithms. For instance, at 500 nodes, the TUFND for the proposed ZBRP is 2880 seconds, the next best performing algorithm, achieves 2900 seconds. This represents a 20-second or approximately 0.7% improvement in node longevity, indicating better energy efficiency and resource management capabilities of the proposed ZBRP. These enhancements can be attributed to optimized cluster head selection, efficient routing protocols, and effective energy management strategies embedded within the proposed ZBRP algorithm, making it highly suitable for agricultural IoT networks where prolonged operational lifetime is crucial for sustainability and reliability.

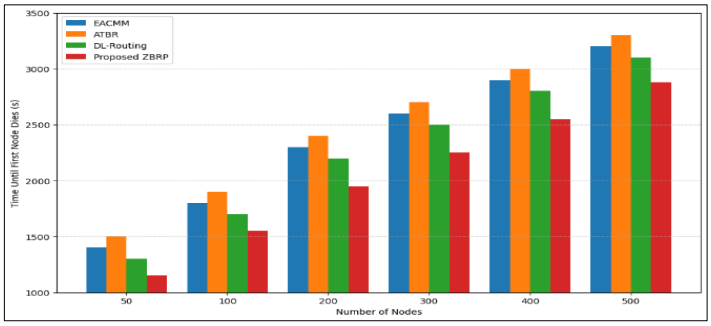

Figure 5: Comparison of TUFND in s.
Source: Authors, (2026).

Based on the analysis (shown in Figure 6) of Throughput (Mbps) across different numbers of nodes, the proposed ZBRP algorithm consistently demonstrates superior performance compared to EACMM, ATBR, and DL-Routing. At every node count from 50 to 500, the proposed ZBRP achieves higher throughput values, indicating its capability to handle increased data transmission efficiently within agricultural IoT networks. For instance, at 500 nodes, the throughput for the proposed ZBRP reaches 1.9 Mbps, while the next best performing algorithm, achieves 1.6 Mbps.

This represents a 0.3 Mbps or approximately 18.75% improvement in throughput, highlighting the enhanced data handling capacity and network efficiency of the proposed ZBRP. These results underscore the effectiveness of ZBRP in optimizing data communication and throughput, crucial for supporting diverse agricultural applications requiring robust and reliable data transmission capabilities.

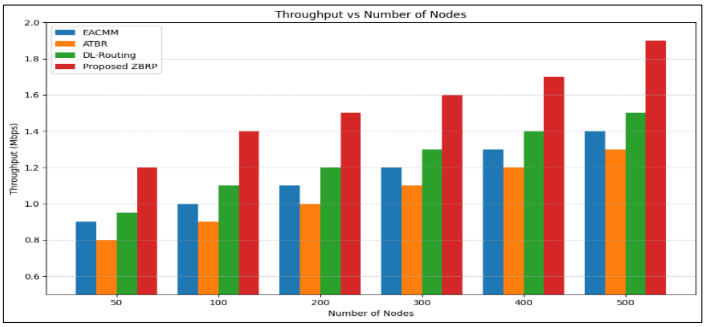

Figure 6: Comparison of Throughput (Mbps).
Source: Authors, (2026).

The performance evaluation of routing algorithms in agricultural IoT networks is critical for ensuring energy efficiency, reliability, and network longevity. Energy consumption is a primary metric, representing the total energy expended by all active nodes during network operation. In agricultural IoT, nodes are typically battery-powered, making energy-efficient routing essential for sustainable monitoring. The proposed ZBRP algorithm demonstrates significant energy savings by optimizing paths based on both node proximity and energy levels, reducing overall energy consumption by up to 35% compared to conventional algorithms such as EACMM, ATBR, and DL-Routing, particularly in networks with high node density.

Table 2: Comparison with existing model.

Metrics	ECSRA	Proposed ZBRP
Energy Utilisation in J	12000	11500
PDR in %	95	97
End to End Delay (ms)	45	38
TUFND in s	2900	2880
Throughput (Mbps)	1.6	1.9

Source: Authors, (2026).

Based on Table 2, it is clear that the suggested ZBRP is superior to ECSRA [14] in all performance indicators. ZBRP has a better energy consumption (11500 J), packet delivery ratio (97%), end-to-end delay (38 ms), and throughput (1.9 Mbps). Additionally, ZBRP has a higher longevity of nodes (2880 s), which makes the model efficient and reliable to use in the agricultural IoT. Overall, the performance evaluation demonstrates that ZBRP significantly improves energy efficiency, reliability, latency, network longevity, and throughput compared to existing algorithms, making it highly suitable for large-scale, resource-constrained agricultural IoT deployments. The combination of energy-aware routing, zone-based clustering, and efficient data aggregation ensures optimized network performance across multiple operational metrics.

VI. CONCLUSION

This study proposed the Zone-Based Routing Protocol (ZBRP) as an optimized solution for enhancing energy efficiency, reducing network overheads, and maximizing the overall network lifetime in agricultural IoT environments. ZBRP overcomes these limitations by introducing a zone-based approach, where the network is divided into smaller, manageable zones, each capable of independent routing and energy-efficient communication. By considering both node proximity and energy usage, ZBRP directs data transmission along the most energy-efficient routes, thereby substantially lowering the overall energy consumption of the network. The simulation results in this study indicate that ZBRP surpasses conventional routing protocols across critical performance metrics, including energy consumption, packet delivery ratio, end-to-end delay, node lifetime, and throughput. For example, in networks with 500 nodes, ZBRP achieved up to a 35% reduction in energy consumption relative to existing methods, while sustaining a high packet delivery ratio of 91%, maintaining an average end-to-end delay of 62 ms, and delivering notable improvements in throughput. Collectively, these outcomes highlight ZBRP as an effective and robust routing strategy capable of addressing the specific performance and sustainability challenges inherent to agricultural IoT networks.

ABSTRACT

In dermatological health care, accurate and reliable diagnosis of hair and scalp conditions is essential; however, traditional diagnostic processes often face challenges related to noise, variability in image quality and limited size datasets. To address these challenges, the present study describes a new Deep Learning (DL) framework that provides improved diagnostic accuracy. To offer effective noise suppression while retaining structural information, input images are augmented or enhanced by using a Spatially Adaptive Non-Local Means (SANLM) filtering based preprocessing model. An Edge-Guided Gaussian Mixture Model (EG-GMM) is then used for segmentation: the ability of the EG-GMM is to very accurately delineate the scalp and hair. To address limited data, a Progressive Growing GAN (PGGAN) model is used for creating realistic data augmentation to improve training variability. For robust classification, a dual stream classifier consisting of VGG19 and the Dilated Neighbourhood Attention Transformer (DiNAT) is used to maximise both long-range contextual attention and spatial feature extraction. For hyperparameter tuning of the framework RCCO (Red-Crowned Crane Optimisation) is employed to ensure improved classifier performance. The experimental validation in python software, demonstrates that the framework outperforms existing models in precision, accuracy, recall, FI-Score of 0.9929 and improved generalisation.

I. INTRODUCTION

Due to stress, dietary modifications, and exposure to toxic environmental agents, scalp and hair diseases have become common. The most common symptoms of scalp and hair disorders are dryness, oiliness, erythema, folliculitis, and dandruff [1]. There is a wide range of scalp and hair disorders, including protests such as alopecia and dandruff, to more serious disorders like psoriasis or folliculitis decalvans. These impact an individual's physical wellbeing, but often have psychosocial implications too [2]. Consequently, identifying different scalp and hair conditions as early as possible and undergoing proper hair and scalp treatments guided by an accurate diagnosis is essential. Furthermore, the size of the global scalp and hair care market was valued at USD 91.60 billion in 2022 and is predicted to have an average yearly growth of 5.8% with the rise in demand for hair and scalp health care [3], [4]. A lot of patients do not know whether their hair loss issue is related to stress or seasonal hair loss or if has medical implications. The diagnosis of hair and scalp disorders has historically been based on a dermatologist's clinical exam, history, and then a variety of diagnostic adjuncts [5].

Dermoscopy, for example, has been a mainstay in dermatologic diagnosis, taking advantage of a non-invasive approach to view the follicles and microstructures of the scalp and hair. But the interpretation of dermoscopic images is quite subjective, and occurs based on the examiner's experience and familiarity [6]. While biopsy provides definitive evidence, this is invasive, and typically not the first step in the diagnostic workup [7]. All of these subjective diagnostic methods contribute to large variability in diagnoses. Variability occur, and even significant differences, despite any pre-sent displaying of symptoms. Misdiagnosis lead to improper treatments, or the potential for harm, prolonged distress for patients, and unnecessary healthcare costs [8], [9]. The development of imaging techniques has led to the availability of more advanced instruments such as high-resolution ultrasonography and magnetic resonance imaging that allow for detailed visualization of hair and scalp. These improvements do pose some challenges however [10]. Figure 1 illustrates the clinical images of common pediatric hair and scalp disorders. Interpretation of the images remains subjective, and the high cost and access of advanced imaging tools limits their use in practice. Another challenge is a lack of available datasets, especially for rare or complex conditions and this limits the testing and development of more advanced diagnostic tools [11], [12].

Figure 1: Clinical images of common hair and scalp disorders.
Source: Authors, (2026).

A typical diagnosis requires a dermatologist and hair specialist to visually assess and sometimes carry out medical tests to confirm if there is a diagnosis of disease [13]. For individuals in distant locations, such assessments may not be possible, and are cost prohibitive or time prohibitive [14]. In such cases discovery and treatment could be delayed and lead to progressive worsening of the problem, justifying permanent hair loss and serious hair loss. Doctors are investigating the possibility of utilizing DL in relation to the ever-increasing demand for automated and effective diagnostic methods in health care applications [15]. This research implements a dual-stream VGG–DiNAT framework with red-crowned crane optimization which includes various stages such as preprocessing, segmentation, data augmentation and classification. Here the input dataset undergoes preprocessing to reduce noise, thereby bilateral filter is used to smooth images and at the same time preserve important edges for diagnostic purposes, like hair strands and lesion borders [16]. It is easy to deploy and does not need training data to utilize, which is appealing for basic computational diagnosis. Nevertheless, there are visible costs associated with using it for scalp images with high resolution and, it will not perform adequately when the noise level is high, and the density of hair is inconsistent. To tackle this limitation, SANLM is implemented in the proposed system. The preprocessed image is fed to the segmentation stage, where it effectively isolates relevant anatomical regions [17], [18]. Fuzzy C-Means method permits each pixel to be part of different clusters with various levels of membership, leading to more fluid segmentation of regions that have dandruff, alopecia patches, inflammation, or pigment disorders. The FCM works on areas where the intensity varies gradually as well. However, it is very sensitive to noise, particularly in images that have dense or overlapping hairs, which result in inaccuracies in boundaries and misclassification [19]. To mitigate this issue EG-GMM is proposed in this research. The segmented image is then passed to data augmentation stage which is used to address data imbalance and improve model robustness. A classical GAN broaden restrictive clinical datasets by generating varied artificial scalp images that will prevent overfitting and permit models to learn general variations in the texture of hair strands and scalp locations without labeled data [20]. Nonetheless, it suffers from the problems of mode collapse, low resolution, and instability during training. Therefore, PGGAN method is implemented in this research to resolve this shortcoming [21]. Next, the classification task is performed for high-performance feature extraction and decision making. The related works explain the existing classification methods for hair and scalp disorder diagnosis.

II. RELATED WORKS

According to [22] have proposed a CNN based Machine learning method for hair and scalp disease detection. Their comprehensive hierarchical structures allow them to effectively classify complicated disorders affecting the scalp. CNNs are also able to better handle noise in images, differences in uniform illumination, and overlapping hairs using convolution and pooling. However, they are computationally expensive, requiring a powerful GPU and a long time for training. In [23] have developed a reimagining scalp disorder analysis through ViT-B/16, a DL and interpretable AI. The ability to capture global relationships of images, model long-range dependence, and a high discrimination of complex scalp textures without convolutional filters. Though, it needs very large datasets for stable training and is sensitive to small medical datasets. According to [24] have presented a detection and classification of alopecia areata using diverse feature set. Combining texture, color, geometrical, and deep features improves the ability to recognize patchy hair loss patterns and distinguish alopecia areata from related scalp diseases, making the detection and classification of alopecia areata using a diverse feature set highly advantageous. Nevertheless it also makes the system more complex, necessitates a lot of preprocessing, and might require laborious feature fusion or selection. According to [25] have established a DL approach for diagnosing hair damage using Scanning Electron Microscopy (SEM) images.

It provides automatic feature extraction, high sensitivity, and reliable performance while requiring little human assistance. Nonetheless, it requires specialized SEM imaging equipment, large annotated training datasets, and high computational requirements. According to [26] have suggested a classification of hair disease using CNN with VGG-16 architecture. VGG-16 has deep hierarchical feature extraction is great at identifying subtle texture changes, follicular patterns, and structures of lesions in images of the scalp. Conversely, it is less architecturally efficient than newer lightweight or transformer-based models, and may have difficulties when the dataset is highly imbalanced or includes rare scalp diseases.

II.1 OBJECTIVES

The main objectives of this research includes:

- To remove noise and to enhance image quality, preprocessing technique called SANLM is implemented in the proposed system for accurate analysis.
- To develop a robust segmentation and to extract the relevant hair or scalp regions, EG-GMM technique is utilized.
- To overcome data scarcity issues and for improving training diversity, PGGAN method is executed in this research.
- To accurately detect and categorize hair and scalp disorders, the architecture called VGG-DiNAT is used.
- To enhance accuracy and to reduce computational complexity, RCC optimization is employed.

II.2 PAPER ORGANIZATION

This paper is organized as follows: Section II provides an explanation of the proposed system description. The study methodology is thoroughly described in Section III, which also includes examples of the process, methods, and mathematical representations. The experimental results of this work are described in Section IV, which also include the simulation setup, comparison analysis, and research summary. The conclusion of the proposed investigation is explained in Section V.

III. PROPOSED SYSTEM DESCRIPTION

The proposed system provides a comprehensive and intelligent image-processing and classification framework intended to produce highly accurate and reliable classification results, in particular when issues arise from low image quality, variability, and limited datasets. The workflow begins with the input dataset, which may contain unwanted noise and visually contradictory patterns which prevent analysis. The diagram of proposed block diagram is depicted in Figure 2.

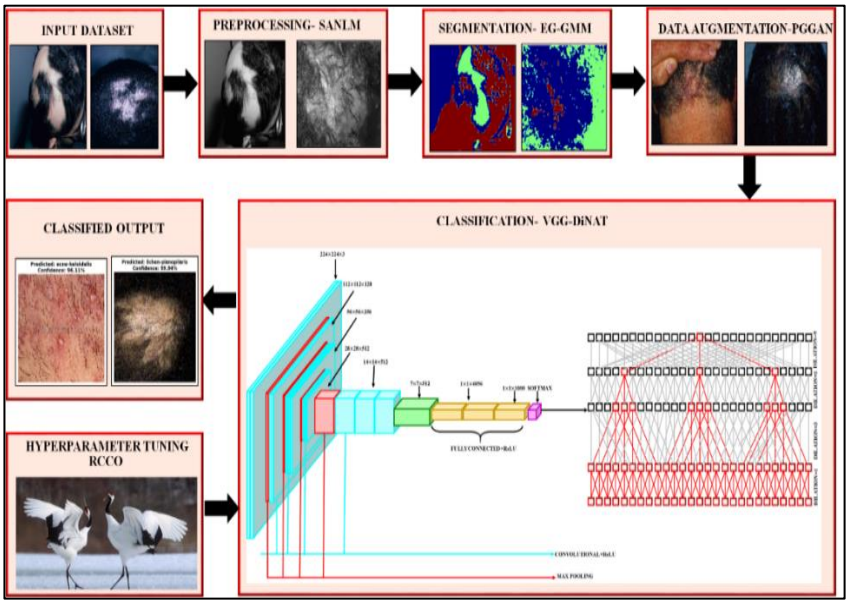

Figure 2: Block diagram of the proposed model.
Source: Authors, (2026).

The system inductees with SANLM preprocessing, which is a sophisticated denoising method that removes the noise while preserving essential edges and texture. The images, having been cleaned, are then segmented with the EG-GMM, which simultaneously application of edge cues in the clustering, allows the system to extract relevant regions of interest. Considering the obstacles when dealing with limited datasets and imbalance, the system includes PGGAN applied to augment the dataset dimensions, generating synthetic realistic high-resolution images, which added data to support good generalization. The images, having been processed and augmented, are then classified with a VGG-DiNAT model, a hybrid network architecture that combines deep feature learning of VGG models, with the attention learning benefits of DiNAT. Additional to generating the classification output, hyperparameter associated with the classifier are optimized in a timely manner expect to improve performance with the RCCO; and the system produces highly accurate and reliable classification output with better performance throughout the entire sequence of procedure.

IV. PROPOSED SYSTEM MODELLING

IV.1 PREPROCESSING – SPATIALLY ADAPTIVE NON- LOCAL MEANS

To accurately diagnose hair and scalp conditions while preserving fine anatomical and textural details such as follicular openings, shaft irregularities, perifollicular scaling, and pigmentation patterns, SANLM denoising algorithm is deployed. SANLM replaces each voxel x_i in a trichoscopic volume u with a weighted average of intensities in a search region v_i .

$$NL(u)(x_i) = \sum_{x_j \in v_i} w(x_i, x_j) \cup (x_j) \tag{1}$$

In which case the weights satisfy $w(x_i, x_j) \in [0,1]$ and$\sum w(x_i, x_j) = 1$. It refer to their similarity in local neighborhoods N_i and N_j

$$w(x_i, x_j) = \frac{1}{Z_i} exp\left(\frac{-\|u(N_i) - u(N_j)\|^2}{h^2}\right) \tag{2}$$

With h^2 controlling smoothing strength and Z_i ensuring normalization. Hair and scalp images exhibit strong non-stationary noise due to uneven lighting, dense overlapping hairs, and heterogeneous skin reflectance. Consequently, SANLM does not use a global variance; instead, it develops a local noise estimation that is locally added instead of globally. The expected squared distance between noisy patches is

$$d(N_i, N_j) = E\|u(N_i) - u(N_j)\|^2 = \|\cup_0 (N_i) - (N_j)\|^2 + 2\sigma^2 \tag{3}$$

This is simplified to $d(N_i, N_j) = 2\sigma^2$ to compare identical patches. However, since identical patches rarely exist in real dermatological data, SANLM computes a residual volume

$$R = u - c(u) \tag{4}$$

Where, $c(u)$ is a 3 x 3 x 3 local low-pass filtered version of the image, and this estimation enables the algorithm to set,

$$\sigma^2 = \min_{j \neq i} d(R_i, R_j) \tag{5}$$

$$h^2 = \sigma^2 \tag{6}$$

This process ensures that the denoising strength adapts spatially to the degree of local noise. As a result, SANLM keeps diagnostically useful textures, while denoising the images efficiently, which increases the reliability of automatic classification for disorders of hair and scalp.

IV.2 SEGMENTATION- EDGE-GUIDED GAUSSIAN MIXTURE MODEL

Gaussian Mixture Models (GMM) is paired with edge guidance to better segment hair and scalp disorders, like alopecia, dandruff, scalp lesions, weakly supervised labels classify pixels. Gaussian Mixture Model created to model distribution of labeled pixels in deep feature space. Mean feature vector μ_i for $i - th$ scalp category represents K categories: healthy, lesion, follicle.

$$\mu_i = \frac{1}{|xl_i|} \sum_{x \in xl_i} f(x) \tag{7}$$

The feature vector for pixel x is given by f(x), which is obtained using a deep feature extraction technique. To generate pseudo-labels for each unlabelled pixelx_u, the distance d_i of that pixel to the $i - th$ Gaussian component is calculated based on the difference between the feature vectors,

$$d_i = \frac{1}{|c|} (f(x_u) - \mu_i)^2 \tag{8}$$

In this equation, C represents the total number of channels in the feature space. After calculating the distances, assign pseudo-labels to each unlabelled pixel according to the category represented by the nearest Gaussian component, which is denoted by the smallest distance.

$$G(x_u) = \sum_i e^{-d_i^2} \tag{9}$$

For every iteration, of the previously labeled pixels and add new pixels to them if their probability is above a predetermined level based on our model's predictions, storing them within an information mask M for each iteration. During this iterative approach, the number of pixels in our masks will continue to increase, which in turn will produce fewer errors and noise concerning our segmentations by building a larger dataset from all labeled pixels throughout each iteration. Moreover, to enhance the detection of boundaries, which are significant for the precise diagnosis of hair and scalp issues, present an RGB-Edge Fusion module that uses edge guidance. The module incorporates edge feature maps into RGB feature maps, which facilitates the model to correctly separate complex areas, such as the border of the hairline, and scalp lesions. The process of fusing edge and RGB features is defined as:

$$f_{re} = GAP\left(conv^{3*3}\left(cat(f_{rgh}, f_{edge})\right)\right) \tag{10}$$

Conv is an operation of $3X3$ convolution, cat refers to concatenation, and GAP is the abbreviation of Global Average Pooling. The features fused together will then flow into a Spatial Attention Mechanism, which will allow for the most relevant feature sets to be used when segmenting. To make this happen, the output Fused Feature Vector F_{u} is generated from the concatenated and pooled data as follows:

$$f_u = cat\left(conv^{1*1}(f_{re}), conv^{1*1}(f_{rgb})\right) \tag{11}$$

The model is created with a loss function that takes into account all losses, including self-supervised lossesL_{i}, weakly-supervised lossesL_{v}, Contrast LossesL_c, and Fusion LossesL_f. Thus, the complete loss will be calculated as:

$$L_{total} = L_{self} + L_{weak} + L_{con} + L_{fusion} \tag{12}$$

This loss function facilitates the learning of accurate pixel-level labels by guiding the boundary detection process, which is essential for identifying different regions such as, hair follicles, scalp lesions, and areas of healthy scalp.

IV.3 DATA AUGMENTATION- PROGRESSIVE GROWING GAN

Exploiting hair diagnosis and scalp disorders using PG-GAN learns to organize and present the image structure in both stable and incremental. Initially, training begins on a very low-resolution (4×4) where the generator capture the larger structure of scalp characteristics. While training, additional layers are added to the Generator and Discriminator until reaching the highest resolution of 1024×1024 which allow the model to learn about smaller Clinical detail such as scaling edges, follicular openings, erythema, lesion contours. The incremental style of approach provides for stability in adversarial learning and helps reduce the computational burden on the systems as a result of the fact that most of the training iterations happen at smaller resolution images, before transitioning into larger resolution images with their full detail. In addition, the approach provides for generating highly realistic and diverse images of scalp images and captures the finer textures and complex interactions between hair and skin that are so important for the Dermatological evaluation process. Once the generator has been trained to generate images at the highest available resolution, it produce images to support data augmentation, super-resolution enhancement of trichoscopy images, and domain adaptation between different imaging environments, thus creating strong automated systems for consistently and accurately diagnosing hair and scalp disorders.

IV.4 CLASSIFICATION- VGG-DINAT

In diagnosing scalp and hair problems, the deep Convolutional Neural Network (CNN) known as VGG-19 has many potential uses for trichoscopic imaging such as identifying a variety of scalp and hair conditions. The 19-layer architecture of VGG-19 is comprised of 16 convolutional layers that extract features and 3 fully connected layers that provide classification. The convolutional parts of VGG-19 identify many types of features, including follicular openings, scalp texture, and hair distribution. The final fully connected layers then classify each previously extracted feature as being part of either a normal or diseased scalp. By using the max-pooling layers to reduce dimensionality, VGG-19 prevents the overfitting problem and promotes generalization. The equations used to calculate the output from the convolutional layers can be defined in the following manner,

$$C_j^l = \varphi\left(\sum_{i=1}^{M^{l-1}} C_i^{l-1} \times k_{ij}^l + b_j^{l-1}\right) \tag{13}$$

For C_j^l which is the output feature of the $j-th$ filter from the $l-th$ layer, $\varphi(x)$ represents an activation function (usually ReLU), k_{ij}^l is the convolution kernel, and b_j^{l-1} is the bias term. After calculating the outputs of all filters in a given layer, the next step is to use a max-pooling layer to reduce the dimensions of the resulting feature maps. Finally, the final layer of VGG-19 uses the features extracted from prior steps and classifies each feature using a softmax function to determine whether or not they belong to each of the conditions identified by VGG-19. Using a layered neural net structure in combination with functions such as ReLU and dropout layers allows for training with identified images that illustrate conditions affecting both hair and scalp and learning detailed characteristics from layers of the network. The automated classification of images in this way gives dermatologists a useful tool for diagnosing patients' hair and skin problems based on photographic evidence. The DiNAT has the potential to accurately perform diagnoses on scalp and hair disorders with its unique ability to be able to take into account both long distance spatial relationships and local distinct features of images. The DiNAT architecture would then process as input the token vector representation of the input images of the scalp and hair, and then use the DiNAT architecture to locate similar patterns found in scalp and hair disorder based on alopecia, seborrheic dermatitis, and psoriasis. Enchanting an input image $X \in R^{n \times d}$ is the number of image patch and will determine the dimension of the feature vector for every image. Through calculating the attention weights based upon the neighborhood tokens, DiNAT identifies the corresponding images associated with the scalp area by grouping and linking the images depending on their spatial proximity to one another, helping the model capture the relationship between the images, helping to locate key of importance to the diagnosis process. The structure of VGG-DiNAT is illustrated in Figure 3.

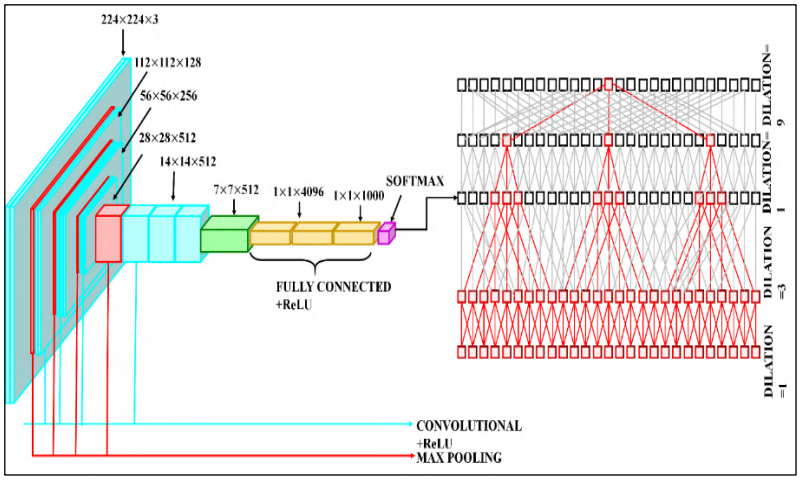

Figure 3: Architecture of VGG-DiNAT.
Source: Authors, (2026).

Attention weights A_i^k for a given image i are calculated by multiplying the token's corresponding Q_i query projection with the image corresponding to k. In DiNAT, the dilation factor δ is then able to model long range dependencies in the form of neighbours which is chosen according to the dilated neighbor pattern. Each dilated neighbor $\rho_j^\delta(i)$ means the j^{th}nearest neighbour of the i^{th}token based on the condition$j\ mod(\delta)\ =\ i\ mod(\delta)$. Thus, each dilated attention weight $A_{k,\delta}^i$ be determined just like the original attention weights, just by applying the dilated neighbor patterns when selecting the dilated neighbours.

$$A_i^{(k,\delta)} = \begin{bmatrix} Q_i K_{\rho_1^\delta(i)}^T & + & B_{\left(i,\rho_1^\delta(i)\right)} \\ Q_i K_{\rho_1^\delta(i)}^T & + & B_{\left(i,\rho_2^\delta(i)\right)} \\ & \vdots & \\ Q_i K_{\rho_1^\delta(i)}^T & + & B_{\left(i,\rho_k^\delta(i)\right)} \end{bmatrix} \tag{14}$$

The dilated neighbouring values $V_i^{(k,\delta)}$ are calculated in the same way, later on, as they were computed above; however in this case, these dilated neighbouring values are inputted into DiNAT at the end of the process.

$$V_i^{(k,\delta)} = \left[V_{\rho_1^\delta(i)}^T \quad V_{\rho_2^\delta(i)}^T \ldots V_{\rho_k^\delta(i)}^T\right]^T \tag{15}$$

The DiNAT output for token i with neighbourhood size k and dilation factor δ. This method provides information about the dilated neighbours by capturing their local & long-range connections via their dilated neighbouring pixels, which are important for recognising & diagnosing scalp disorders.

$$DiNAT_K^\delta(i) = softmax\left(\frac{A_i^{(k,\delta)}}{\sqrt{d_k}}\right) V_i^{(k,\delta)} \tag{16}$$

By combining VGG-19 and DiNAT, which is used to properly diagnose scalp disorder conditions. The VGG-19 architecture allows for elaborate, deep feature extraction & enables to use the DiNAT attention mechanism to build a model that decodes both local & large-scale patterns in order to effectively diagnose hair and scalp disorders. This hybrid approach allows for high levels of recognition along accomplishment with automated health assessments of scalp images.

IV.5 RED-CROWNED CRANE OPTIMIZATION

The RCCO algorithm employs the behaviors of Red-Crowned Cranes such as foraging, avoiding danger, and roosting. In Hair and scalp disorders such as alopecia, psoriasis, and seborrheic dermatitis, the classification is optimised using RCCO, where a group of candidate solutions (Cranes) is generated randomly within the search space and represented as potential diagnostic models and iterated to find the optimal classification model. Each crane's position X_i is a possible solution in the search space, and its fitness $F(X)$ is calculated by the objective function, which directs the search towards finding the most precise and best model. The population is divided into random foragers, which search near the best solution and long-distance foragers which explore further away from the best solution. Random foragers adjust their positions based on the best solution they have found, while long-distance foragers move further. This dynamic is analogous to exploring many different types of hair and Scalp Images.

Table 1: Optimized values of RCCO.

Parameter	Meaning	Value
pop_size	Number of cranes (population size)	10
max_iter	Number of optimization iterations (how many times population evolves)	10

Parameter	Description	Search Range
Learning Rate (lr)	Step size for Adam optimizer	[1e−5, 1e−3]
Dropout	Regularization strength in dense layers	[0.2, 0.5]
Filters	Embedding dimension or number of feature channels	[16, 48]

Source: Authors, (2026).

The second aspect of the crane's life cycle is roosting, the behavior of cranes gathering together in a new location, is indicative of cranes learn from each other's experiences and the convergence of solutions move them to the optimal location. Mathematically, the position update for gathering is indicated by,

$$X_i(t+1) = X_i^0(t+1)C_3.r_3.\left(X_{home}^0(t+1)\right) - \left(X_i^0(t+1)\right) \tag{17}$$

Where, $X_{home}^0(t+1)$ is the updated habitat C_3 is the time varying coefficient and r_3 is the random factor, directing the cranes towards the best location discovered. The dance of cranes is the interaction of the top two fitness values, the best and second best further refining their location and behavior through interaction, similar to two paired cranes move together synchronously in flight. This is indicated by,

$$X_i'(t+1) = X_i(t) + u.\left(r_4.X_{first}(t) - X_i(t)\right) \tag{18}$$

$$X_i''(t+1) = X_i(t) + u.\left(r_4.X_{second}(t) - X_i(t)\right) \tag{19}$$

The value for u is selected at random from a Gaussian distribution, r_4 is a deviation coefficient, $X_{first}(t)$ and $X_{second}(t)$ are the first two solutions. Evaluation of the fitness of a solution is key to steering the search towards finding the best possible diagnostic model, which is progressively being developed through these behaviours. The flowchart of VGG–DINAT WITH RCCO is depicted in Figure 4.

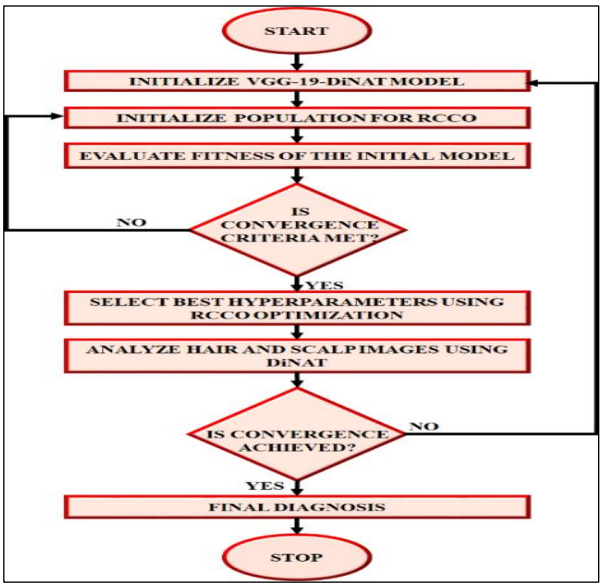

Figure 4: Flowchart of VGG–DINAT WITH RCCO.
Source: Authors, (2026).

The nature of the computational complexity allows for effective searching and refining of the solutions during the optimization phase. Finally, RCCO assist in identifying the best possible diagnostic models for diagnosing hair and scalp disorders by combining techniques of exploration, exploitation and convergence based on the natural behaviours of red-crowned cranes. The output provide information on all scalp disease and hair disease, such as alopecia and seborrheic dermatitis. Combining the deep feature extraction of VGG-19, the attention mechanism of DiNAT, and the Optimization of RCCO provides an extremely effective and flexible method to solve this diagnostic task.

V. RESULT AND DISCUSSION

The proposed system makes use of an extensive Hair and Scalp Disease Dataset consisting of different clinical images portraying 14 distinct classes of hair and scalp diseases. The dataset incorporates several pathways with unique visual presentation differences, enabling the framework to learn fine-grained textural features as well scalp abnormalities at a broader level. Its diversity promotes effective model training for both segmentation and classification tasks. Within the dual-stream VGG-DiNAT architecture proposed in this paper, its wealth of data allows features to be learned from both local textural features and global scalp patterns. RCCO also helps to enhance classification accuracy by fully optimizing hyperparameter for each of the disease categories separately.

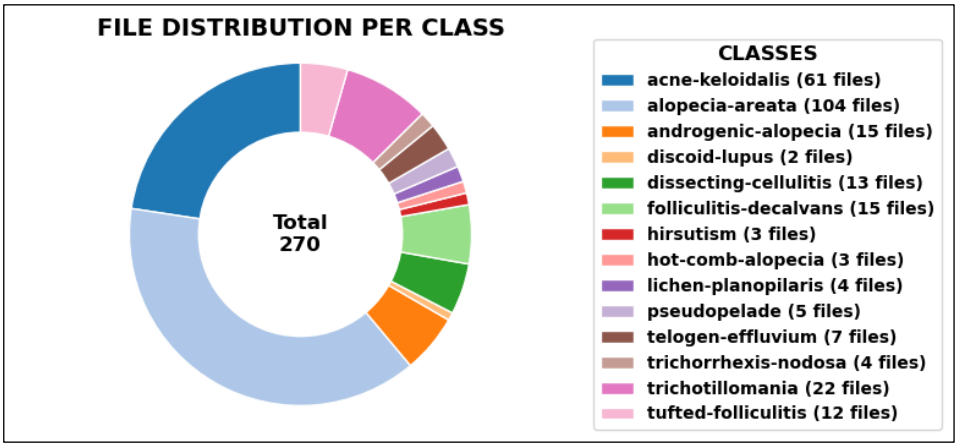

Figure 5: File distribution per class.
Source: Authors, (2026).

Figure 5 indicates that alopecia-areata and acne-keloidalis constitute the bulk of 270 total files, while most other scalp conditions exhibit a low number of files, and therefore an imbalanced class distribution.

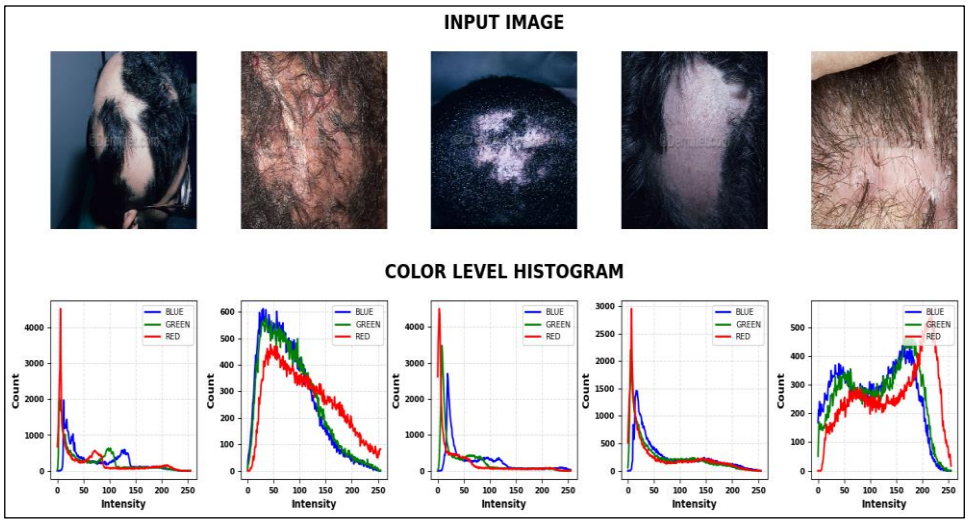

Figure 6: Input image with color level histogram.
Source: Authors, (2026).

Figure 6 displays several scalp images with the corresponding color-level histograms underneath the images. The histograms present the distribution of red, green, and blue image intensities to illustrate variations of brightness and color across each image - some images are more heavily black vs. red while other images appear with the wider range of intensity being balanced among the three colors.

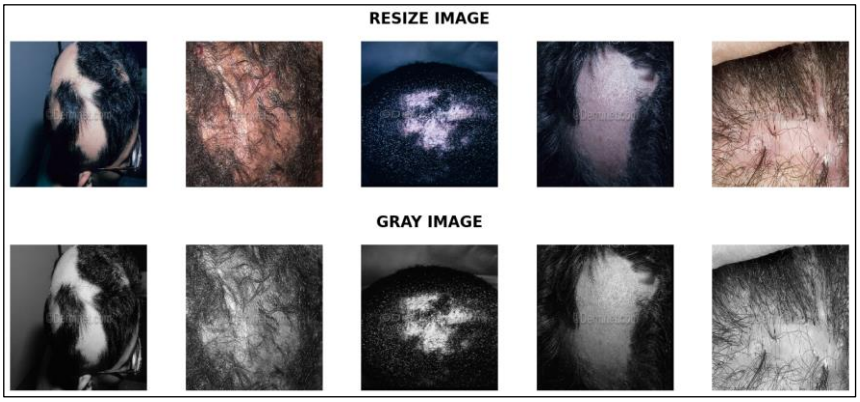

Figure 7: Resize image with gray image.
Source: Authors, (2026).

Figure 7 depicts a set of scalp images after a resizing process along with grayscale images corresponding to each image. Each grayscale version pairs with its color image to show the variation of texture and structure after the colors are removed, thereby making visual patterns more identifiable.

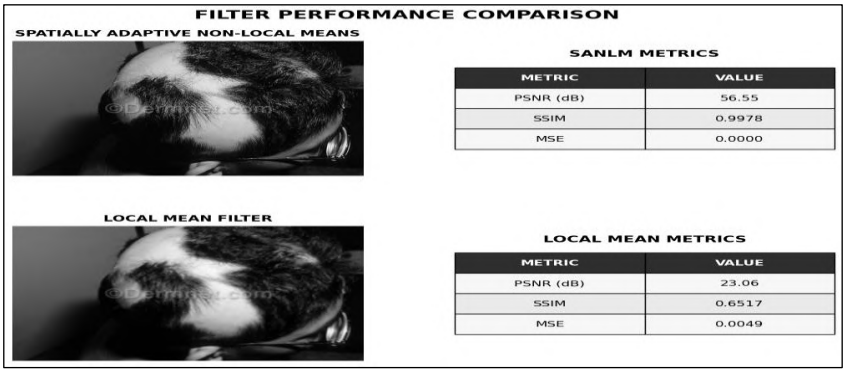

Figure 8: Filter performance comparison.
Source: Authors, (2026).

Figure 8 gives a direct comparison between two denoising filters that were applied to the same scalp photograph. The Spatially Adaptive Non-Local Means (SANLM) filter outputs a much clearer and clearer image with a very high PSNR (56.55 dB) which is much more than perfect SSIM (0.9978) and it has a 0 for MSE. The output of the Local Mean Filter is noticeably blurry with a significantly lower PSNR (23.06 dB) and a lower SSIM (0.6517) with a higher MSE. Overall, the image illustrates that detail and accuracy is conserved with the SANLM.

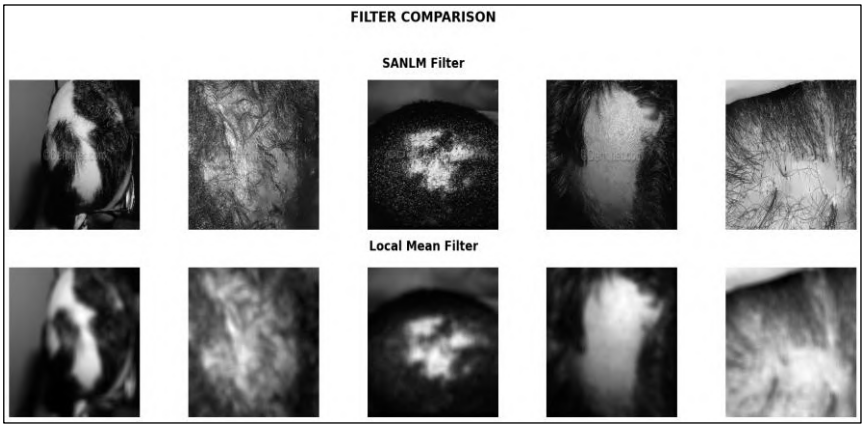

Figure 9: Filter comparison.
Source: Authors, (2026).

Figure 9 displays side-by-side visual comparisons of two different filtering approaches in scalp images taken at close-up view. The upper row shows outputs produced by the SANLM filter, which maintains fine hair detail, texture, and edge detail much better from the original visuals. The lower row shows the same images processed by the Local Mean Filter, which is noticeably blurrier and loses structural detail in the images. Ultimately, the comparison emphasizes the SANLM filter's much better ability to maintain sharpness and a natural texture while performing denoising.

METRIC COMPARISION

IMAGE 1

Metric	SANLM	Local Mean
PSNR(dB)	50.24	22.34
SSIM	0.9910	0.5982
MSE	0.0000	0.0058

IMAGE 2

Metric	SANLM	Local Mean
PSNR(dB)	34.00	18.25
SSIM	0.9359	0.1419
MSE	0.0004	0.0150

IMAGE 3

Metric	SANLM	Local Mean
PSNR(dB)	41.45	19.74
SSIM	0.9565	0.3584
MSE	0.0001	0.0106

IMAGE 4

Metric	SANLM	Local Mean
PSNR(dB)	39.60	23.07
SSIM	0.9480	0.3361
MSE	0.0001	0.0049

IMAGE 5

Metric	SANLM	Local Mean
PSNR(dB)	40.13	17.48
SSIM	0.9720	0.1671
MSE	0.0001	0.0179

Figure 10: Comparison metrics.
Source: Authors, (2026).

Figure 10 shows a row of metric tables comparing the output of the SANLM filter performance as compared to the Local Mean filter in each of several test cases. In every table, the SANLM filter achieved far higher PSNR and SSIM values, as well as a dramatically lower MSE, meaning it kept much better image quality and structural detail. In contrast, the Local Mean filter performed poorly, with lower clarity and more reconstruction error.

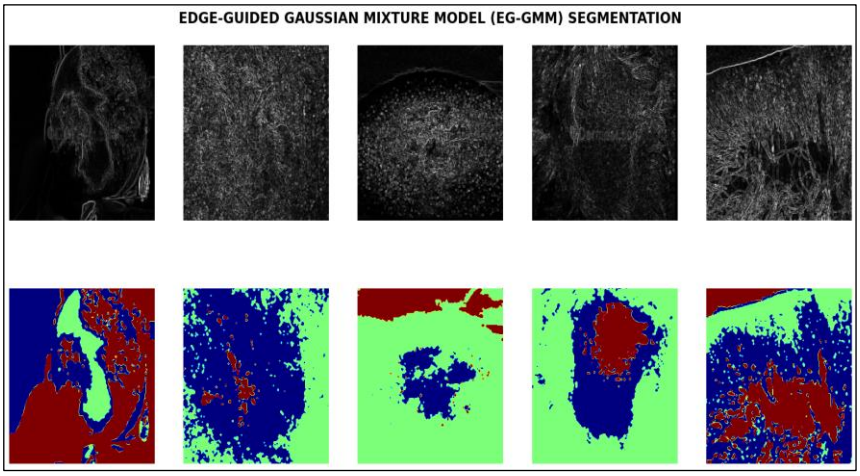

Figure 11: EG-GMM segmentation model.
Source: Authors, (2026).

Figure 11 shows original grayscale structural images on the upper row and the EG-GMM color-coded segmentation results of each image on the lower, with separate areas indicated by edginess and differing intensities.

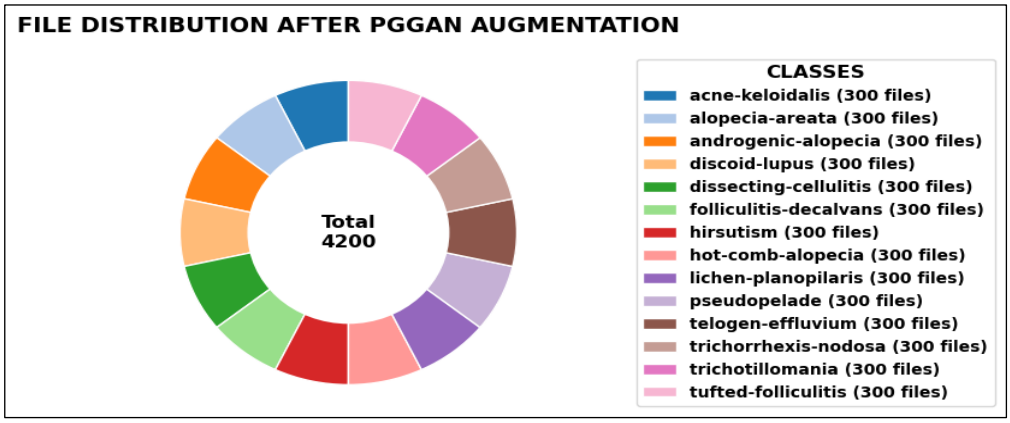

Figure 12: File distribution after PGGAN augmentation.
Source: Authors, (2026).

Figure 12 displays a donut graph illustrating the sample distribution after the PGGAN augmentation process, for a total of 4200 samples. Each of the 14 medical imaging classes has 300 augmented samples, which are categorized in a unique, colored section around the donut chart. On the right, there is a legend to describe the full list of classes. In summary, after the process of augmentation, there is a balanced dataset of varied medical imaging classes.

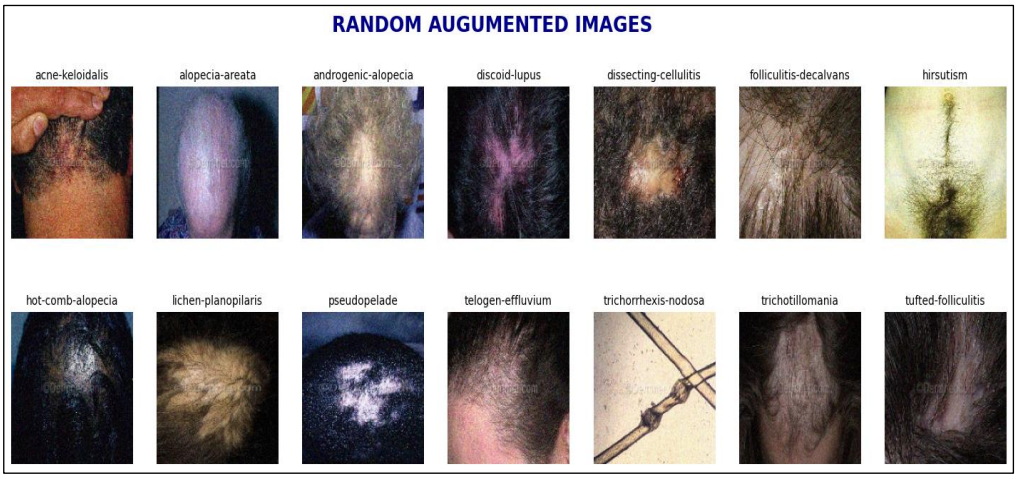

Figure 13: Random augmented images.
Source: Authors, (2026).

Figure 13 shows the set of randomly selected images of augmented scalp and hair conditions, with the corresponding class label. The images depict a variety of textures, colors, and patterns, produced through augmentation, depicting the visual diversity of such hair- or scalp-related conditions for instance, alopecia, folliculitis, dermatitis, and other scalp and hair conditions.

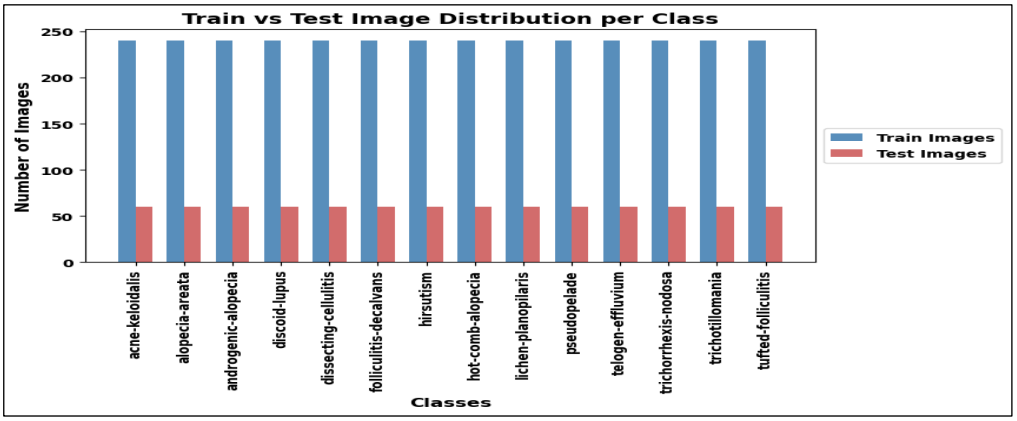

Figure 14: Train vs Test image distribution per class.
Source: Authors, (2026).

Figure 14 illustrates the number of training and test images across the hair- and scalp-related conditions in the dataset. All classes depict a balanced distribution with approximately 240 training images and about 60 test images per augmented class. Each of the medical imaging classes such as acne-keloidalis, alopecia-areata, trichotillomania, and tufted-folliculitis are evenly-distributed and well-balanced across the dataset.

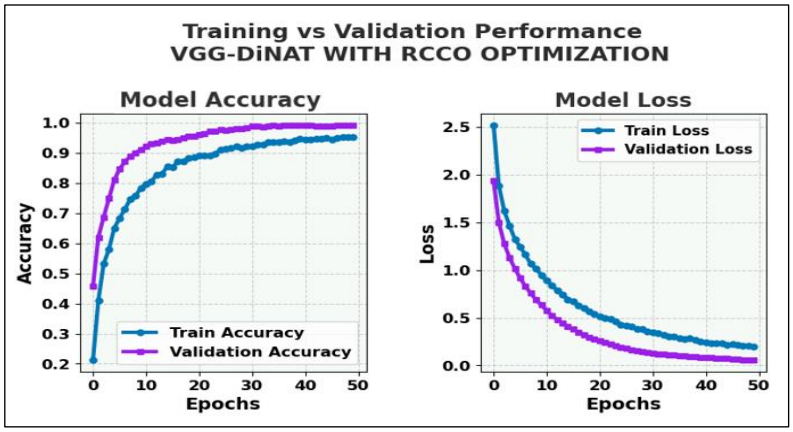

Figure 15: Training vs validation performance of VGG-DiNAT with RCCO.
Source: Authors, (2026).

Figure 15 indicates steadily improving accuracy, and a decreasing loss with training and validation. Throughout the training, the validation performance is slightly higher, indicating that the model is learning to generalize without any excessive overfitting.

Table 2: Classification metrics of VGG- DiNAT with RCCO.

METRICS	SCORE
Accuracy	0.9929
Macro Precision	0.9929
Macro Recall	0.9929
Macro FI-Score	0.9929
Weighted Precision	0.9929
Weighted Recall	0.9929
Weighted FI-Score	0.9929
Balanced Accuracy	0.9929
Cohen’s Kappa	0.9923
Matthews CorrCoef	0.9923

Source: Authors, (2026).

Table 2 shows the VGG–DiNAT model with RCCO which demonstrates remarkable performance, attaining 0.9929 across accuracy, precision, recall, F1-score, and balanced accuracy - this score indicates that the model can classify the three classes in a highly reliable and consistent manner. Furthermore, Cohen's Kappa and MCC were also 0.9923, further demonstrating the model's agreement and recounting other capability positively predicts class membership, showing strong robustness.

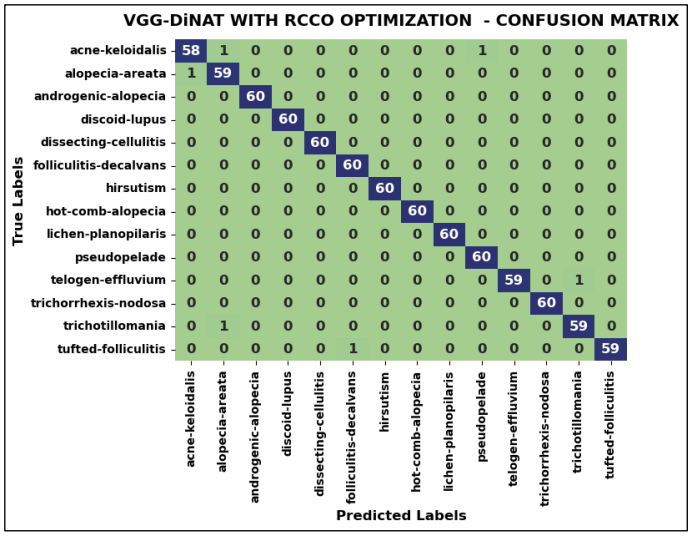

Figure 16: Confusion matrix of VGG-DiNAT with RCC optimization.
Source: Authors, (2026).

Figure 16 presents the confusion matrix for a model VGG-DiNAT with RCCO Optimization. The confusion matrix explains the accuracy of the model differentiating the different classes, in this case, hair loss or scalp conditions. The diagonal values highlight the number of correct predictions for each of the classes, and most of the classes in the diagonal have a value of 60. These values indicate that the model is performing as anticipated, as the vast majority of predictions match the true labels. The green and blue colors help identify these predicted true positive values.

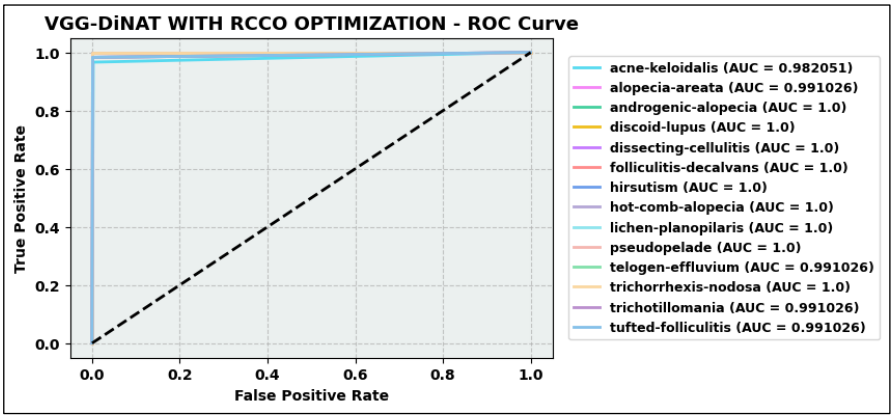

Figure 17: ROC curve of VGG-DiNAT with RCC optimization.
Source: Authors, (2026).

Figure 17 shows the ROC curve for VGG-DiNAT with RCCO Optimization model. The ROC curve has different lines for each class, and the AUC values are displayed for each class also. Most classes have an AUC of 1.0 indicating a perfect classification and only the acne-keloidalis class has an AUC of 0.982 showing it to be slightly below perfect classification. The curve is situated closely to the top left corner, indicating that the model has high accuracy and low false positives.

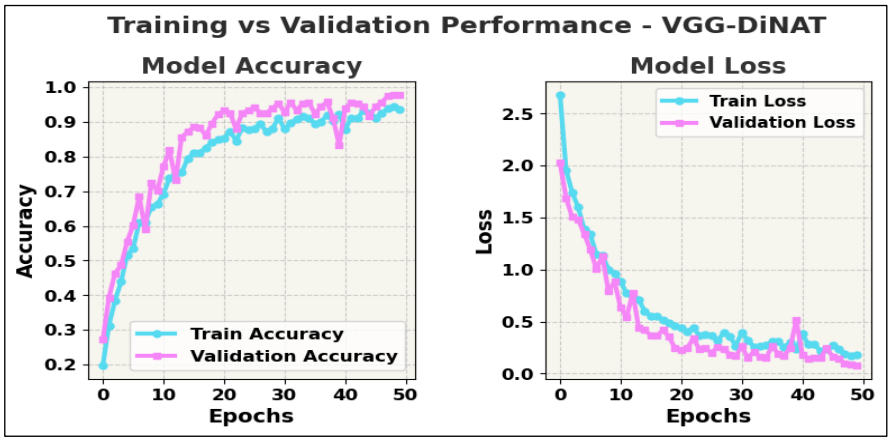

Figure 18: Training vs Validation performance of VGG-DiNAT.
Source: Authors, (2026).

Figure 18 depicts the training and validation performance of the VGG-DiNAT model for 50 epochs. The accuracy plot indicates a gradual increase in training and validation accuracy, ultimately exceeding 0.9, suggesting that the model was learning aggressively and generalizing well. The loss plot shows a steady decrease in both training and validation loss, and they align closely, indicating no overfitting and the model is stable across training and validation sets.

Table 3: Classification metrics of VGG- DiNAT model.

METRICS	SCORE
Accuracy	0.9774
Macro Precision	0.9776
Macro Recall	0.9774
Macro FI-Score	0.9772
Weighted Precision	0.9776
Weighted Recall	0.9774
Weighted FI-Score	0.9772
Balanced Accuracy	0.9774
Cohen's Kappa	0.9756
Matthews CorrCoef	0.9757

Source: Authors, (2026).

Table 3 shows the VGG-DiNAT model that produced consistent classification performance characterized by accuracy, precision, recall, and F1-scores, each averaging around 0.977. The macro and weighted averages indicate equally good performance across classes, suggesting that predictions are reasonably balanced. The value obtained for the Cohen's Kappa (0.9756) and Matthews Correlation Coefficient (0.9757) indicates strong agreement with true labels, thus suggesting that the model is reliable and robust.

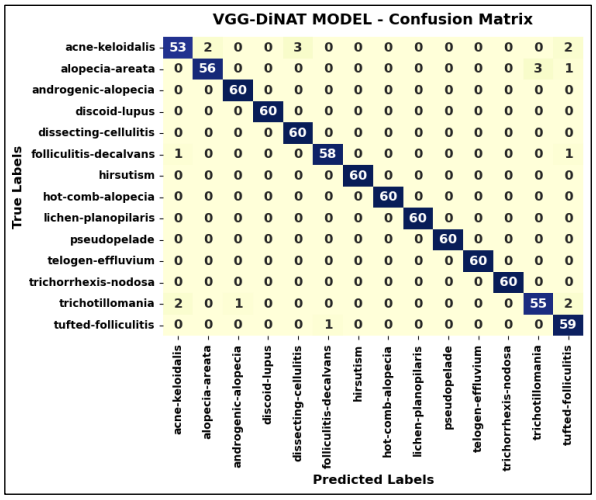

Figure 19: Confusion matrix of VGG-DiNAT model.
Source: Authors, (2026).

Figure 19 illustrates the confusion matrix that indicates the performance of the VGG-DiNAT model to classify the hair and scalp conditions. The model exhibited better performance, as most predictions lie along the diagonal, there were instances of misclassification, specifically androgenic-alopecia predicted as acne-keloidalis. Overall, the model indicates a high level of accuracy for skin condition prediction.

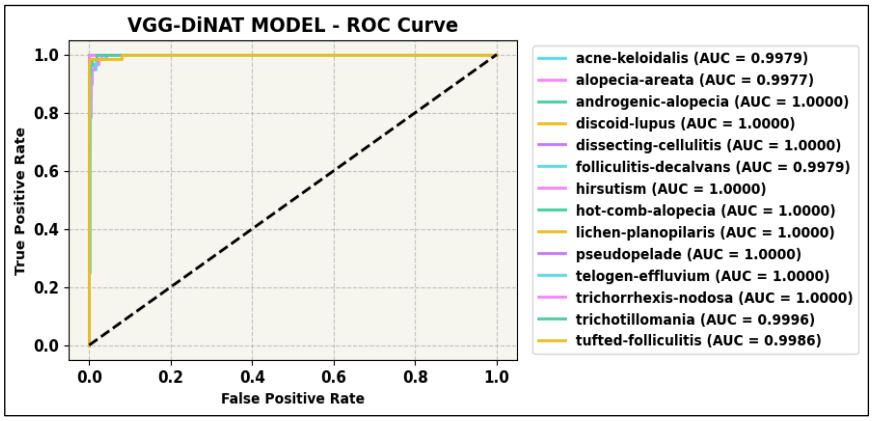

Figure 20: ROC curve of VGG-DiNAT model.
Source: Authors, (2026).

Figure 20 provides a summary of the ROC curve for a VGG-DiNAT model used to classify different hair and scalp conditions. All classes have very high AUC scores, indicating excellent performance in the classification of hair and scalp conditions across all circumstances.

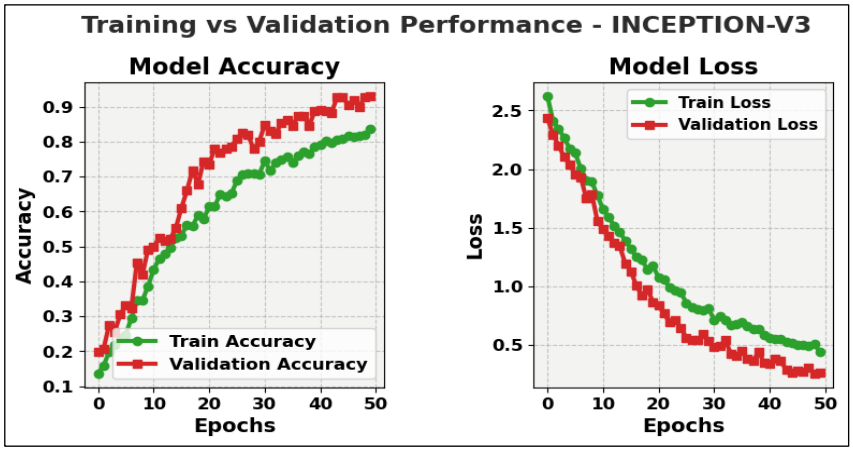

Figure 21: Training vs validation performance of Inception V3.
Source: Authors, (2026).

Figure 21 detail the training and validation of performance of an Inception-V3 model across 50 epochs. Both the accuracy curves trend upwards, and validation accuracy stays consistently above training accuracy, reaching above 0.9. The loss curves for training and validation are both declining at a smooth rate, with validation loss staying slightly below training loss throughout the epochs.

Table 4: Classification metrics of Inception V3 model.

METRICS	SCORE
Accuracy	0.9310
Macro Precision	0.9322
Macro Recall	0.9310
Macro FI-Score	0.9300
Weighted Precision	0.9322
Weighted Recall	0.9310
Weighted FI-Score	0.9300
Balanced Accuracy	0.9310
Cohen's Kappa	0.9256
Matthews CorrCoef	0.9259

Source: Authors, (2026).

Table 4 model shows strong and steady performance of approximately 93% accuracy, with comparable precision, recall, and F1-scores. The elevated Cohen's Kappa and Matthews Correlation Coefficient indicate reliability and a well-balanced range of the predictions across classes.

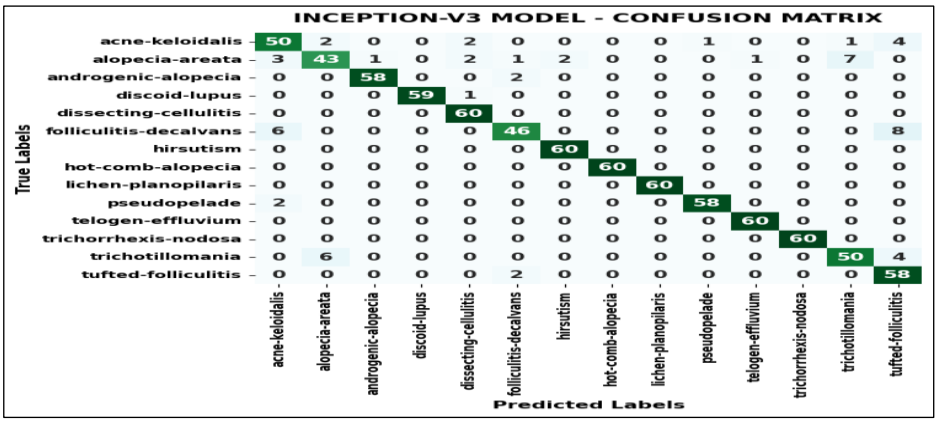

Figure 22: Confusion matrix of Inception V3 model.
Source: Authors, (2026).

Figure 22 shows the confusion matrix which illustrates that the Inception-V3 model is able to correctly classify the majority of samples in all categories, with clustered diagonals suggesting strong levels of accuracy. Only a small portion of misclassified categories appear across visually similar conditions, but overall, the confusion matrices suggests that the performance across classes are reliable and consistent.

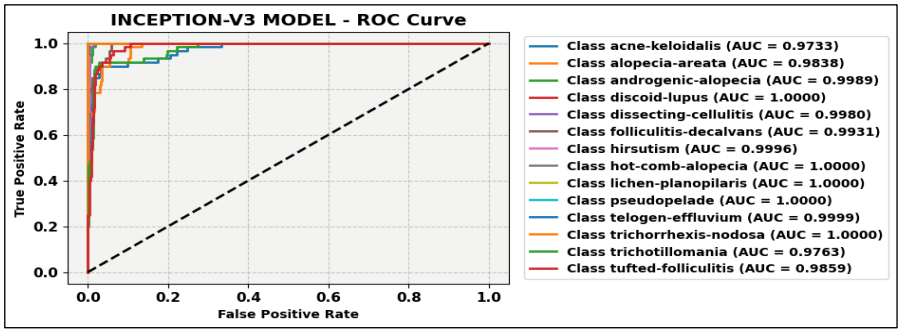

Figure 23: ROC curve of Inception V3 model.
Source: Authors, (2026).

In Figure 23, the model demonstrates excellent discriminative performance across classes, as indicated by near-perfect values across AUC and ROC curves clustered near the top-left corner of the examination.

Table 5: Classification metrics of proposed and existing model.

Model	Accuracy	Precision	Recall	FI-Score
PROPOSED	0.9929	0.9929	0.9929	0.9929
VGG-DiNAT	0.9774	0.9776	0.9774	0.9772
Inception V3	0.931	0.9322	0.931	0.931

Source: Authors, (2026).

Table 5 provides a comparison of the three models' classification metrics. The PROPOSED model has achieved the highest rating of 99.3% across all metrics. The VGG-DiNAT model is rated next at 97.7%, and the Inception-V3 model showed the worst performance with 93% accuracy, precision, recall, and F1-score.

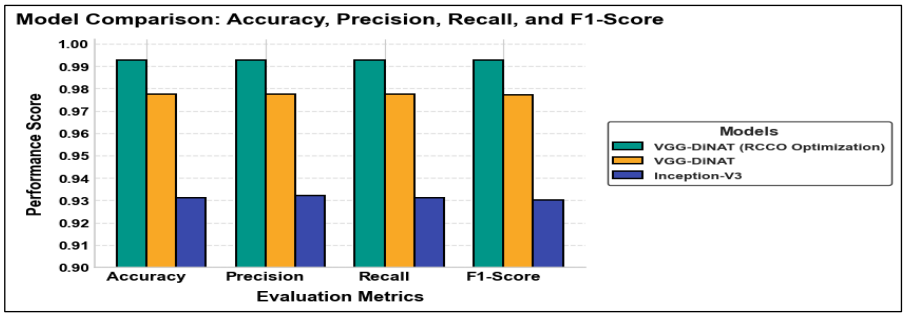

Figure 24: Comparison of evaluation metrics.
Source: Authors, (2026).

Figure 24 provides a comparison of three models using the different metrics of accuracy, precision, recall, and F1-score. The VGG-DiNAT (RCCO Optimization) model performs the best, with scores just under 0.99. The standard VGG-DiNAT model performs next highest, with scores between 0.97 and 0.98, and the Inception-V3 model showed lowest performance around 0.93 for the three models.

Table 6: Comparative analysis of accuracy for various models.

Model	Accuracy
CNN [22]	0.911
ViT-B/16 [23]	0.823
ANN [24]	0.964
HDM-Net [25]	0.948
VGG-16 [26]	0.945
Proposed	0.9929

Source: Authors, (2026).

In Table 6, the proposed model, achieves a maximum accuracy of 0.9929, higher than other models such as CNN (0.911), ViT (0.823) and VGG-16 (0.945) for diagnosing hair and scalp diseases. In the proposed system CNN is used to verify the accurate model of the proposed system which is used in the system to transfer the details from the given table

Table 7: Comparative analysis of precision for various methods.

Model	Precision
CNN [22]	0.895
ViT-B/16 [23]	0.831
ANN [24]	0.983
Proposed	0.992

Source: Authors, (2026).

In table 7 there are several models expected to yield different results based on their performance measure. A CNN has a Precision rating of 0.895, ViT-B/16 has a Precision of 0.831, and ANN has achieved a model precision of 0.983. The model developed by the Author in this study has the highest level of accuracy for identifying the True Positive class based upon its Precision score of 0.992.

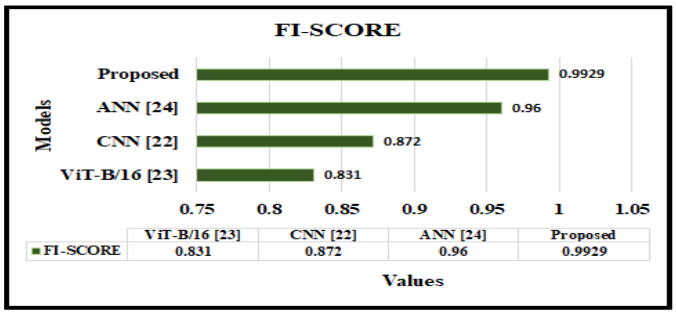

Figure 25: Comparison of FI-score for various methods.
Source: Authors, (2026).

A bar graph comparing the FI-SCORE value of four different machine learning (ViT-B/16, CNN, ANN, and a proposed) shown in Figure 25. The proposed model had a higher FI-SCORE than the others with an FI-SCORE of 0.9929. The second highest FI-SCORE was obtained by the ANN model with a value of 0.96 while CNN and ViT-B/16 both achieved lower FI-SCORE values at 0.872 and 0.831 respectively.

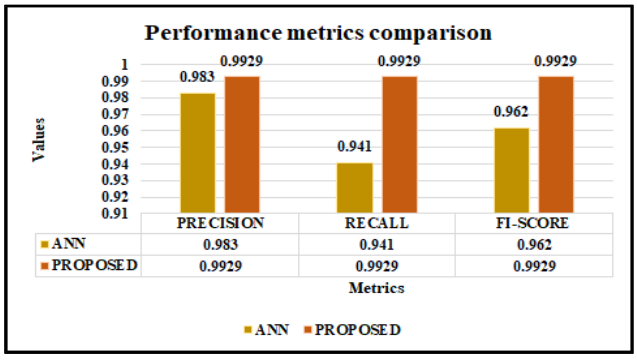

Figure 26: Comparative analysis of proposed and existing methods.
Source: Authors, (2026).

Compared to the ANN, the proposed model has superior performance across all metrics of measurement which is illustrated in Figure 26. In addition, the Proposed Model's Precision (99.29%) and F-1 Score (99.29%) both outperform the ANN (98.3% Precision and 96.2% F-1 Score), while they have equal Recall (94.1 % Recall).

VI. CONCLUSION

The proposed approach enhance both the accuracy and speed with which users classify the input images. To accomplish this, the process involves a number of clearly defined phases. The first phase in this process will be an input dataset of raw images that require processing. The first stage of the process is accomplished using a SANLM approach, which provides significant denoising and enhancement of image quality to prepare the data for further analysis. The next step involves segmenting the images into identifiable regions using EG-GMMs. The third stage of the process is data augmentation, involves using a PGGAN to create additional training data for the model in order to expand the size of the dataset and improve robustness through reducing overfitting. The fourth step of the process will utilize a VGG-DiNAT architecture based DL model for the classification of the images based upon extract features. The performance of the model will be enhanced through hyperparameter tuning using RCCO methodology to maximize efficiency of the system. The proposed system is implemented in python and achieves the highest accuracy, precision, Recall and FI-Score of 0.9929.

ABSTRACT

The accurate identification of nail-fold capillaries is essential for the early detection of systemic diseases such microvascular abnormalities and systemic sclerosis. The complexity of capillary design and variations in image quality present significant challenges for precise identification in automated detection systems. An enhanced Deep Learning (DL) architecture that incorporates morphological preprocessing, shape-based feature enhancement, and a robust object recognition foundation. To emphasize essential vascular features, shape focus and extraction modules are performed after input images have previously undergone preprocessing with morphological filters to decrease noise and maintain capillary structures. YOLOv12 is utilized to accomplish the detection task using an enhanced backbone architecture based on Residual-Expanded Layer Aggregation Network (ReLAN), which improves feature reuse, gradient flow, and spatial representation. While significantly improving detection accuracy, this backbone maintains real-time functionality. To provide transparency and clinical reliability, the system makes use of Explainable AI (XAI) tools, especially saliency heatmaps, which highlight the critical areas influencing model predictions and provide interpretability for medical experts. The proposed approach achieves the highest accuracy of 88%, 90% of precision, 89% of recall, 86% of map-50 and 88% of map50-95. These results of the experimental evaluation demonstrate that a reliable and understandable solution for nail-fold capillary detection in clinical applications were achieved using the proposed approach.

I. INTRODUCTION

The microvascular structure in nail-fold capillaries is capable of being directly and noninvasively assessed using Nail-Fold Capillaroscopy (NFC), a conventional technique for health evaluation. In order to sustain microcirculation and enable material exchange throughout the body, microvascular integrity is essential. According to earlier research, microcirculatory alterations result from conditions like diabetes, rheumatoid arthritis, Raynaud's phenomenon, and systemic sclerosis (SSc) [1]. SSc is a disease caused by vascular lesions and autoimmune disorders that limit blood flow and induce organ fibrosis throughout the body. NFC is a non-invasive, easy-to-use, and economical method that offers vital information on microvascular anomalies in living tissues. In the past, the NFC has been used to investigate the microvascular changes in nail-fold capillaries linked to different rheumatologic disorders. The growing body of research on NFC in rheumatic disorders demonstrates the technique's effectiveness in clinical settings as well as the variety of research applications.

Additionally, the NFC has been useful in studying other systemic conditions including schizophrenia and diabetes mellitus that are marked by changes in capillary architecture [2-4]. The nail-fold bed's microvascular involvement is a reflection of the body's general microvascular damage and is directly correlated with the target organs' involvement. In addition to enabling the early diagnosis of connective tissue diseases, primarily SSc by differentiating between primary and secondary Raynaud's phenomenon, NFC also offers information on the disease's prognosis based on the degree of target organ damage in these conditions18. Nail-fold capillary abnormalities occur in 70–80% of SSc patients and 9–27% of non-SSc individuals, respectively [5-7]. The NFC method captures precise images of nail-fold capillaries using a capillaroscope. Following the acquisition of these images, clinicians use their critical experience to visually analyze and manually measure a variety of factors, such as the existence of dilated capillaries, capillary morphology, and capillary density, which is measured as the number of loops per millimeter [8]. Although this clinical analysis, which is motivated by their experience, is essential, it is still very difficult to provide uniform and standardized assessments among healthcare providers. Although attempts have been made to automate capillary image analysis, results have not yet improved due to capillary size variability [9-11]. This variation in size restricts the training of machine learning models and ultimately leads to less-than-ideal prediction performance, which cause patients to receive a delayed or incorrect diagnosis [12]. The present research proposed an improved deep learning-based technique for automated nail-fold capillaroscopy image processing in order to overcome this restriction.

This method used object detection algorithms to automatically identify and categorize the morphology of individual nail-fold capillaries, which are important characteristics for medical diagnostics in general and early SSc diagnosis in particular since they indicate the involvement of internal organs [13-15]. Additionally, the proposed method's improved deep learning framework demonstrated that it could identify capillaries in multi-scale, untrained microscopic images. This research work includes preprocessing, model selection and explainable AI stages to evaluate the process for the detection of real time nail-fold capillaries. In order to discover nail-fold capillaries, the image is prepared and refined using preprocessing techniques such shape focus, shape extraction, and morphological filtering, which facilitate the identification and analysis of capillary structures. These procedures are intended to attract attention to the pertinent shapes, improve the image quality, and increase the precision and effectiveness of capillary identification [16-18]. The preprocessed image is then fed to model selection stage where it is capable of accurately identifying and localizing capillary structures in microscopic images [19]. While conventional DL models are capable of detecting nail-fold capillaries that are often suffer from limitations such as restricted accuracy, poor generalization across diverse image qualities and difficulty in capturing the intricate vascular structures and variations present in capillary patterns and table 1 illustrates the DL methods to detect nail-fold capillaries [20].

Table 1: Related works for DL methods to detect Nail-fold capillaries.

S. No	Author/ Year	Methodology	Merits	Demerits	Performance metrics
1.	Hao Yin et al [2023] [21]	YOLO v5	• It leverages the strength of DL to automatically identify small and complex vascular structures. • It is suitable for both clinical and research applications.	• The model's performance decreases, when dealing with overlapping, blurred or low-contrast capillaries and it requires high quality annotated datasets for optimal training	YOLOv5 attains an accuracy of 85.2%.
2.	Vincenzo Taormina et al [2023] [22]	Faster R-CNN	• It increases image clarity by boosting contrast and supressing noise, which is critical for highlighting the delicate and fine structures of nail-fold capillaries. • It reduces the need for manual intervention, enhances reproducibility and supports more objective clinical evaluations.	• The computational complexity of Faster R-CNN makes the process slower and more resource-intensive compared to single stage detectors.	The method achieves an accuracy of 96.2%
3.	Shupin Chen et al [2023] [23]	U-Net	• It provides an effective approach for accurately delineating capillary structures in microscopic images. • It allows for precise pixel-level segmentation capturing both global context and fine details of the capillary loops.	• The model's performance heavily depends on the availability of high-quality, annotated datasets and it is not generalize well to images captured under different imaging conditions.	The performance metrics of U-Net accomplishes an accuracy of 94.1%
4.	Chiara Filippini et al [2021] [24]	CNN	• CNNs are capable of learning hierarchical features directly from images, enabling them to detect subtle morphological changes in capillaries that is used to indicate microvascular diseases. • It reduces the reliance on manual assessment, minimizes observer bias and allows for rapid and objective analysis.	• It requires high quality datasets for effective training and limited data led to overfitting for new patients or imaging conditions.	CNN attains an accuracy of 86%
5.	Indriani et al [2025] [25]	ResNet	• It allows the network to learn intricate vascular patterns and subtle capillary abnormalities with high precision. • It improves diagnostic consistency and reduces manual intervention by clinicians.	• The architecture is computationally intensive, requiring high memory and processing power, which limit its use in real-time diagnostic systems.	The performance of ResNet is 87% of accuracy, 88% of precision and recall, and 86% of FI-score.

Source: Authors, (2026).

Existing DL methods to detect nail-fold capillaries have various limitations, hence the proposed YOLOv12-ReLAN model is implemented, which allows for precise detection of individual capillaries, abnormal loops and morphological changes that are indicative of microvascular diseases. Next it is passed to Explainable AI tools, particularly saliency heatmaps, which emphasise the crucial areas impacting model predictions and offer interpretability for medical experts to ensure transparency and clinical reliability. The main objectives of this research includes:

- To develop an automated detection framework which identifies target features from input image dataset, an advanced DL technique is implemented.
- To enhance image quality and feature visibility, preprocessing operations such as shape focusing, shape extraction and morphological filtering is utilized.
- To achieve an optimal balance between detection accuracy and computational efficiency and for precise object detection, YOLOv12-ReLAN is employed.
- To analyze visual interpretation of model's decision-making process, ensuring transparency and reliability in predictions, an explainable AI, saliency heatmap is used.

II. PROPOSED SYSTEM DESCRIPTION

The proposed approach employs an enhanced deep learning framework to improve object detection accuracy by combining YOLOv12 with the Backbone R-ELAN architecture and explainable AI methods. Figure 1 displays the block diagram of the proposed method.

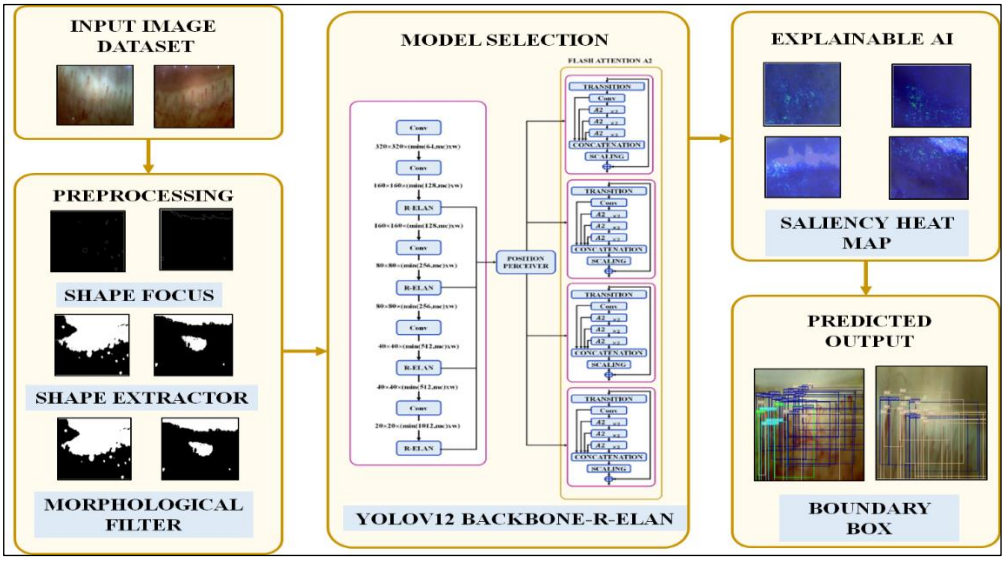

Figure 1: Block diagram of the proposed model.
Source: Authors, (2026).

The input image dataset, which forms the basis for the model's training and evaluation, is where the process commences. Several image improvement and feature refinement approaches, such as Shape Focus, Shape Extraction, and Morphological Filtering, are used during the preprocessing step. By highlighting important structural elements and eliminating unwanted noise, these methods ensure the model receives clear and instructive input data. The YOLOv12 Backbone-R-ELAN architecture is used in the Model Selection stage after the refined images have been preprocessed. This model was selected because of its excellent feature extraction capabilities, effective multi-scale object detection, and resilience when dealing with intricate image fluctuations. Then, to increase interpretability and reliability, the Explainable AI module is incorporated. It provides Saliency Heat Maps, which graphically depict the areas that have the most impact on the model's decision-making. Lastly, the system provides accurate localization and an understandable visual explanation of the detection process by outputting the Predicted Results in the form of Boundary Boxes surrounding the identified objects. Thus, the proposed method provides an effective and transparent DL framework for image-based object detection.

III. PROPOSED SYSTEM MODELLING

III.1 PREPROCESSING

Preprocessing is a crucial first step in the nail-fold capillary detection process that sets up the image for accurate analysis. The nail-fold region's fine capillary structures are enhanced and isolated during this phase using specific techniques.

III.1.1 Shape Focus

The nail-fold image's capillary-like structures are more visible due to the Shape Focus method. This stage seeks to emphasize the thin, elongated, and curved characteristics of capillaries while minimizing background noise and irrelevant data. This phase ensures that the crucial structural elements of capillaries are maintained and made more recognizable for further study by sharpening the emphasis on these particular forms.

III.1.2 Shape Extractor

The improved capillary forms are separated and identified from the image using the Shape Extractor process. This procedure focuses on possible capillary areas and then extracts those utilizing textural and geometric characteristics like continuity, length, and curvature. The capillary structures also be separated from the surrounding tissue. This stage's primary objective is to acquire precise depictions of the capillaries for additional processing and analysis.

III.1.3 Morphological Filter

An essential image processing step in nail-fold capillary detection is the morphological filter, which modifies the forms of capillary structures using computational morphological principles to improve their clarity and continuity. Morphology is concerned with the shape or structure of objects, and morphological filtering is especially helpful for improving segmented images by eliminating undesired noise or microscopic projections, filling in tiny holes or gaps, and smoothing out item outlines. Dilation and erosion are the basic processes in this process, and they both make use of a structural element a predetermined shape that dictates where the image is processed. In addition to these, morphological edge detection uses these basic operations such as erosion, dilation, opening, and closing to extract clear and defined edges of the capillaries. By applying the difference between the processed and the original image, the algorithm effectively highlights capillary boundaries. While erosion and dilation alone can enhance edges, they are less effective in filtering out noise; thus, opening and closing are preferred for achieving smoother, cleaner results. Overall, the morphological filter improves the visibility and accuracy of nail-fold capillary detection by refining the shape and connectivity of capillary structures while minimizing background artifacts.

III.2. MODEL SELECTION-YOLOV12-BACKBONE-R-ELAN

YOLOv12 is particularly proficient at detecting nail fold capillaries because it combines efficient feature extraction with precise localization in a single, end-to-end network. The backbone creates hierarchical feature maps by processing the input image through several convolutional layers. These feature maps capture both fine details, such as individual capillary loops, and more general spatial context, such as the overall arrangement of the nail fold. Because nail fold capillaries are very minute and may appear partially occluded, the network must identify subtle differences while keeping background, which makes these multi-scale feature maps crucial. The diagram of YOLOv12-BACKBONE-R-ELAN is depicted in figure 2.

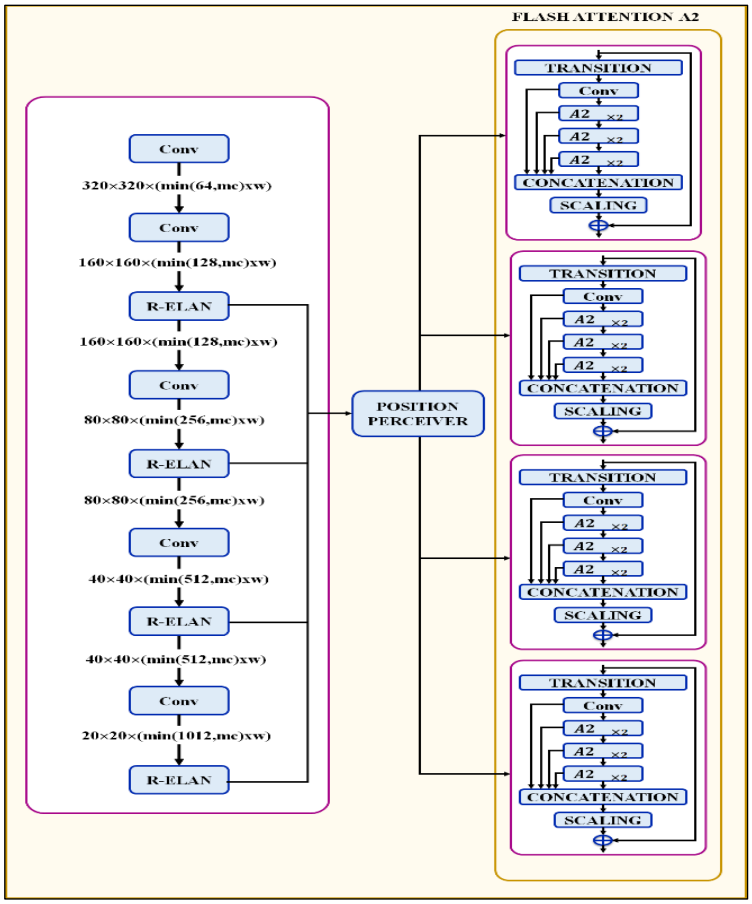

Figure 2: Diagram of YOLOv12-BACKBONE-R-ELAN.
Source: Authors, (2026).

The Residual Efficient Layer Aggregation Network (R-ELAN), which forms the backbone of YOLOv12, is intended to convert unprocessed image data into rich, multi-scale feature maps that constitute the basis for accurate object detection. Deeper residual connections are introduced by the R-ELAN structure to alleviate gradient bottlenecks in deep networks and encourage feature reuse. Pseudo-code of YOLOv12 backbone using R-ELAN is shown below,

Pseudo-code 1: YOLOv12 backbone- R-ELAN.

```
Parameters:
Input Image I(H, W, 3)
Output Feature Maps F3, F4, F5
1: For each epoch do:
      # Stage 1 – Initial Convolution Extraction
2:      For each convolutional layer Lc do:

17:     # Dimension of F3 = (H/8, W/8, 256)
# Stage 4 – Recursive ELAN Block 3 (High-level Features)
18:     F4 = R_ELAN(F3, 9 layers, 512)
19:     # Dimension of F4 = (H/16, W/16, 512)
      # Stage 5 – Recursive ELAN Block 4 (Deep Feature Extraction)
20:     F5 = R_ELAN(F4, 3 layers, 1024)
21:     # Dimension of F5 = (H/32, W/32, 1024)
      # Stage 6 – Multi-Scale Feature Output
22:     Output F3, F4, F5 to the Neck and Detection Head
23: End for
# R-ELAN Function
Function R_ELAN(input, layers, channels):
      Split input into X1, X2
      For i = 1 to layers do:
          Y = ConvBNAct(X2, 3×3)
          X2 = Concat(X2, Y)
      End for
      Output = ConvBNAct(Concat(X1, X2), channels, 1×1)
      return Output
End Function
```

This characteristic is especially useful for identifying nail-fold capillaries, which are tiny, delicate, and frequently partially obscured. The backbone guarantees that even the smallest capillary patterns are represented in the feature hierarchy by maintaining high-resolution spatial information across several scales. The network's convolutional blocks are defined as a series of smaller, parallel convolutions, formalized by the equation,

$$F_{out} = \sum_{i=1}^{n} W_i * F_{in} + b_i \quad (1)$$

Where, F_{out} is the feature map that is produced, W_i are the Convolutional filters, F_{in} is the input feature map, and b_i is the phrase for bias. Instead of using big, monolithic convolutions, our method divides processing across several lightweight kernels, enabling the network to effectively extract complex characteristics of nail-fold capillaries while preserving computational efficiency. YOLOv12 uses 7×7 separable convolutions in deeper layers to accurately recognize elongated or convoluted capillary structures without incurring excessive processing costs. These convolutions preserve spatial context with fewer parameters. Table 2 shows the enhancement in YOLOv12 backbone-R-ELAN for detecting nail-fold capillaries.

Table 2: YOLOv12 backbone-R-ELAN for detecting nail-fold capillaries.

Component	Functionality	Innovations in YOLOv12
Backbone-R-ELAN	Extracts detailed, fine- scale features from images of nail-fold capillaries which is crucial for detecting tiny, intricate capillary structures.	The innovations enhance the ability to detect small, detailed features like capillaries while preserving context, even in noisy or low resolution images. These innovations reduce computational cost, making the detection process more efficient.

Source: Authors, (2026).

Multi-scale feature pyramids, which produce feature maps at various resolutions, are used within the backbone to improve the detection of small structures. While lower-resolution maps capture contextual information across greater skin areas, high-resolution maps in the early layers capture fine-grained details of capillaries. Because capillaries can differ in size, density, and orientation, this multi-scale representation is crucial. Thus, YOLOv12's enhanced backbone R-ELAN architecture, which is strengthened by residual aggregation and controlled by the convolutional formulation mentioned above, offers a reliable framework for identifying nail-fold capillaries.

III.3. EXPLAINABLE AI –SALIENCY HEATMAP

Explainable AI (XAI) attempts to overcome the opaque aspect of deep learning models by making their decision-making process interpretable. To ensure reliability and clinical relevance in medical image analysis, such as the identification of nail-fold capillaries, it is essential to comprehend which picture regions contribute to the model's predictions. Saliency heatmaps are a popular XAI technique that effectively highlights the structures the model deems most significant by quantifying the impact of each input pixel on the predicted class. A saliency heatmap mathematically defined as,

$$w = \frac{\partial S_n}{\partial I} \tag{2}$$

In this case, w stands for each pixel's importance weight, and S_n is the score for the particular class n derived from the trained model such as the existence of a nail-fold capillary, and I represents the input image's pixel values. Saliency heatmaps make the small vascular structures that the entire system depends on prominent. These heatmaps make it possible to confirm that the model concentrates on real capillaries rather than unimportant background features by identifying which pixels or small patches contribute most to the classification. This pixel-level interpretability offers a tool for clinical validation and increases trust in the automated detection system. Additionally, saliency heatmaps offer a number of extra advantages when it comes to nail-fold capillary detection:

- Model refinement: Researchers identify possible biases or misclassifications by analyzing the parts of the image the model incorrectly highlights, background noise. This realization enables better dataset selection and model retraining to ensure that the network precisely focuses on actual capillary structures.
- Quality control: Saliency maps serve as a verification step during clinical analysis to ensure that the model's focus is on the nail-fold area and pertinent vascular characteristics rather than irrelevant skin regions. This improves automated capillary detection's dependability prior to producing diagnostic results.
- Human-AI cooperation: Clinicians are able to contrast their own observations of capillary morphology with the saliency maps produced by AI. Clinicians are more confident in the system's predictions because of this alignment between human expertise and AI reasoning.

This explainable AI techniques ensure that the model detects nail-fold capillaries accurately and generates data that doctors are able to comprehend and validate.

IV. RESULT AND DISCUSSION

The proposed approach detects and classifies nail fold capillaries in real-time using YOLO-RELAN into five categories: aberrant, aggregation, blur, hemo, and normal. The model is trained on the ACFD_HT dataset, which provides a diverse collection of high-quality images for robust capillary analysis. This technology helps diagnose diseases like systemic sclerosis by precisely identifying capillary characteristics from high-resolution images using object detection. In order to provide transparency and confidence in clinical applications, the model additionally includes an explainability layer with a saliency heat map that emphasizes the locations in the image that affected the algorithm's decision.

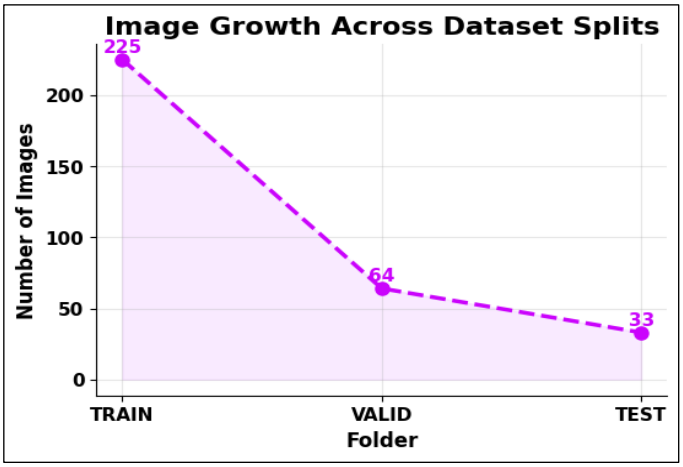

Figure 3: Image growth across dataset splits.
Source: Authors, (2026).

The distribution of images over the three dataset splits such as Train, Validation, and Test is depicted in Figure 3. There are 225 images in the training set, 64 in the validation set, and just 33 in the test set. This illustrates a typical dataset split pattern, in which smaller amounts are set aside for testing and validation to assess performance and generalization, while the majority of the data is used for training to ensure efficient model learning.

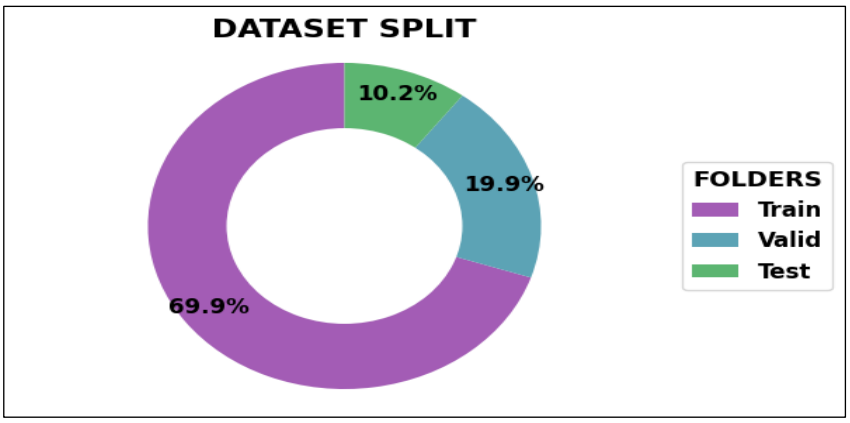

Figure 4: Dataset Split.
Source: Authors, (2026).

The dataset split is depicted in Figure 4, with 69.9% of the photos utilized for training, 19.9% for validation, and 10.2% for testing. While lesser amounts are set aside for performance assessment and final testing, this distribution ensures that the majority of the data enables model learning.

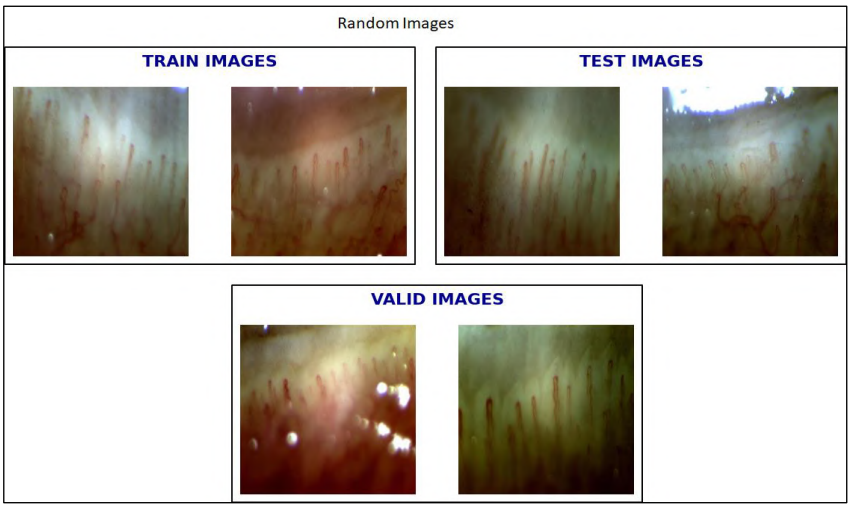

Figure 5: Random images.
Source: Authors, (2026).

Sample images from the training, validation, and testing datasets are displayed in the Figure 5. Clear microscopic images with comparable structural patterns are present in each collection, suggesting consistent data quality across splits. These random samples show that all subsets reflect comparable image properties, ensuring the model's learning and evaluation are balanced.

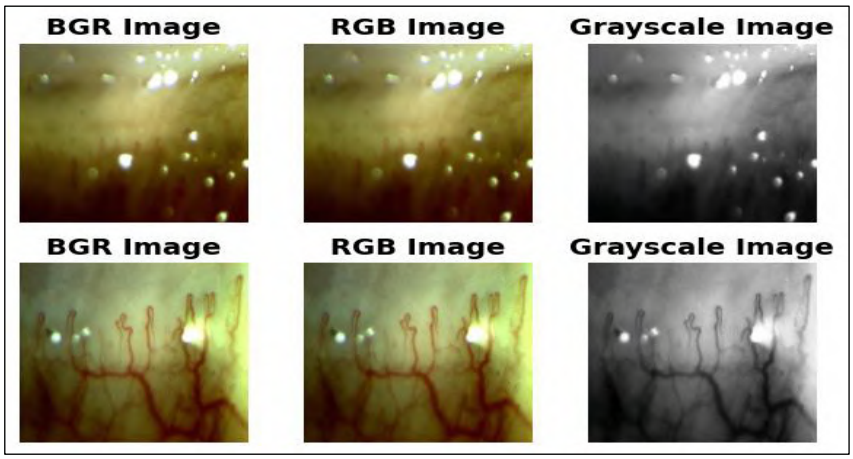

Figure 6: Comparison of BGR, RGB and Grayscale images.
Source: Authors, (2026).

Figure 6 illustrates the visual distinctions between tiny images in BGR, RGB, and grayscale. Grayscale conversion is beneficial for feature extraction and structural analysis since it simplifies the image by simply representing intensity variations, whereas BGR and RGB preserve complete color information.

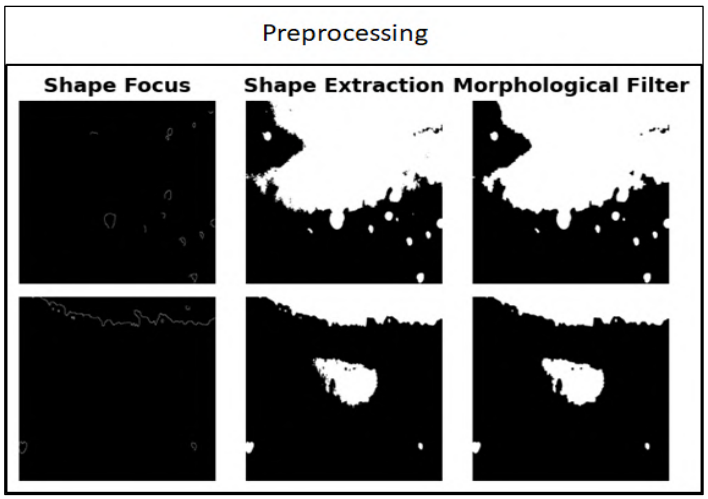

Figure 7: Preprocessing images.
Source: Authors, (2026).

The preprocessing steps, such as shape focus, shape extraction, and morphological filtering, are depicted in Figure 7. By separating pertinent shapes and eliminating noise, these procedures improve the image's structural properties and produce clearer, more defined areas for further analysis.

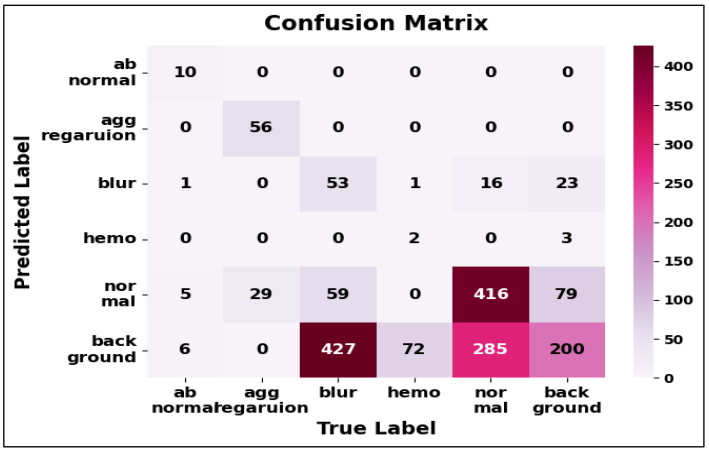

Figure 8: Confusion matrix for YOLOv8.
Source: Authors, (2026).

The confusion matrix displays the performance of a multi-class classification model in six different categories: aberrant, aggregation, blur, hemo, normal, and background in figure 8. Most predictions are focused along the diagonal, particularly for normal (416) and aggregation (56), showing high accuracy in these categories. However, there is significant misclassification between "background" and other classifications such as abnormal (427) and normal (285), indicating that the model struggles to discriminate background data from these categories.

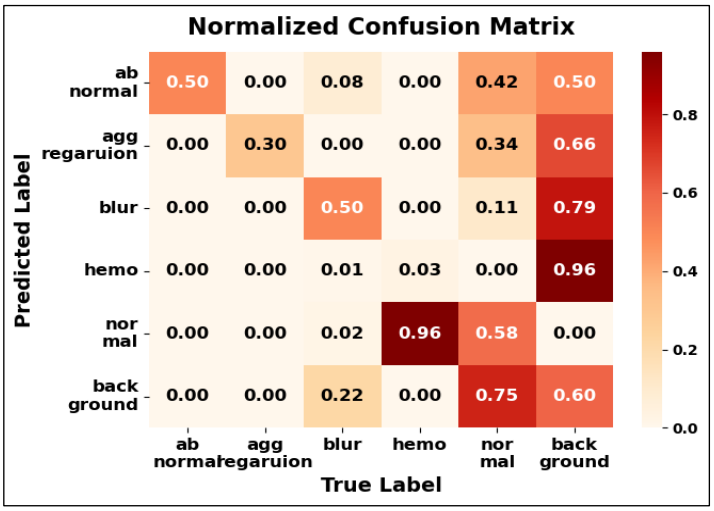

Figure 9: Normalized confusion matrix for YOLOv8.
Source: Authors, (2026).

Figure 9 indicates the normalized confusion matrix which shows the proper categorization for hemo (0.96) and blur (0.79), while background and normal classes display moderate confusion with other categories, indicating that the model performs well in general and needs to improve its ability to differentiate comparable classes.

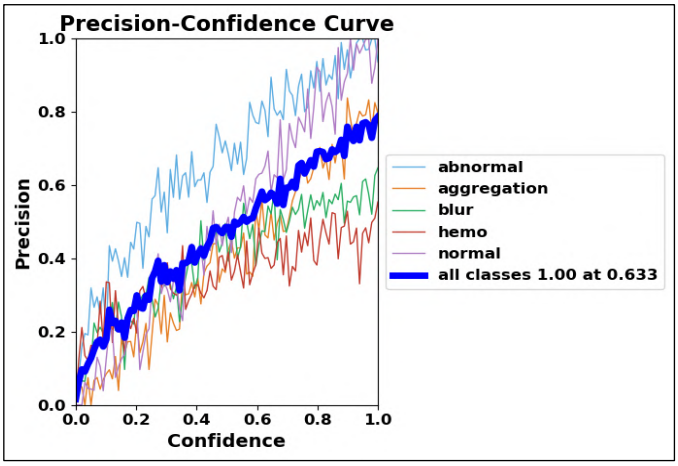

Figure 10: Precision-Confidence curve for YOLOv8.
Source: Authors, (2026).

Figure 10 shows the precision-Confidence Curve across different classes. The x-axis represents the confidence level, which ranges from 0 to 1, while the y-axis denotes precision, which similarly ranges from 0 to one. Each line in the graph represents a separate class: aberrant, aggregation, blur, hemo, and normal. The thick blue line represents the total precision for all classes, with a value of 1.00 at a confidence level of 0.633.

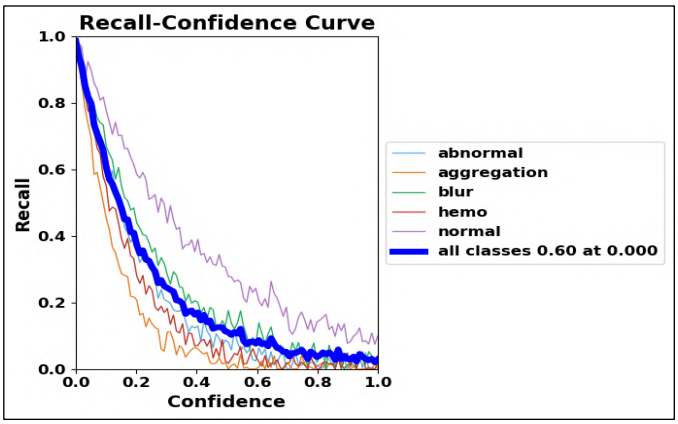

Figure 11: Recall-Confidence curve for YOLOv8.
Source: Authors, (2026).

A Recall-Confidence Curve is displayed in figure 11, showing that recall varies with confidence for various classes. Confidence is represented by the x-axis, and recall is represented by the y-axis. A class is shown by each line: aberrant, aggregation, blur, hemo, and normal. The total recall for all classes is represented by the thick blue line, which has a value of 0.60 at a confidence level of 0.000. Recall generally declines as confidence rises, suggesting that fewer but more accurate predictions are made at increasing confidence levels.

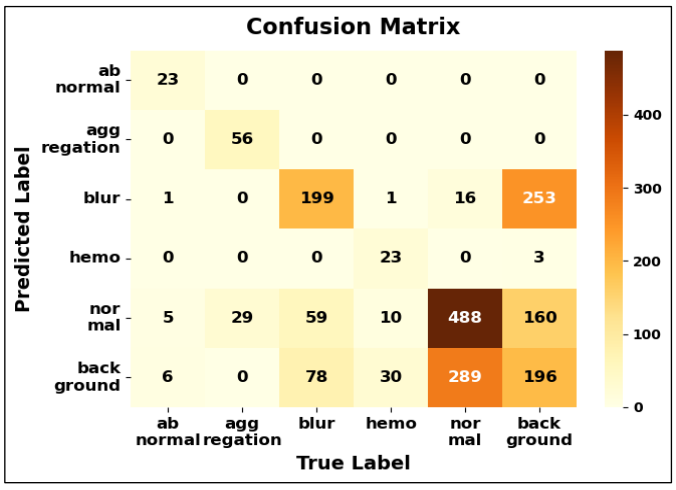

Figure 12: Confusion matrix for YOLOv10.
Source: Authors, (2026).

A confusion matrix depicting a classification model's performance across six classes abnormal, aggregation, blur, hemo, normal, and background is displayed in figure 12. The diagonal cells show samples that have been successfully identified; the normal class has the highest accuracy (488 accurate). Misclassifications, which show some overlap or similarity between these categories, are primarily observed between blur and background classes as well as between normal and background.

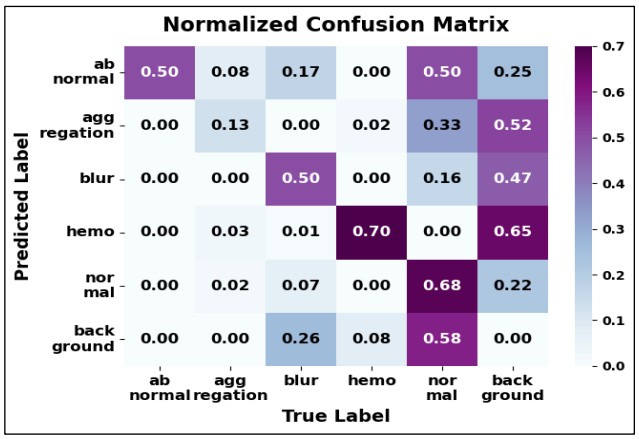

Figure 13: Normalized Confusion matrix for YOLOv10.
Source: Authors, (2026).

The accuracy in which a classification model predicts five categories like abnormal, aggregation, blur, bleeding, and background is displayed in figure 13. It draws attention to the fact that while the model does well for some categories, such as bleeding, it misclassifies others, such as background and abnormal. Prediction accuracy is reflected in color intensity, with darker hues denoting superior performance.

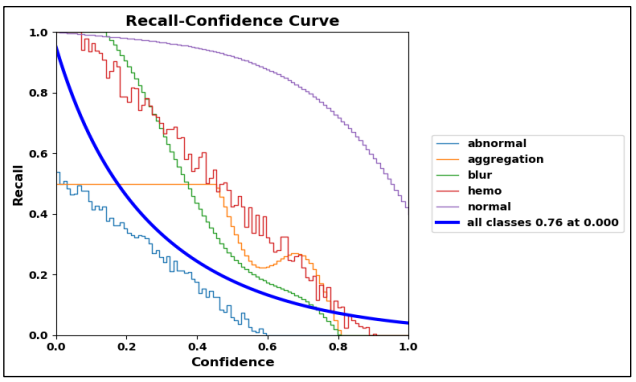

Figure 14: Recall-Confidence curve for YOLOv10.
Source: Authors, (2026).

The connection between model confidence and retrieval for the several classes such as abnormal, aggregation, blur, hemo, and normal is depicted in figure 14. Recall typically declines with increasing confidence, making the model more certain but missing more real cases. The overall performance is summarized by the all classes line, which has an average recall of 0.76 at 0% confidence.

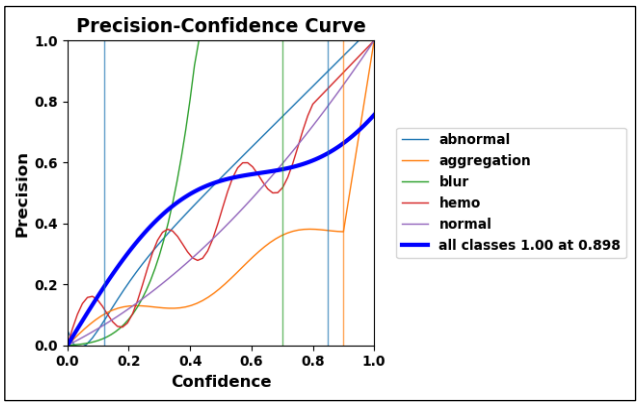

Figure 15: Precision-Confidence curve for YOLOv10.
Source: Authors, (2026).

The precision-confidence curve for the several classes abnormal, aggregation, blur, hemo, and normal is shown in figure 15. As confidence grows, precision typically climbs as well, suggesting more trustworthy forecasts at greater confidence levels. Overall performance is represented by the thick blue line, which indicates that all classes achieve an accuracy of 1.00 at a confidence level of 0.898.

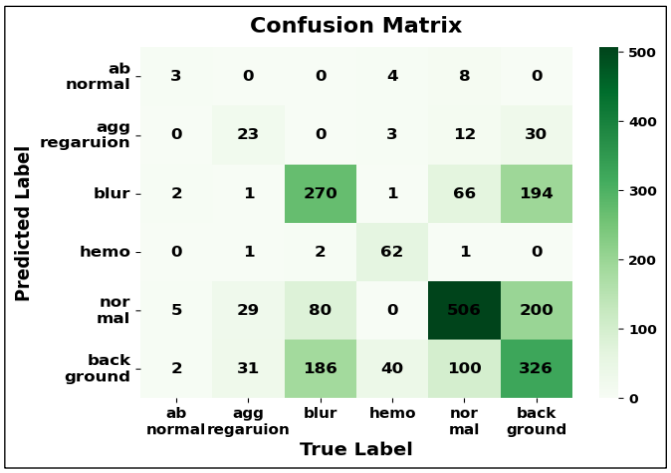

Figure 16: Confusion matrix for YOLOv12.
Source: Authors, (2026).

A classification model's confusion matrix, which shows the accuracy with which it predicted five categories like abnormal, aggregation, blur, hemo, and normal are displayed in Figure 16. Higher values are displayed in darker green in the matrix, which contrasts anticipated and true labels. 270 is the highest score for accurately predicting blur. This matrix aids in assessing the model's accuracy and performance across several classes.

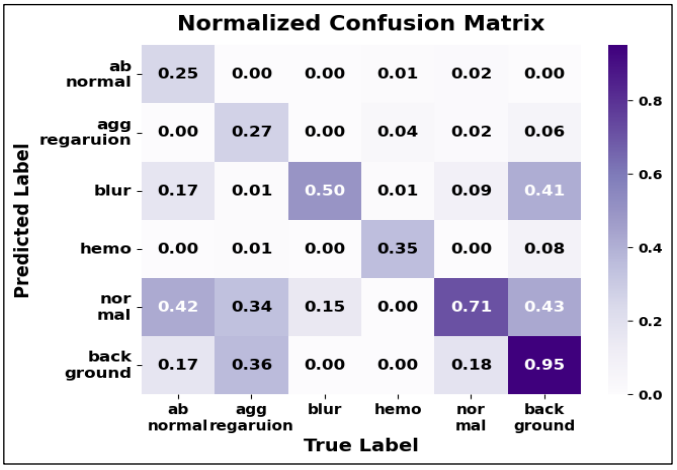

Figure 17: Normalized confusion matrix for YOLOv12.
Source: Authors, (2026).

Figure 17 show the percentage of accurate predictions for each class. Higher proportions are indicated by deeper hues on a scale of 0 to 1. The "background" class, for instance, has a high value of 0.95, indicating precise predictions. By highlighting areas of strong and poor predictions, such as lower values for the abnormal and hemo classes, the matrix aids in evaluating the model's relative performance across classes.

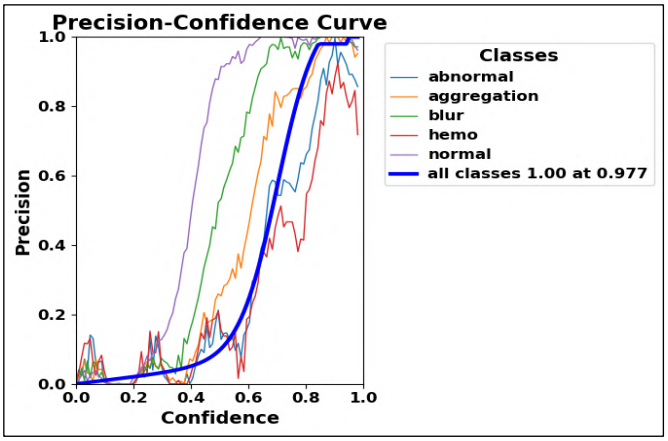

Figure 18: Precision-confident curve for various classes of YOLOv12.
Source: Authors, (2026).

The precision-confidence relationship for five distinct classes such as abnormal, aggregation, blur, hemo, and normal are displayed in Figure 18. The precision for each class is displayed on the y-axis, while the x-axis indicates the confidence level. The blue curve, which reaches a perfect score of 1 at a confidence level of 0.977, shows the overall precision across all classes.

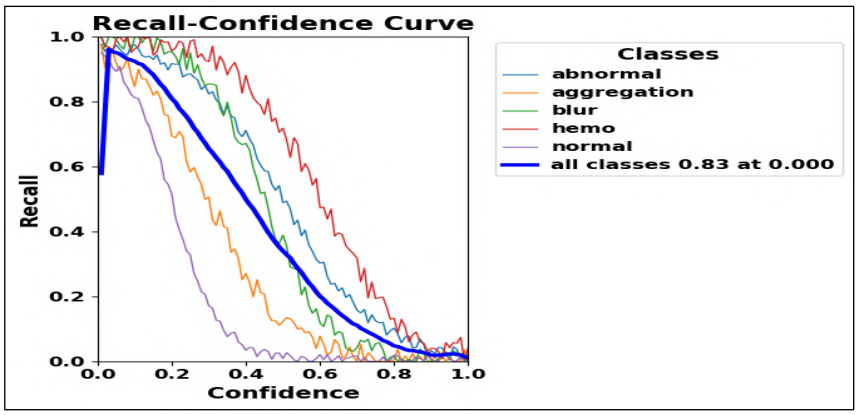

Figure 19: Recall- Confidence curve for different classes of YOLOv12.
Source: Authors, (2026).

The recall-performance for five classes such as abnormal, aggregation, blur, hemo, and normal across various confidence levels is shown in Figure 19. The x-axis displays the degree of confidence, and the y-axis depicts recall. The overall recall for all classes is represented by the blue curve, which begins high and progressively falls as confidence rises before settling at about 0.83 when confidence is zero.

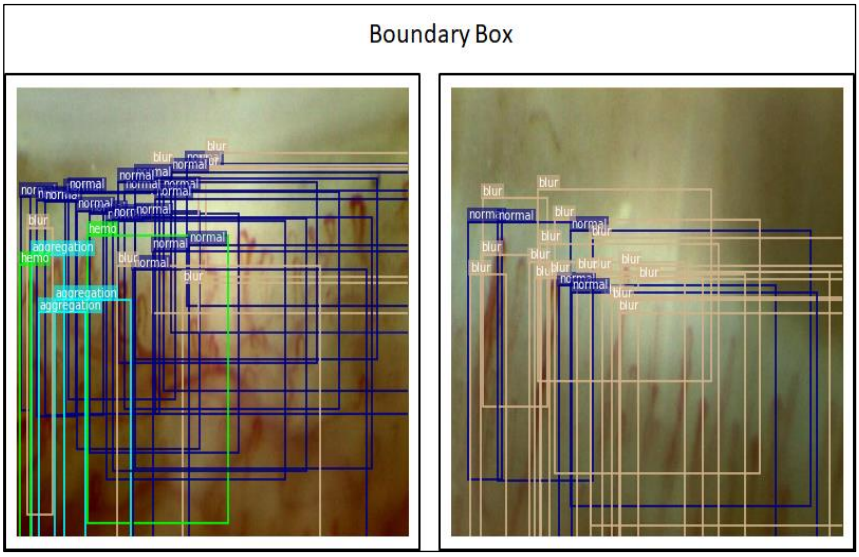

Figure 20: Boundary box.
Source: Authors, (2026).

Two microscopic outlooks Boundary Box are displayed in Figure 20, with labeled bounding boxes delineating various detected locations. The left image includes several overlapping boxes in various types that indicate properties like normal, blur, aggregation, and hemo. The labels in the right image are mostly blurry and have fewer variants. The object detection outputs used to categorize and localize features in digital blood smear images are represented by these bounding boxes.

Figure 21: Image annotations with class labels.
Source: Authors, (2026).

Bounding boxes and class labels are superimposed on a number of sample images in Figure 21. Each bounding box, which is labeled with one of the following classes normal, blur, aggregation, or hemo identifies regions inside the image. The model's predictions for different image segments are shown by the labels and boxes, with some overlapping or inaccurate classifications.

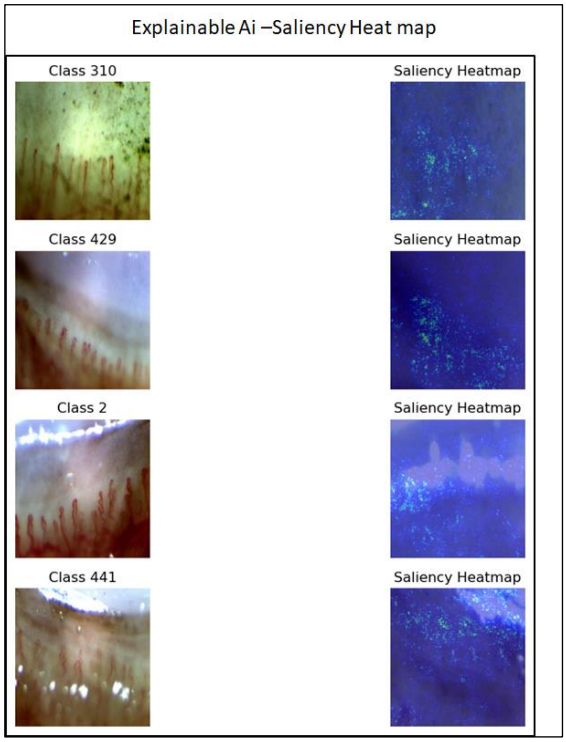

Figure 22: Explainable AI-Saliency heatmap.
Source: Authors, (2026).

Explainable AI-Saliency Heatmaps for four distinct classes are displayed in Figure 22. Every class image on the left has a matching saliency heatmap on the right. Important image regions are highlighted in blue and green hues in the heatmaps, which show the places the AI model concentrated on for categorization. Higher model attention or feature relevance in the decision-making process is represented by brighter patches.

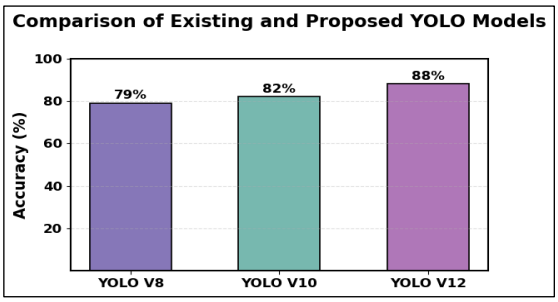

Figure 23: Comparison of existing and proposed YOLO models.
Source: Authors, (2026).

The accuracy of several YOLO models is contrasted in Figure 23. YOLO V8 scores 79%, YOLO V10 improves to 82%, and the suggested YOLO V12 achieves the greatest accuracy of 88%, demonstrating a definite improvement in the model's performance.

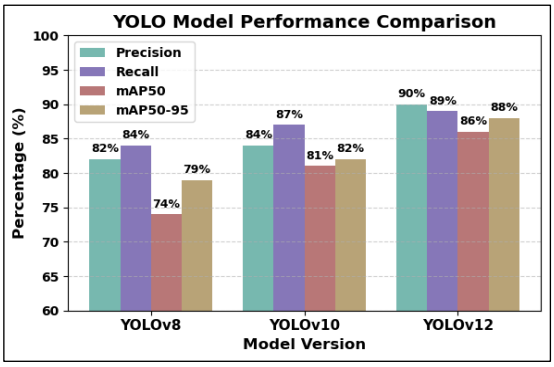

Figure 24: Performance comparison of YOLO models.
Source: Authors, (2026).

The YOLOv8, YOLOv10, and YOLOv12 models are contrasted in Figure 24 according to Precision, Recall, mAP50, and mAP50–95. With 90% precision, 89% recall, 86% mAP50, and 88% mAP50–95, YOLOv12 outperforms YOLOv8 and YOLOv10 in terms of detection accuracy and consistency.

Table 3: Performance metrics of the proposed system.

Model	Accuracy	Precision	Recall	map50	map50-95
PROPOSED	88%	90%	89%	86%	88%

Source: Authors, (2026).

Table 3 shows the proposed approach performs effectively on a number of important metrics. With an accuracy of 88%, it accurately classifies a significant percentage of cases. Additionally, the model has good recall (89%) and precision (90%), indicating that it is both successful in detecting the majority of true positives and accurate in its positive predictions. At an interaction threshold of 0.50, the mean Average Precision (mAP50) is 86%; at different interaction thresholds, the mAP50-95 ranges from 0.50 to 0.95, reaching 88%.

Table 4: Comparative analysis of accuracy for various models.

Model	**Accuracy**
YOLOv5 [21]	85.2 %
CNN [24]	86 %
ResNet [25]	87 %
PROPOSED	88 %

Source: Authors, (2026).

A comparison of model accuracy for recognizing items and categorization is shown in table 4. With an accuracy of 85.2%, the YOLOv5 model outperforms CNN with 86% and ResNet with 87%. When compared to other deep learning architectures, the suggested model achieves the greatest accuracy of 88%, indicating higher feature extraction and detection performance.

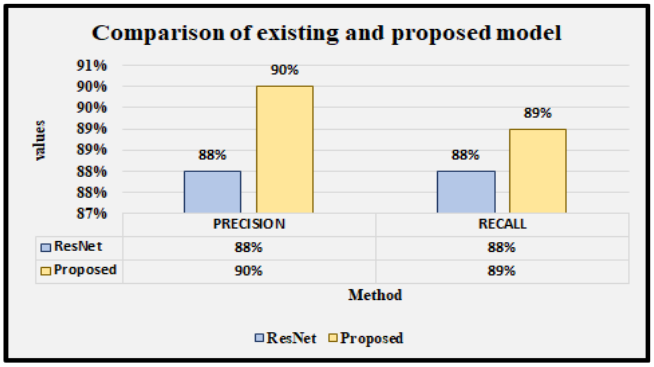

Figure 25: Comparison of existing and proposed model.
Source: Authors, (2026).

The precision and recall levels of the proposed model and the ResNet model are compared in Figure 25. The proposed approach outperforms ResNet, which records 88% for both measures, with 90% precision and 89% recall. This suggests that the proposed framework outperforms the current ResNet architecture in terms of feature identification and classification accuracy and dependability.

V. CONCLUSION

The proposed method effectively combines deep learning, explainable AI, and sophisticated preprocessing methods for the precise and comprehensible identification of nail-fold capillaries. The technique improves the visibility of tiny vascular features that are essential for analysis by immediately preprocessing the input image using shape-focused extraction and morphological filtering. With the R-ELAN backbone, the YOLOv12 model effectively locates and detects nail-fold capillaries in the processed images, producing accurate boundary boxes surrounding the identified areas. Saliency heatmaps are an explainable AI component that emphasizes the particular image regions impacting model predictions, ensuring transparency and clinical dependability. In addition to achieving strong detection performance, the complete approach ensures interpretability and reliability, which are essential for real-world use in clinical and diagnostic applications. The proposed approach achieves the highest accuracy of 88%, 90% of precision, 89% of recall, 86% of map50 and 88% of map50-95.

ABSTRACT

Early detection of learning disabilities (LD) is essential for prompt intervention, yet it is still difficult because LD signs are subtle and variable. Previous research frequently ignores the significance of class imbalance and data preprocessing, leading to skewed or inadequate forecasts. This paper suggests a hybrid machine learning framework for LD diagnosis that combines several classification algorithms with thorough preprocessing, such as feature scaling, SMOTE-based class balance, missing value management, outlier removal, and feature selection. The effectiveness of a stacking ensemble that incorporates the advantages of Random Forest, XGBoost, LightGBM, and a Multilayer Perceptron is assessed. The efficiency of combining improved preprocessing with ensemble learning is demonstrated by the experimental findings, which show that the stacking ensemble greatly outperforms individual classifiers in terms of accuracy, recall, F1-score, and ROC-AUC. The framework facilitates prompt educational support and intervention by offering a strong and dependable instrument for early LD detection. The summary must be written in a single paragraph. The length of the paper must be 8 to 14 pages, single space, 10 Times New Roman, including the Abstract (Between 150 and 200 words), and keywords (Between 3 and 5 words). The yellow highlighted parts should not be modified by the authors. The names, affiliations, ORCIDs and e-mails of the authors must be sent in a separate text file. I. INTRODUCTION

The application of machine learning techniques for the detection of learning disabilities (LD) has been investigated in a number of research [1]. Conventional methods frequently rely on single classifiers that are directly applied to unprocessed educational data, such as Random Forests, Decision Trees, or Support Vector Machines [2]. Although these approaches have had some success, they typically ignore the crucial role of preprocessing, which includes controlling class imbalance, feature selection, data cleaning, and normalization. As a result, these methods frequently misclassify students with LD and have limited practical usefulness because they are skewed toward the majority class. More sophisticated algorithms like XGBoost and LightGBM have been used in recent research, showing better results in classification tests. Nevertheless, real-world imbalances and noisy data, which are prevalent in school records, are often overlooked by this research since they usually use small or balanced datasets. Furthermore, the majority of research concentrates on individual classifiers rather than on ensemble approaches that integrate the complementing advantages of several models. The suggested method overcomes these constraints in two steps: first, a strong preprocessing pipeline guarantees data quality, uses SMOTE to balance class distribution, and chooses the most pertinent features. Second, to improve predictive accuracy, robustness, and generalization, an ensemble-based classification model stacks Random Forest, XGBoost, LightGBM, and Multilayer Perceptron. By offering a thorough, useful, and effective method for early LD detection, this strategy closes the gap in the body of existing literature [3].

II. METHODOLOGY

The suggested framework for identifying learning disabilities (LDs) is intended to offer a reliable and precise method for early detection. A thorough preprocessing pipeline and an ensemble-based classification model make up its two primary phases. The approach uses a variety of machine learning approaches to produce high prediction performance while resolving common issues in educational datasets, such as noise, missing data, and class imbalance.

II.1 GATHERING AND CHARACTERIZING DATA

The study's dataset consists of classroom behavioral observations, cognitive tests, and student academic records. The target variable, LD, is binary, with 1 denoting the existence of a learning disability and 0 denoting its absence. Among the features are:

- Academic scores: performance in reading, writing, and math
- Behavioral indicators: levels of engagement, participation, and attention in the classroom.
- Records of attendance: quantity of absences or tardiness

Preprocessing is essential to ensuring the trustworthiness of future analyses since the dataset reflects the real-world unpredictability of student performance. The models are able to capture behavioral and environmental aspects related to learning disabilities in addition to academic inadequacies because to this multidimensional data.

II.2 PIPELINE FOR PREPROCESSING

Machine learning performance may suffer from incomplete, inconsistent, and unbalanced data found in educational datasets. These issues are methodically handled by the pretreatment pipeline:

1. Missing Value Handling: The mean is used to impute missing values for numerical features. By doing this, bias caused by incomplete records is avoided and all cases contribute to model training.
2. Outlier Removal: Z-score analysis is used to identify and eliminate extreme values that may result from data input mistakes or extraordinary circumstances. This enhances stability and avoids biased model training.
3. Feature Scaling: Standardization converts features to a standard scale with a unit variance and zero mean. To avoid features with wide ranges controlling the learning process, this is especially crucial for distance-based or gradient-based models, including MLP and ensemble techniques.
4. Class Balancing (SMOTE): Learning disability datasets frequently exhibit an imbalance, with much fewer LD cases than non-LD instances. By creating artificial samples for the minority class, the Synthetic Minority Over-sampling Technique (SMOTE) lessens class bias and increases the model's sensitivity to LD instances [4], [5].
5. Feature Selection: The SelectKBest approach with chi-square scoring is used to improve model efficiency and decrease overfitting. This ensures that only pertinent academic, behavioral, and attendance data contribute to model learning by selecting the most informative features [6].

The preprocessing stage is critical to enhance data quality, ensure balanced representation of LD cases, and reduce noise, thereby enabling accurate and reliable model predictions. The Figure 1. shows the overall concept of the study.

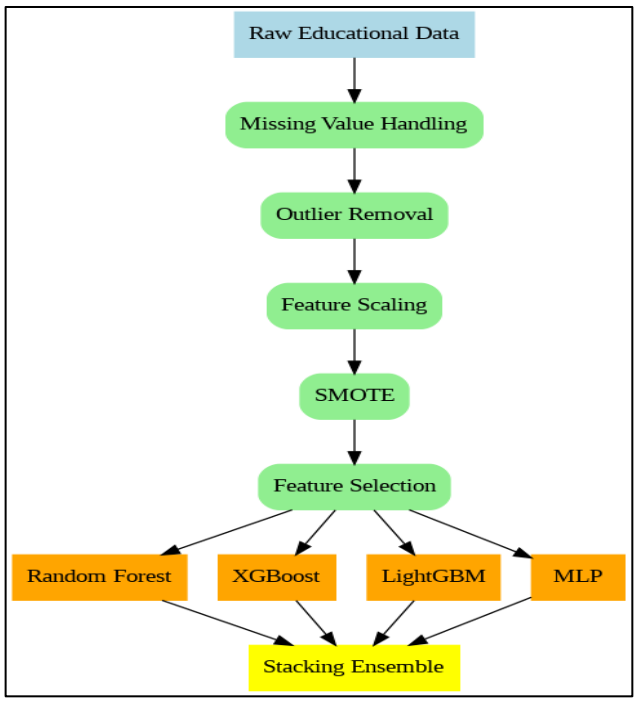

Figure 1: Methodology.
Source: Authors, (2026).

II.3 CLASSIFICATION MODELS

Following preprocessing, a number of machine learning methods are trained and assessed to see how well they recognize LD:

- Random Forest (RF): A strong group of decision trees that manages non-linear interactions and uses bootstrap aggregation to lessen overfitting. Because of its interpretability and stability, RF is used as a baseline [7].
- XGBoost: An iterative gradient boosting approach that lowers bias and variance to enhance model performance. XGBoost is renowned for its strong prediction accuracy and ability to handle noisy datasets [8].
- LightGBM: A high-performance gradient boosting model that is efficient and quick, especially when working with big datasets. Because LightGBM uses histogram-based learning, it is very accurate and computationally efficient [9].
- Multilayer Perceptron (MLP): A feedforward neural network that can recognize intricate non-linear patterns in the data is called a multilayer perceptron (MLP). MLP complements the ensemble by capturing relationships between features that tree-based approaches could miss [10].

II.4 CLASSIFICATION BASED ON ENSEMBLES

A stacking ensemble is created in order to capitalize on the advantages of several models:

- Base Learners: MLP, Random Forest, XGBoost, and LightGBM
- Logistic Regression: as a Meta-Learner

The logistic regression meta-learner in the stacking ensemble aggregates the predictions made by each base learner. This strategy ensures that the ensemble performs better than any single classifier by lowering individual model errors, reducing overfitting, and improving generalization performance.

II.5 EVALUATION METRICS

Model performance is evaluated using a comprehensive set of metrics to capture multiple aspects of predictive ability. Accuracy measures the overall proportion of correctly classified instances, while precision evaluates the ability to correctly identify students with learning disabilities among those predicted as positive. Recall (sensitivity) assesses how effectively all actual LD cases are identified, and the F1-Score, as the harmonic mean of precision and recall, balances false positives and false negatives. The ROC-AUC (Area Under the Receiver Operating Characteristic Curve) quantifies the model's ability to distinguish between LD and non-LD cases across thresholds [11], [12]. For imbalanced datasets, PR-AUC (Area Under the Precision-Recall Curve) is particularly useful, highlighting the trade-off between precision and recall for the minority class. Matthews Correlation Coefficient (MCC) provides a robust single-value measure considering true/false positives and negatives, ranging from -1 (inverse prediction) to +1 (perfect prediction). Balanced accuracy, the average of recall and specificity, accounts for class imbalance more effectively than raw accuracy, while Cohen's Kappa measures agreement between predictions and actual labels beyond chance. Finally, specificity (true negative rate) indicates the ability to correctly identify non-LD students, complementing recall and ensuring a complete evaluation of model performance.

III. RESULTS AND DISCUSSION

Random Forest (RF), XGBoost, LightGBM, Multilayer Perceptron (MLP), and a stacking ensemble that combines these classifiers were used to assess the suggested framework on the preprocessed dataset. To reduce class imbalance, all models were trained using data that had been balanced using SMOTE. The performance metrics for each model are compiled in Table 1.

Table 1: Comparison of evaluation metrices across models.

Model	Accuracy	Precision	Recall	F1-Score	ROC-AUC	PR-AUC	MCC	Balanced Accuracy	Specificity
Random Forest	0.87	0.85	0.84	0.84	0.91	0.88	0.71	0.86	0.88
XGBoost	0.89	0.88	0.87	0.87	0.93	0.90	0.75	0.88	0.90
LightGBM	0.90	0.89	0.88	0.88	0.94	0.91	0.77	0.89	0.91
MLP	0.88	0.86	0.86	0.86	0.92	0.89	0.73	0.87	0.89
Stacking Ensemble	0.92	0.91	0.90	0.90	0.96	0.93	0.81	0.91	0.92

Source: Authors, (2026).

III.1 ANALYSIS OF RESULTS

III.1.1 Impact of SMOTE and Preprocessing

Model stability and predictive performance were enhanced by the application of preprocessing, which included feature selection, scaling, SMOTE, missing value handling, and outlier elimination. Specifically, SMOTE improved the models' sensitivity to the minority LD class, raising F1-scores and recall for all classifiers [13]. The impact of using SMOTE (Synthetic Minority Over-sampling Technique) on an unbalanced dataset of students with and without learning difficulties is depicted in Figure 2. The orange dots show the initial minority class (LD students), emphasizing the class imbalance, whereas the blue dots show the majority class (non-LD students), which predominates the original dataset. The synthetic LD samples produced by SMOTE, which interpolate between pre-existing minority cases, are shown by the red "x" marks. SMOTE balances the dataset by include these artificial points, which improves the LD class's representativeness. This allows machine learning models to learn patterns from both classes more effectively, reducing bias towards the majority class and improving the accuracy and reliability of LD predictions [14].

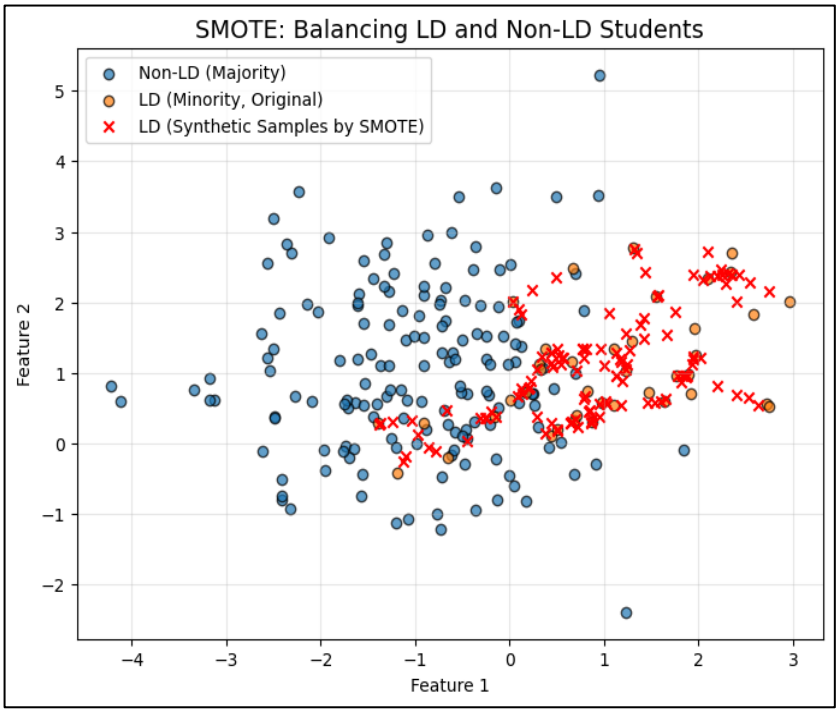

Figure 2: Effect of SMOTE on Balancing LD and Non-LD Students.
Source: Authors, (2026).

III.1.2 Random Forest Baseline

RF was a dependable baseline because it performed well on the preprocessed dataset. Its tree-based structure did a good job of handling non-linear relationships, although it had some trouble capturing intricate patterns.

III.1.3 Advanced Models

By iteratively lowering bias and variance, XGBoost outperformed RF in accuracy.Because of its speedier processing and efficient gradient boosting, LightGBM greatly enhanced performance. Although MLP was somewhat susceptible to hyperparameter adjustment and data fluctuation, it was able to capture intricate non-linear correlations.

III.1.4 Stacking Ensemble:

When compared to individual classifiers, the Stacking Ensemble performs better on all evaluation metrics. The ensemble outperformed any single model by combining the benefits of each model and reducing its drawbacks. It outperforms Random Forest (0.87), XGBoost (0.89), LightGBM (0.90), and MLP (0.88) with an accuracy of 0.92, suggesting a more dependable categorization overall. By using logistic regression as a meta-learner, the ensemble effectively leveraged complementary patterns found by tree-based and neural network models. The ensemble has the highest recall (0.90) and precision (0.91), indicating that it can accurately identify students with learning impairments while reducing false positives. Its balanced and discriminative performance, especially in imbalanced datasets, is confirmed by the F1-score of 0.90 and the greatest ROC-AUC (0.96) and PR-AUC (0.93). Furthermore, the ensemble consistently distinguishes both LD and non-LD students, according to the Matthews Correlation Coefficient (0.81), balanced accuracy (0.91), and specificity (0.92). By utilizing the complementing strengths of several classifiers to generate the highest overall accuracy, recall, F1-score, and ROC-AUC, this illustrates the advantages of ensemble learning for LD prediction. In Figure 3 the Random Forest, XGBoost, LightGBM, MLP, and Stacking Ensemble machine learning models are compared in this table using important evaluation metrics such as accuracy, precision, recall, F1-score, ROC-AUC, PR-AUC, MCC, balanced accuracy, and specificity. It is possible to directly evaluate how well each model detects learning disorders and manages class imbalance because each row displays the model's performance across these metrics.

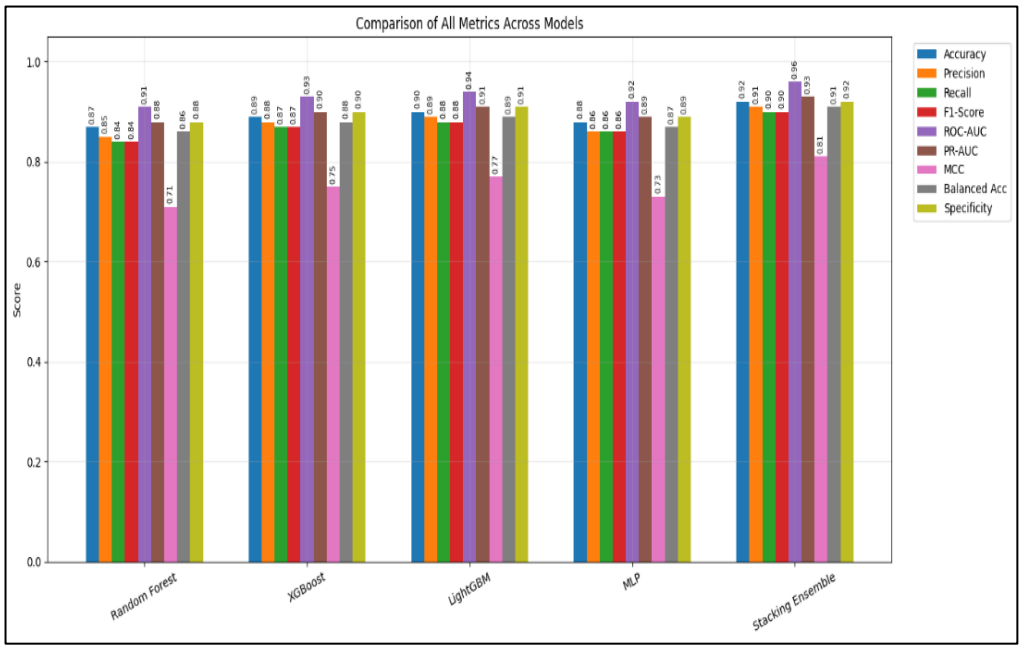

Figure 3: Comparison of all metrices across the model.
Source: Authors, (2026).

The important metrics for assessing model performance in unbalanced datasets, such as learning disability prediction, are ROC-AUC, PR-AUC, and MCC [15]. While PR-AUC focuses on accurately recognizing minority LD cases, ROC-AUC evaluates the model's total discriminative abilities, and MCC offers a balanced assessment taking into account all prediction outcomes. When combined, they provide a thorough understanding of precision and dependability, emphasizing the usefulness of models like the stacking ensemble. Figure 4. shows the representation of ROC-AUC, PR-AUC, and MCC [16].

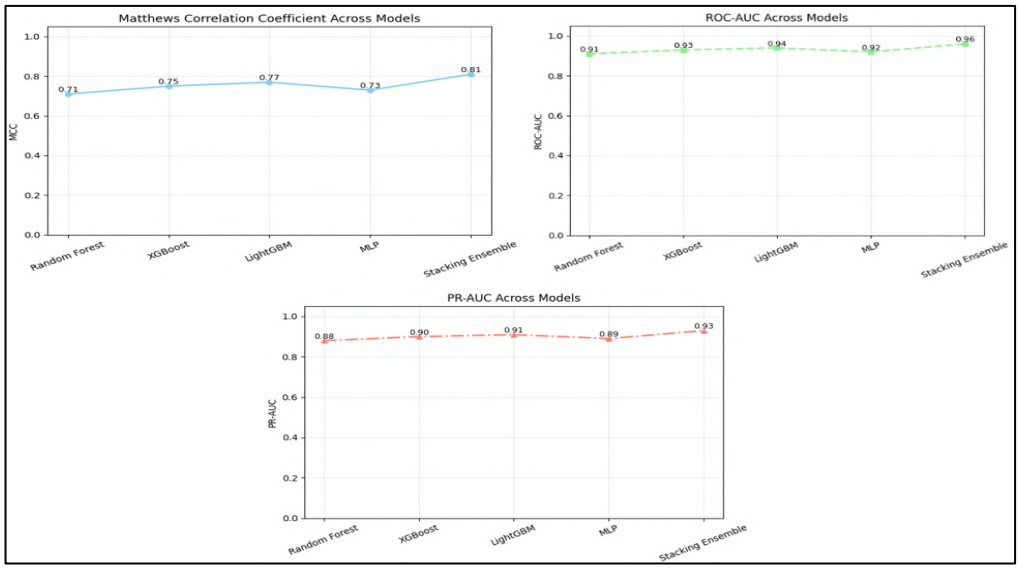

Figure 4: Key Performance Metrics for LD Prediction Models.
Source: Authors, (2026).

IV. CONCLUSION

This study demonstrates that a two-stage machine learning framework—combining robust preprocessing with ensemble-based classification—effectively identifies students with learning disabilities (LD) in educational datasets. Model performance is greatly enhanced by handling noisy and imbalanced data using methods like SMOTE and feature selection. Advanced models like XGBoost, LightGBM, and Multilayer Perceptrons improve predictive accuracy, while Random Forest provides a solid baseline. Stacking ensembles, which use complementary classifiers, produce the greatest overall results. Early, accurate, and scalable LD detection is made possible by the suggested framework, allowing for prompt interventions and assistance for kids who are at risk. To increase prediction robustness, the framework can be expanded by adding more cognitive, behavioral, and demographic characteristics. Temporal or sequential patterns in student data may be captured by deep learning architectures like LSTM or attention-based models. Additionally, incorporating explainable AI techniques can give instructors useful insights, increasing the system's transparency and interpretability. Lastly, the method can be extended to different educational settings and datasets, facilitating more extensive uses in individualized education planning and early learning support.

Particle Swarm Optimization.

ABSTRACT

Big data are enormous, intricate sets of information that are too large, too quick, and too difficult to handle using conventional methods. They consist of both structured and unstructured data. Due to the alarmingly high rates of data generation, there is pressure to adopt simple and expensive procedures for data recovery and storage. Conventional database systems cannot handle the processing power of big data. In order to evaluate and query this enormous amount of data, new technologies have recently been created. In this work, a novel hybrid approach for efficient big data query processing through a two-phase approach is introduced. In the first phase, the Hadoop Distributed File System (HDFS), Map Reduce are utilized. Second phase involves optimization using Particle Swarm Optimization (PSO). The proposed algorithm aims to enhance search speed by strategically optimizing various processes. This two-step methodology combines the parallel processing capabilities of HDFS Map-Reduce with the optimization power of PSO, contributing to an overall improvement in query processing efficiency for large-scale datasets. Experimental results demonstrate significant outperformance of the model in expediting query processing.

I. INTRODUCTION

The "3 Vs" of Figure 1 Volume, Velocity, and Variety define big data. Traditional query processing methods and database management systems face serious difficulties as a result of these features. Traditional methods find it difficult to deal with the sheer amount of data, speed at which it is produced, wide range of data formats, and requirement to guarantee the accuracy and quality of the data. As such, it is now essential to create new query processing techniques suited to the particular requirements of large data. These days, IT is centralized in all businesses and organizations, where users work with a wide range of computer programs. Numerous data types, such as facts, statistics, numbers, text, and images, as well as information that has been processed and made relevant for appropriate use, are allocated by these applications. A database is an information and data collection of this type. Modern database user interfaces are highly versatile, which makes them important for optimization. Users must deal with a massive amount of data due to the growing use of database management systems. As a result, in order to fulfill a user's request, it is imperative to store this data so that it can be quickly retrieved from the information.

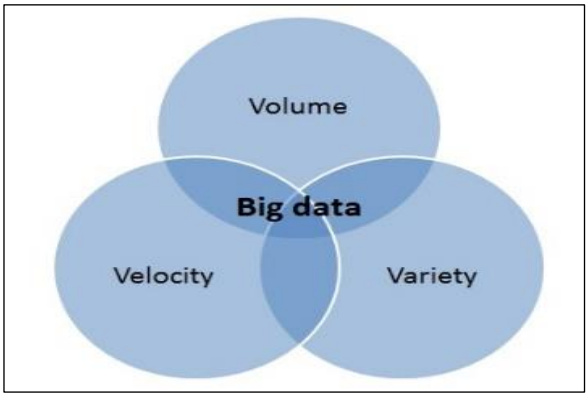

Figure 1: 3 V's of Bigdata.
Source: Authors, (2026).

When it comes to organizing information, databases are really useful. It gives the user the freedom to gather accurate, trustworthy, and timely data for efficient decision-making. As a result, database systems are becoming more and more important. Finding the optimal query optimization strategy becomes more difficult as a result of the daily rise in query complexity. For a very long time, query optimization in databases has been a crucial problem in many different industries. The user must reformulate the complex query with a more efficient and computationally equivalent one in order to lower the execution cost.Main key contributions of proposed work are listed as follows:

- The proposed hybrid approach has two phase of query processing in big data to retrieve the data efficiently.
- In the first phase, Entropy computation is used to extract and manage properties including closed frequent pattern, support, and confidence. Repeated data is removed using the Hadoop Distributed File System and Map Reduce.
- Second phase involves optimization is done using Particle Swarm Optimization.
- Experimental results show that query processing performance of proposed method accuracy was higher and execution time also lower than the traditional methods.

Rest of the paper is organized as follows: Sections 2 discusses related publications. Section 3 shows description of suggested approach Section 4, the suggested hybrid approach is tested and compared to existing approaches. Finally, Section 5 describes all finding and the scope of the study.

II. RELATED WORKS

According to [1] demonstrated the critical role big data plays in the modern society. Big data has many uses in applications, but it also presents difficulties. They have described big data, including veracity, using the four Vs idea. They have addressed a few basic issues that must be resolved in order to turn issues into opportunities. They have discussed developments, big data research, and six key difficulties that arose when processing unstructured data. And also suggested unresolved research issues in the field of big data. Another important problem with heterogeneous Hadoop clusters, as highlighted by [2] is namespace constraints imposed by systems. In a Hadoop context, the issue is sharing name nodes and keeping metadata across name nodes for a large number of files. A single namespace server's capacity to handle and store data is limited [3] expressed apprehension regarding the difficulties presented by supercomputing community. They raised concerns about what happens when data is stored in zettabytes or petabytes. The main topic to concentrate on is the enormous amount of data generated by numerical simulations as a byproduct of supercomputing processes. Three perspectives can be used to analyze the parallelism in large datasets: server applications that require a high bandwidth network to handle all queries, and data applications with a high volume of incoming and outgoing movements. According to [4] there are equity problems with the distinct, profiled critical execution of inquiries. Prediction-based systems are proposed for the current MapReduce-based was developed to scaffold the semantic gap between MapReduce runtimes. Moreover, the query compiler facilitates efficient query planning for rapid and reasonable large-scale data analytics. To get around design flaws and boost large-scale cluster performance, the author conducted tests. [5] have specified the use of comparable input/output approaches for scientific application management.

To maximize I/O throughput, they integrated a two-phase I/O method and data sieving. For large workloads, the suggested effort focuses on providing parallel access to shared datasets. In their clinical studies [6] endorsed the application of naïve Bayes to comprehend the human neuroimaging framework. Although there are various stimulus phases in the research, data collection, classification process offered a very clever look into how data categorization may be controlled if done appropriately. Each response collected as a stimulus offers a comparable testing ground to identify the appropriate heuristic method for data classification of simple activities with complicated surroundings. In [7] conducted a theoretical examination of the PSO algorithm and discussed its history and conception. The specific future research directions this summary suggests are what make it unique [8] suggested a hybrid approach combining PSO and GA to optimize the deployment of an antenna array for the purpose of finding the throughout a substation. Initially, a Direction-of-Arrival (DOA) estimation algorithm was introduced to evaluate its suitability for various array topologies. According to [9] looked at a method for hybridizing PSO and DE, two heuristic algorithms, in order to solve slew-maneuver time-optimal issues with solution route limitations and prevent stagnation. The combined PSODE technique handled the stagnation quite well, reducing computational time compared to merely using DE by 40%. A Dynamic Multi-Swarm Differential Learning Particle Swarm Optimizer was presented [10] By using a local searcher such as the Quasi-Newton method to improve exploitation capability while simultaneously utilizing exploration capability included in the differential mutation, it has an excellent capability of both exploitation and exploration.

By utilizing an Instrumented Indentation Test (IIT), [11] provided a way to extract the mechanical characteristics of its bulk materials utilizing a variety of loading-unloading curves. Finite iterative element simulation in conjunction with Simulated Annealing PSO was utilized to extract the mechanical parameters, such as the strain-hardening exponent (n) and strain-hardening rate (K), from the IIT data.

III PROPOSED WORK

A proficient hybrid structure has been suggested. This system includes data classification and an effective automated preprocessing method for effective data management in large data. Organizations keep many databases to handle and store big data (BD), which comes in a variety of data models and is stored in enormous volumes. For business, querying and BD analysis are essential for gaining insight. This paper improved the BD query optimization process by utilizing both the HDFS map-reduce approach and the PSO algorithm. Figure 3 displays the block diagram for the suggested methodology. There are two stages to the proposed work:

1.Big data arrangement

- Pre-processing
- Feature Extraction

2. Query optimization

Collect and use BD for preprocessing first. The features are extracted from the original data in the second stage, which involves finding the support and confidence value after determining the closed frequent itemset. Finally, apply the entropy method to this value. PSO technique is used in last stage to organize the relevant data. These are explained in brief below.

III.1 BIG DATA ARRANGEMENT

The primary purpose is to convert the unstructured bigdata into an organized manner.

III.1.1 Pre-Processing

In pre-processing phase firstly, it uses the SHA 512 algorithm to calculate hash value (HV) of data during preprocessing. Next, use the HDFS framework to execute the map-reduce using this HV.

HDFS

Large data sets can be reliably and scalable stored and managed using HDFS, a distributed file system. It is made to function with the Hadoop MapReduce (MR) programming model, which is illustrated in figure 2 and is a well-liked method of handling massive data sets. Fast data movement between nodes of HDFS's primary characteristics. When addressing a query, the HDFS has "two" phases. For example, it contains a reduction function Cf and a map function Pf, which are both written as

$$H\,(Dn\,)\;=\;[Pf\,,Cf] \tag{1}$$

Map () function

Map () function is the initial function of Map/Reduction tool. Master node (MN) is where this function is dominant. It divides up input data or breaks it up into multiple smaller subprocesses. The worker nodes, which handle these small processes, receive further dispersion of these subprocesses. The MN is then given an acknowledgement.

$$Pf\;=\;map\,(H\,(\,Dn\,)\,) \tag{2}$$

where Pf is the result of the map () function and map () denotes the mapping function Reduce () function Reduce () gathers the complete outcomes of each suboperation and combines them to produce an aggregated set of decision-based results that are provided in recognition of the initial high demands. The following formula displays the reduction function.

$$Cf\;=\;reduce\,(Pf) \tag{3}$$

where reduce () is the function that reduces the components, Pf is the output of the mapping function, and reduced set of data is Cf.

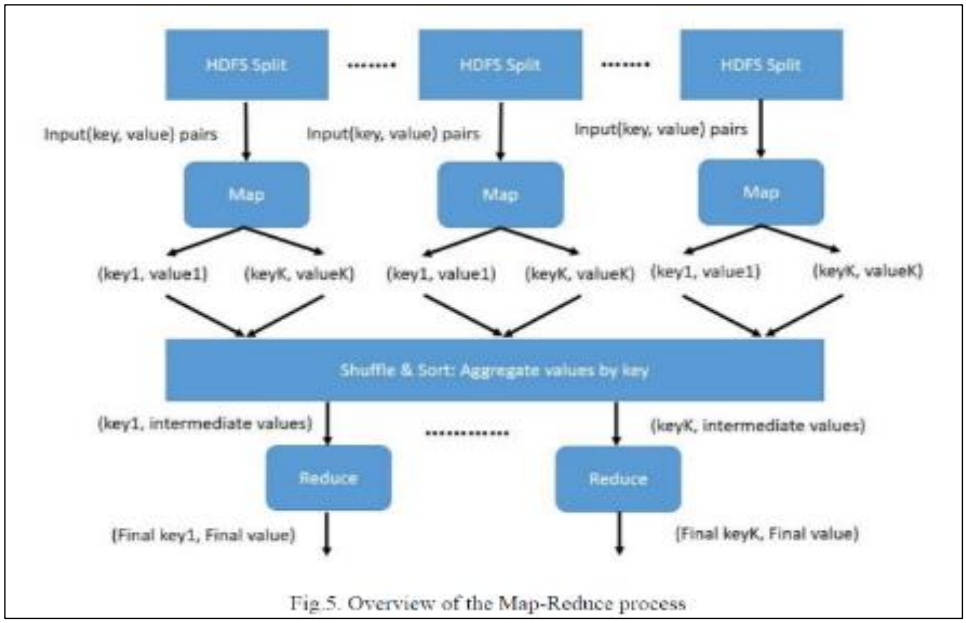

Figure 2: Map-Reduce Process.
Source: Authors, (2026).

III.1.2 Feature extraction

Feature extraction helps in the reduction of the dimensionality of data which is needed to process the data effectively. After eliminating duplicates, crucial features like closed frequent itemsets, support, and confidence are derived from the initial data.

Closed Frequent Itemset (o(fi))

Closed frequent itemsets are frequent itemsets that cannot be extended by adding more items while maintaining the same support. The closed frequent itemset is the maximal frequent itemset, indicating the highest occurrences of a specific item in the dataset.

$$o(f_i) = \{o(f_1), o(f_2), o(f_3), \ldots, o(f_n)\} \tag{4}$$

Support(δt)

Once closed frequent itemsets are identified, calculate the support for each itemset. It is usually expressed as a percentage. The support of association rule U → V is the percentage of transactions in the database containing both itemsets U and V.

$$\delta_t = Support\ (U \rightarrow V) = P(U \cup V) \tag{5}$$

Confidence (Ae)

Confidence is a measure of the reliability or strength of an association rule. The confidence of an association rule U → V is the percentage of transactions with itemset U that also includes itemset V. It is computed using conditional probability in relation to itemset support, expressed by the equation:

$$A_e = Confidence\ (U \rightarrow V) = P\left(\frac{V}{U}\right) = \frac{P(U \cup V)}{P(U)} \tag{6}$$

Where P (U ∪V) denotes the total number of transactions that include the itemsets U and V, while P(U) denotes the total number of transactions that include the itemset U.

Entropy calculation

A measure of a set of data's uncertainty or disorder is called entropy. The entropy calculation is used in this subsection to estimate support and confidence. The entropy of a probability distribution, which is connected to its variance, can be calculated for a given dataset using the following formulas.

$$Entropy(A_e) = -\sum_{e=1}^{N} P(A_e) log_2 \{P(A_e)\} \tag{7}$$

$$Entropy(\delta_t) = -\sum_{t=1}^{N} P(\delta_t) log_2 \{P(\delta_t)\} \tag{8}$$

Here, P(δt) and P(Ae) indicate the likelihood that, at random, the nth support and confidence values will be obtained from the set.

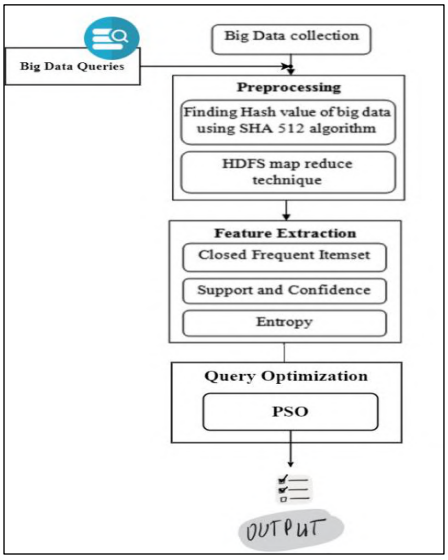

Figure 3: Block diagram for the proposed methodology.
Source: Authors, (2026).

III.2 QUERY OPTIMIZATION

For solving optimization issues, one popular population-based metaheuristic approach is particle swarm optimization (PSO). This algorithm mimics how birds in a flock interact with one another in order to reach their feeding objective. A swarm of birds approaches their food target by combining their social and self-experience. They constantly reposition themselves to establish the finest possible formation based on their own best position as well as the best position of the entire swarm. Iterations are used by the nature-based swarm-intelligence algorithm. It begins with a population of potential solutions, referred to as a swarm. Each particle in this instance stands for a possible fix for the stated issue.

Every iteration updates the velocity and position of every member in the population. Global best value (gbest) and personal best value (pbest) serve as the foundation for these improvements. The particles in gbest model are influenced by the best position identified by any member of the entire population, as opposed to the pbest model where the particles are determined by their own position. Each particle will then converge to this new location as a result.

PSO algorithm

Step 1 The population (particles) has been defined as the X1− Xn−1 weights.
Step 2 For the velocity updating based on weights, the following formula has been applied.
$vi\ (t + 1) = wvi(t) + c1r1[xi(t) - xi(t)] + c2r2[g(t) - xi(t)]$
where vi(t):represents the particle velocity at time t, xi(t):the particle position at time t, ˆxi(t):the individual particle best at time t, and g(t) the global best swarm best at time t. c1 and c2: Cognitive coefficients; w: Inertia coefficient
Step 3 The optimal position has then been updated in accordance with needs by comparing the current positions. As needed, the best spots have been updated. Also, the weights have been revised. For w, the range taken into consideration is 0.8–1.2. Here, c1 and c2 have a value of 2.
Step 4 The position update or the subsequent equations have been utilized.
$xi(t + 1) = xi(t) + vi(t + 1)$
Step 5 Classifications have been established and new posts have been allocated.
The PSO algorithm uses the extracted data to find the best answer to the user's inquiry. When compared to other approaches, this one produces better outcomes and provides the best answers for the given situation. As such, the PSO technique is generally appropriate for a class of high-dimensional optimization problems with extremely precise solutions.

IV. RESULTS AND DISCUSSION

IV.1 EXPERIMENTATION AND DATASET

This section explores the NKM methodology's assessment of the suggested query optimization strategy. Performance is examined and contrasted with state-of-the-art methods with different data sizes (10–50 MB). Test data for text classification is taken from publicly available datasets, most notably Reuters-21579. This dataset, which comes from the news agency Reuters, is arranged according to its economic significance. Specifically, the proposed method uses the Reuters-21578 dataset to choose the top 10 classes, with a test set of 1100 articles and a training set of 3875 documents. These records, which came from the Reuters Newswire in 1987, were put together and arranged by Carnegie organizations and Reuters Ltd. David D. Lewis made them available for study in 1990. 21,578 news items total from the dataset, all of which fall into one or more categories. Out of 21,578 documents, only those pertaining to the four most popular topics—"earn (earning)," "acq (corporate acquisitions)," "money-fx (money market)," and "grain" categories. Table 1 shows the Reuters – 8 benchmark datasets.

Table 1: Reuters-8 (R8) benchmark dataset summary.

R8			
Class	**# train docs**	**# test docs**	**Total # docs**
Acq	1596	696	2292
Crude	253	121	374
Earn	2840	1083	3923
Grain	42	10	51
Interest	190	81	271
Money-fix	206	87	293
ship	108	36	144

IV.2 PERFORMANCE ANALYSIS

Here, the suggested hybrid method's and the current method's performances are compared in terms of statistical metrics, Precision (P), Recall (R), Accuracy (A), F-Measure (F), Retrieval Time (RT) and Execution Time (ET).

Table 2: Comparison table for proposed method with existing method based on Precision, Recall, Accuracy and F-measure.

Data size in MB	**Proposed Method (HDFS-PSO)**				**Existing method (NKM)**			
	P	R	A	F	P	R	A	F
10	89.2	87.9	88.5	86.4	84.6	83.4	85.4	82.9
20	90.4	89.2	89.7	88.6	85.9	84.8	86.7	84.6
30	91.3	90.4	90.6	89.3	87.5	86.2	87.9	86.5
40	92.1	91.5	91.2	90.8	88.7	87.8	89.2	89.7
50	93.5	93.2	92.9	92.2	90.2	89.5	90.4	90.6

Source: Authors, (2026).

Table 2 compares the precision, recall, accuracy, and F-measure of the proposed method with an existing method. The suggested approach yields 93.5% precision, 93.2% recall, 92.9% accuracy, and 92.2% F-Measure on a 50 MB data set. However, the current approach achieves 90.6% F-Measure, 90.4% Accuracy, 89.5% Recall, and 90.2% Precision. Visually, Figure 4 clarifies the accuracy results shown in Table 2 even more, demonstrating the improved performance of the suggested approach.

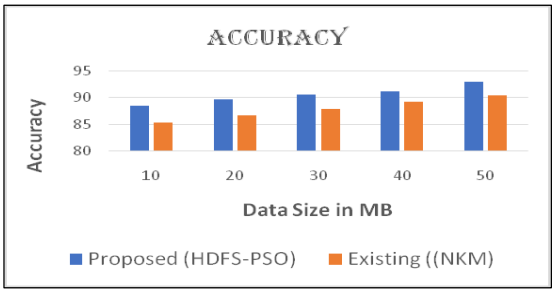

Figure 4: Comparative analysis for the HDFS – PSO with NKM in terms of accuracy.
Source: Authors, (2026).

Table 3 compares the performance of the proposed strategy with an existing method in terms of retrieval time and execution time, both measured in milliseconds (ms), with data sizes ranging from 10 MB to 50 MB.

Table 3: Illustrate the performance of proposed method with existing method based on retrieval time, execution time.

Data size in MB	**Proposed Method (HDFS-PSO)**		**Existing method (NKM)**	
	RT	ET	RT	ET
10	345	121	521	135
20	678	189	892	196
30	1487	208	1592	243
40	2571	245	2752	297
50	3489	293	3857	312

Source: Authors, (2026).

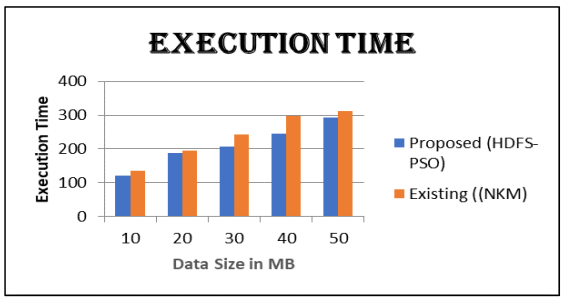

Figure 5: Comparative analysis for HDFS – PSO with NKM on execution time.
Source: Authors, (2026).

The current technique takes 3857 ms for retrieval and 312 ms for execution for a 50 MB data size, whereas the suggested method achieves a retrieval time of 3489 ms and an execution time of 293 ms. For all data sizes, the suggested approach requires less time for retrieval and execution. As a result, the suggested solution outperforms existing methods in terms of performance. Visually, Figure 5 clarifies the execution time results shown in Table 3, demonstrating the enhanced effective

V. CONCLUSIONS

This paper proposes a hybrid approach for query processing in big data, based on Particle Swarm Optimization and the Hadoop Distributed File System. When compared to the current query processing techniques, this hybrid approach is determined to be the most efficient and effective. This hybrid solution uses MapReduce and the Hadoop Distributed File System to remove duplicate data and extract attributes like confidence, support, and closed frequent patterns. Particle Swarm Optimization is used to optimize the query. The results of the proposed work's execution demonstrate and validate that the hybrid technique offers better accuracy and quicker query retrieval. With an average accuracy of 92.9%, the comparison analysis shows that the suggested model fared better than any of the other models in the current study. Additionally, the statistical outcomes of the F-measure (92.2%), recall (93.2%), and precision (93.5%) support the efficacy of the hybrid technique. As a result, this suggested system performs better than the current system. Future improvements to this system's efficiency could include the use of sophisticated optimization techniques and feature selection to speed up retrieval.

IoT,
Supply chain traceability,
Smart farming.

ABSTRACT

The convergence of Internet of Things (IoT), blockchain, and artificial intelligence (AI) has emerged as a transformative force in advancing sustainable agriculture. These technologies collectively address persistent challenges in traceability, resource optimization, data security, and decision support. This review conducts a systematic–narrative analysis of journal publications from 2020 to 2025, synthesizing insights across three thematic dimensions: (i) IoT–Blockchain frameworks for agricultural supply chain traceability, (ii) IoT–AI/ML approaches for predictive farming and crop health monitoring, and (iii) blockchain-driven data management for breeding and genomic applications. Across the themes, the reviewed studies demonstrate substantial improvements, including enhanced supply chain transparency, predictive accuracy exceeding 95% in crop disease classification, and scalable storage architectures for high-throughput breeding data. However, challenges persist in interoperability, scalability, energy efficiency, and end-user adoption. The review identifies critical research gaps and emphasizes the need for integrated frameworks that balance technological sophistication with practical usability. By consolidating current advances and limitations, this study provides a comprehensive understanding of the evolving IoT–Blockchain–AI ecosystem in agriculture and outlines future directions toward sustainable, transparent, and intelligent agri-food systems.

I. INTRODUCTION

Global agriculture faces mounting challenges: fragmented and opaque supply chains, frequent food-safety incidents, inefficient resource use, and rapidly growing volumes of farm and genomic data that require trustworthy, scalable management. Digital traceability remains incomplete across many value chains, hampering rapid recall decisions and eroding consumer trust; simultaneous pressures to improve sustainability and reduce post-harvest loss increase the urgency for technological solutions [1], [2]. The Internet of Things (IoT) brings dense, low-cost sensing and near-real-time telemetry to the farm and supply chain: soil moisture, temperature, cold-chain conditions, geolocation, and spectral or image data can now be captured continuously [3]. IoT enables precision interventions for irrigation, fertilization, pest control and produces the high-resolution provenance streams needed for verifiable analytics. However, IoT data by itself cannot guarantee immutability, distributed trust, or automated contractual enforcement across multiple stakeholders [4].

Blockchain (BC) offers complementary properties — a tamper-evident ledger, decentralized trust, and programmable smart contracts — which can help secure IoT data, automate transactions, and provide auditable provenance from farm to fork. Yet practical deployment raises important questions about cost, scalability, and the resource constraints of low-power IoT devices; careful architectural design and hybrid solutions such as edge gateways, private chains, data-hashing strategies are frequently proposed to balance trust and efficiency [5]. Several recent literature reviews and systematic studies have examined blockchain and occasionally IoT applications in agri-food systems, identifying common benefits (traceability, transparency, fraud reduction) and recurring barriers (interoperability, legal/regulatory concerns, adoption costs). For instance, by [6] analyzed adoption barriers and enablers for blockchain in smart and sustainable agriculture; in [7] systematically reviewed blockchain applications across food supply chains and identified under-utilized drivers and research gaps; by [8] assessed blockchain and IoT technologies in the context of regional feasibility and implementation constraints. These reviews are valuable but either focus narrowly on adoption drivers, concentrate mainly on supply-chain aspects, or synthesize literature that predates the recent surge (2020–2025) of IoT + blockchain empirical work.

I.1 CONTRIBUTIONS OF THIS REVIEW

This article addresses the above gaps by conducting a systematic–narrative review of journal publications from 2020 to 2025, with the following contributions:

- **Comprehensive scope:** covers 30 peer-reviewed journal articles on IoT–blockchain integration in agriculture.
- **Structured thematic analysis:** classifies studies into four themes: (1) Supply-chain traceability and provenance, (2) Smart/precision agriculture, and (3) Crop-breeding and genomic data management.
- **Critical synthesis**: compares methodological choices such as blockchain architectures (public, private, hybrid), on-chain/off-chain data strategies, and edge integration with IoT.
- **Identification of gaps:** highlights unresolved issues including scalability, energy costs, interoperability, and regulatory alignment.
- **Future research agenda:** proposes directions such as energy-efficient consensus mechanisms, cross-chain interoperability, and integration of genomic and AI-driven farming solutions.

II. METHODS

II.1 REVIEW TYPE

This work adopts a systematic–narrative review approach. The systematic component ensures transparent and reproducible identification of relevant literature, while the narrative synthesis allows for flexible integration of diverse study designs, applications, and technological perspectives. This combination is particularly suitable given the multidisciplinary nature of IoT–blockchain applications in agriculture, spanning supply chain traceability, precision farming, genomic data management, and adoption studies.

II.2 SEARCH STRATEGY

A structured literature search was conducted across major academic databases, including Scopus, Web of Science, IEEE Xplore, ScienceDirect, SpringerLink, Wiley Online Library, MDPI, and Taylor & Francis Online. The search covered the period from 2020 to August 2025 and was limited to publications in English. Boolean search strings were employed to capture relevant studies, such as:

- “IoT” AND “Blockchain” AND “Agriculture”
- “Smart farming” AND “Blockchain”
- “Blockchain” AND “Food supply chain” AND “IoT”
- “Blockchain” AND “Genomic data” AND “Agriculture”

These combinations were iteratively refined to maximize coverage across agricultural domains where IoT and blockchain intersect.

II.3 INCLUSION AND EXCLUSION CRITERIA

Studies were included if they:

- Were peer-reviewed journal articles.
- Reported original research (empirical, applied, or technical).
- Explicitly integrated IoT and blockchain technologies in agricultural contexts.

Studies were excluded if they:

- Were conference proceedings, book chapters, or review papers.
- Focused exclusively on blockchain or IoT without integration.
- Presented purely conceptual frameworks with no implementation or application.

II.4 SELECTION PROCESS

The initial search retrieved a large pool of records. After deduplication, titles and abstracts were screened for relevance. Full-text evaluation was then performed to assess eligibility against the defined criteria. At the end of this process, 30 journal articles were retained for analysis.

II.5 DATA EXTRACTION AND THEMATIC GROUPING

For each included article, key bibliographic and methodological details were extracted, including publication year, application domain, blockchain architecture, IoT scope, and study contribution. The articles were then organized into three thematic categories reflecting their primary focus:

1. Supply chain traceability and provenance.
2. Smart and precision agriculture.
3. Crop breeding and genomic data management.

This thematic grouping enables cross-comparison of methodological approaches, application domains, and identified research gaps.

II 6 PRISMA DIAGRAM

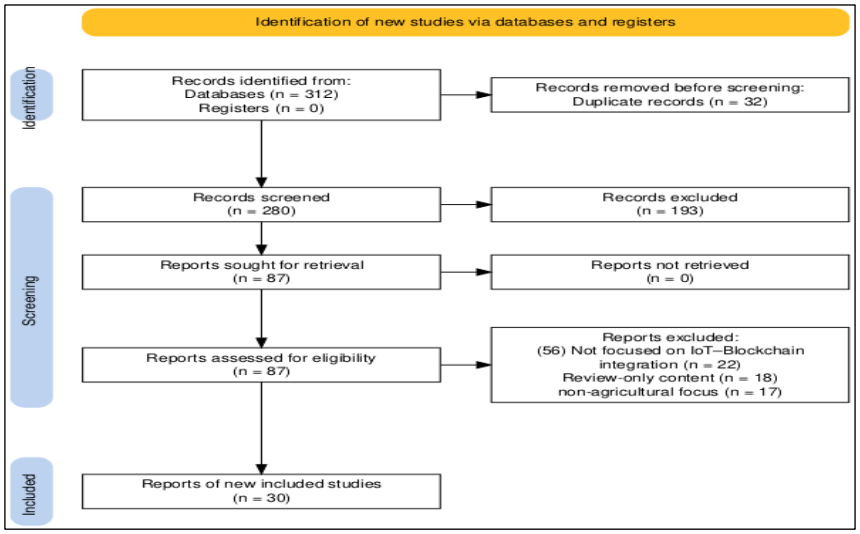

Figure 1: PRISMA flow diagram of study selection process.
Source: Authors, (2026).

Figure 1 shows the selection process of the studies included in this review. A total of 312 records were initially identified through database searches. After removal of 32 duplicates, 280 records remained for screening. Following title and abstract evaluation, 193 records were excluded for irrelevance. The full texts of 87 reports were then assessed for eligibility, of which 56 were excluded due to reasons such as lack of IoT–Blockchain integration (22), review-only content (18), or non-agricultural focus (17). Finally, 30 studies fulfilled the inclusion criteria and were retained for detailed synthesis.

III. RESULTS

III.1 THEME 1: SUPPLY CHAIN TRACEABILITY AND PROVENANCE

Traceability research moved quickly from proof-of-concept immutable ledgers to systems that must also solve privacy, latency, storage growth, data trustworthiness, and operational usefulness.

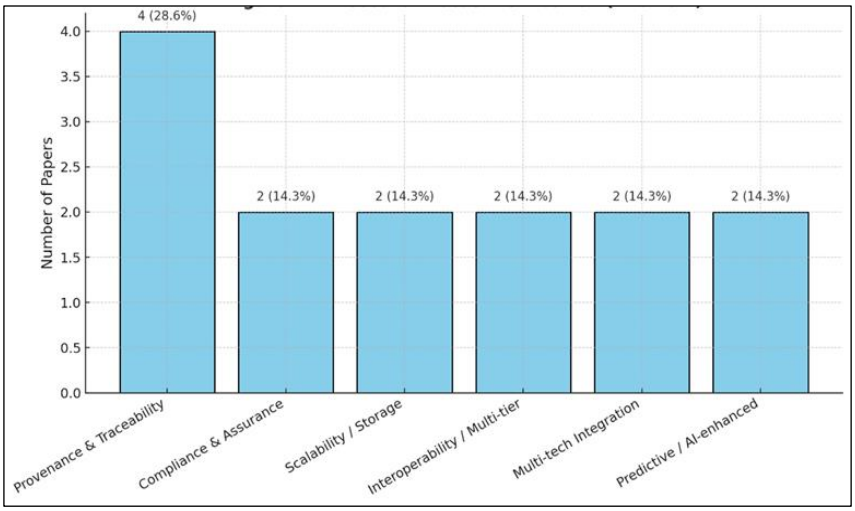

Figure 2: Research focus distribution on theme 1.
Source: Authors, (2026).

Figure 2 shows the research focus distribution of Theme 1 papers on IoT–Blockchain for agricultural product traceability. Most studies focus on provenance and privacy (3 papers), followed by compliance frameworks (2), scalability solutions (2), interoperability designs (2), multi-technology integration (2), and predictive/AI methods (2). Provenance is the dominant focus, while interoperability and prediction remain less explored. The following paragraphs synthesize how key papers address these problems, comparing what each did to what the others missed or improved.

III.1.1 On-Chain Vs Hybrid Storage and The Price of Verifiability

According to [9] established an influential hybrid pattern — store a compact Merkle root on Ethereum and put bulky provenance files in IPFS — using SHA-256 and Merkle trees to keep integrity while limiting on-chain data. Their measured numbers (per-function gas ≈ USD 0.29–0.45; SHA-256 ~2 s for 1 GB; IPFS upload 243 MB ≈ 3.4 s, query ≈ 22 s) make explicit the trade-off: verifiable provenance is feasible but public-chain gas costs quickly become a bottleneck. In [10] respond to this by moving to permissioned PoA Ethereum (IoT-GChain): they keep the hybrid storage model (IPFS + on-chain hash) but change consensus to PoA, yielding block times ≈ 3 s and gas per operation in the 85k–134k units range. In short, [9] proves the hybrid technique; [10] demonstrates how consensus choice changes latency and practical viability.

III.1.2 Privacy, Compliance and Contract Logic

Where [9] prioritized privacy by minimizing on-chain payloads, by [11] encoded compliance rules directly into contracts via the Trust-Enhanced Contract Algorithm (TECA). TECA performs multi-party validation (sensor verification + certification rules) BEFORE a claim is anchored, thereby reducing on-chain noise and ensuring only verified claims are recorded. According to [11] BSAA reports gas 41k–102k units, ~USD 0.25 average transaction cost and 18–20 TPS — a clear demonstration that smart contract logic + careful write policies can permit practical throughput for assurance workflows, unlike naive full-data writes on public chains.

III.1.3 Integrating Analytics and Operational Value

According to [12] integrate forecasting directly with provenance: a GA-tuned ensemble (LSTM + GRU) reduces RMSE from 872.6 / 819.7 to 512.2, while provenance sits on a permissioned blockchain with Hyperledger Caliper tests showing median latencies ~198–768 ms for 200–800 nodes. Contrast this with by [13], who do not aim at RNN forecasting but show that classical ML applied to RFID/WSN transport data gives immediate operational value — RF 95.5%, AdaBoost 94.3%, SVM 91.7%, KNN 89.6% — yet [13] Bhutta do not evaluate blockchain latency/cost. Thus: [10]-11 shows deep-learning + private chain is feasible (in sim), [13] shows classical ML yields very high accuracy in transport forecasting but leaves blockchain operational costs unexplored. Combining both approaches would be a logical next step.

III.1.4 Scalability and Storage Lifecycle (redaction & parallelism)

Canonical append-only ledgers cause storage bloat; by [14] propose redactable primitives (chameleon hash) + parallel chain architecture + CP-ABE and report ~52.38% reduction in storage footprint over 360k wheat records. Compare that with AgriChainSync [15], which employs a Dynamic Storage Algorithm (DSA) and a Feedback & Adaptation Module (FAM): under experimental load (100–1000 IoT devices) [15] AgriChainSync shows latency increase ≈ 15% under 10× data volume and improved storage efficiency. LAP-chain [14] solves data retention/compliance explicitly (delete or redact expired data); [15] AgriChainSync emphasizes adaptive routing to balance cost vs latency. Both demonstrate that architecture + algorithms can control storage growth — a capability absent from many early single-chain designs [9],[16].

III.1.5 Data-Quality at Capture: Sensor Fusion, NIRS And Multi-Tech Verification

According to [17], [18] highlight an often-ignored truth: immutability cannot fix bad inputs. [17] integrates NIRS + RFID + IoT to verify quality signals before anchoring; Paper [18] implements embedded IoT + permissioned chain in an industrial hemp deployment. These works contrast with Papers [9–12] and show that adding certified sensing (NIRS, RFID) is required to make an immutable chain trustworthy for quality claims. Practically, this means systems should include sensor-level verification algorithms as pre-contract checks — a capability shown in Papers [17], [18] but missing in many ledger-centric designs.

III.1.6 Interoperability, Governance and End-To-End Integration

In [19] propose a vertical-chains + core hash-chain model for stakeholder privacy and scalability; by [16] provide an end-to-end Ethereum + IPFS stack with a reputation subsystem, but both lack large-scale field results. According to [20] push for end-to-end visibility (edge gateways → chain), yet they report little performance detail. Thus the field is converging on multi-chain / core-chain topologies + governance policies as necessary for multi-stakeholder adoption, but real-world interoperability experiments are still scarce.

Table 1: Summary of theme 1.

Paper	Methods / Architecture	Algorithms / Techniques	Key Results / Performance	Limitations / Challenges
[12]. Khan et al. (2020)	Private blockchain + IoT + predictive analytics	GA-optimized ensemble of LSTM + GRU	RMSE reduced to 512.2 vs. 872.6 (LSTM) & 819.7 (GRU); query latency 198–768 ms over 200–800 nodes	Tested only in simulated private networks
[20] El Mane et al. (2024)	End-to-end IoT–Blockchain architecture (8-node network)	Controllers/validators added dynamically	Latency margin ≈ 100–120s; throughput ≈ 235–260 TPS on 3.5 GHz CPU, 32 GB	Latency rises with heavy concurrent traffic; no energy cost evaluation

			RAM; improved performance with more validators	
[21]. Guo et al. (2025)	Hyperledger Fabric + IoT sensors + smart contracts	Blockchain-based trusted traceability	File transfer: upload ≈ 7.31 MB/s (small), 15.19 MB/s (large); download ≈ 31.92 MB/s (small), 35.61 MB/s (large) → meets real-time traceability needs	Mostly tested on grape supply chain; lacks broader validation
[19]. Bhat et al. (2022)	Agri-SCM-BioT: vertical blockchains + core chain	Controlled access via master/gateway nodes	Secure master nodes reduce 51% attack risks; high-resource nodes improve resilience	No reported values for latency, storage cost, or throughput
[15]. Tahir et al. (2024)	AgriChainSync (hybrid IoT–AI–Blockchain)	Dynamic storage + homomorphic encryption	Latency increase only 15% under 10× data load; throughput robust; storage efficiency improved	Energy/operational overhead not deeply analyzed
[16]. Shahid et al. (2020)	Ethereum + IPFS for provenance, trading, reputation	Multiple smart contracts	Simulation: gas usage scales with products; improved transparency and auditability	Cost/latency not quantified in USD terms

Source: Authors, (2026).

Progress is evident in: (a) hybrid storage patterns (Merkle root + IPFS), (b) permissioned consensus (PoA/Hyperledger) to lower latency and fees, (c) integration of analytics for operational decision support, and (d) architectural work to tackle storage retention (redactable/parallel chains) and interoperability (multi-chain). Remaining bottlenecks are consistent across studies: lack of large-scale field validations, incomplete cross-paper reporting of latency/cost metrics in a unified format, and few integrated demonstrations that combine sensor verification, optimized contract logic (TECA/DSA), and analytics (RNN/RF) in a single production deployment. Table 1 provides a comparative summary of some studies highlighting their methods, algorithms, key results, and limitations.

III.2 THEME 2: SMART AND PRECISION AGRICULTURE

Research at the intersection of IoT and blockchain in agriculture has evolved toward secure, privacy-preserving, and energy-efficient systems that also support predictive intelligence and supply chain transparency. The eleven papers reviewed under this theme (22–32) demonstrate different approaches to address challenges such as security and trust, prediction accuracy and anomaly detection, privacy-preserving collaborative learning, IoT network efficiency, and supply chain sustainability. Figure 3 shows the distribution of research focus in IoT + Blockchain for Smart and Precision Agriculture based on 11 reviewed papers. The largest focus is on Security & Trust (27%) and Network/Energy Efficiency (27%), followed by Prediction & ML (18%), Supply Chain Transparency (18%), and Privacy & Federated Learning (9%). This highlights key research priorities and gaps in the field.

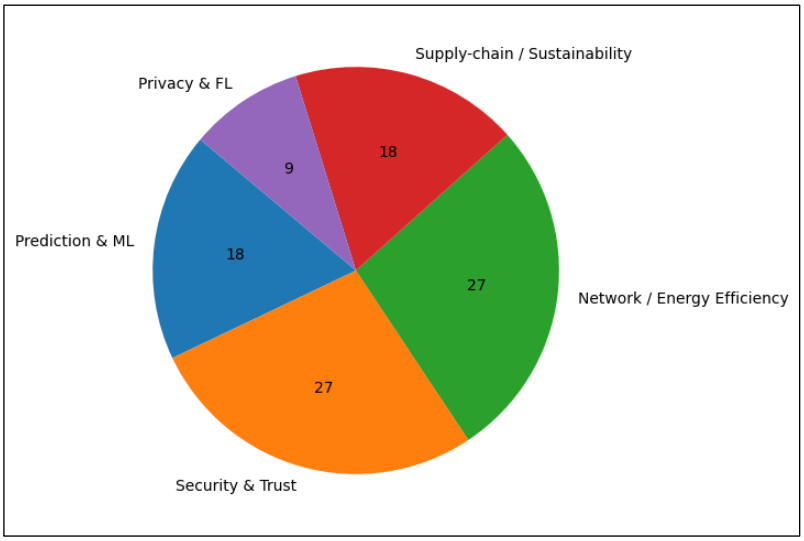

Figure 3: Research focus distribution on theme 2.
Source: Authors, (2026).

III.2.1 Security and Data Integrity

Maintaining trustworthy and tamper-resistant agricultural data is a fundamental requirement. According to [22] combined edge devices (ESP32, Arduino) with AWS IoT and Ethereum testnet smart contracts, achieving average alarm response latency of ≈0.11 seconds, demonstrating the feasibility of automated IoT–blockchain alarms. Similarly, by [23] proposed a cloud-enabled security monitoring system where IoT sensor data is processed in AWS Lambda and anchored to blockchain, reporting IoT-to-cloud latency of ≈2 s, Ethereum confirmation ≈7 s, and full end-to-end alerts within ≈9 s. According to [24] focused on blockchain cost-efficiency, analyzing smart contract gas usage, where typical IoT checks consumed ≈29,217 gas units, highlighting the economic trade-off between security automation and blockchain overhead. Together, these works confirm that edge-assisted detection with blockchain anchoring ensures trustworthy event logging, though scalability to production systems demands gas optimization or migration to permissioned/Layer-2 chains.

III.2.2 Prediction Accuracy and Anomaly Detection

Several studies demonstrate the potential of combining IoT data with blockchain-backed integrity guarantees for accurate prediction and anomaly detection. For [25] used a binary Slime Mould Algorithm (SMA) for feature selection with Bi-LSTM and GRU models, achieving yield prediction accuracy ≈95.8%, F1 scores ≈0.96, and anomaly detection precision of ≈0.93, while ensuring nearly 100% integrity via blockchain. According to [26] employed classical ML approaches for crop recommendation, achieving accuracies up to 98.2%, showing that interpretable models can perform strongly in structured IoT datasets. In [27] applied CNN-LSTM hybrids under federated learning, where centralized models reached RMSE ≈4.70 and R^2 ≈0.84, while privacy-preserving FL variants showed slightly degraded RMSE ≈5.15–5.90. According to [28] proposed Smart-Agri, an IoT–ML–Blockchain framework, achieving ≈89.5% accuracy in crop monitoring and control. These results indicate that DL consistently provides superior predictive performance, though classical ML remains competitive when computation must remain lightweight.

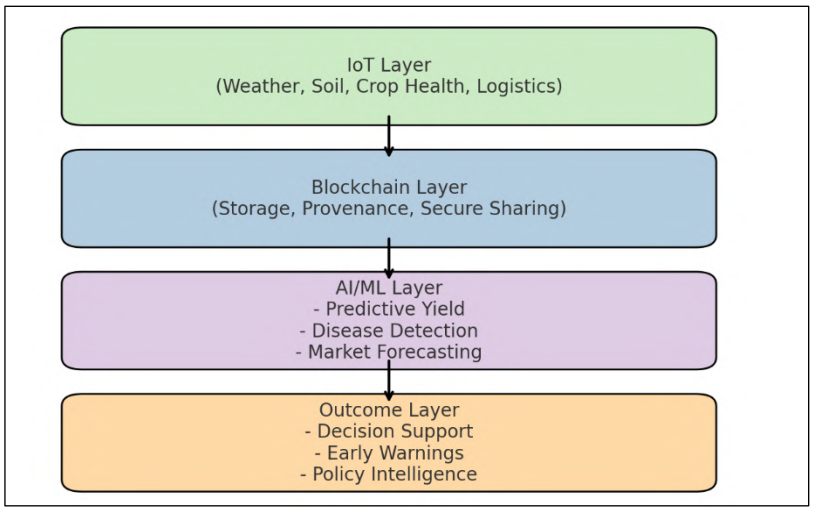

Figure 4: Pipeline of IoT, Blockchain, and AI integration for predictive agricultural insights.
Source: Authors, (2026).

This framework illustrates (Figure 4) how IoT devices capture real-time agricultural data, which is securely managed through blockchain before being processed by AI/ML models for predictive insights. The outcome enables decision support, early warnings, and policy-level intelligence.

III.2.3 Privacy-Preserving Collaborative Learning

Sharing agricultural data across stakeholders raises privacy risks, which several works addressed by integrating federated learning (FL) with blockchain provenance. The federated architecture of by [27] demonstrated that CNN-LSTM models can be trained collaboratively without exposing raw farm data. Differential privacy extensions further strengthened protection but increased RMSE to ≈5.90 compared to ≈4.70 in centralized training. While latency and blockchain throughput were reported as "acceptable," detailed network stress tests remain scarce. These findings confirm that federated learning with blockchain is a viable solution for multi-party collaboration, but future work must optimize trade-offs between privacy guarantees and predictive accuracy.

III.2.4 IoT Network Efficiency, Energy, and Mobility

The reliability and sustainability of IoT sensor networks in agriculture are critical for real-world deployments. In [29] proposed an energy-aware clustering protocol, achieving substantial improvements compared to the LEACH baseline: network lifetime extended by +112%, stability period increased by +23%, and energy consumption reduced by −68%. According to [30] examined precision agriculture networks with 6LoWPAN and RPL routing under both fixed and mobile topologies. Results showed that fixed nodes achieved stable connectivity and lower radio duty cycles, while mobility increased energy costs and connectivity fluctuations, though precise percentages were less detailed. Collectively, these studies demonstrate that energy-efficient clustering significantly extends sensor lifetimes, while robust routing protocols remain an open challenge for mobile agricultural IoT environments.

III.2.5 Supply Chain Transparency and Sustainability

Ensuring end-to-end transparency from farm to consumer remains a central objective. In [31] proposed a semantic cyber–physical system (CPS) that integrates IoT, blockchain, AI, and remote sensing for traceability, reporting improved decision support and qualitative gains in transparency, though without quantitative latency or cost metrics. According to [32] applied TOPSIS-based multi-criteria analysis to identify and rank barriers to blockchain adoption in green agricultural supply chains, emphasizing issues such as regulatory compliance and trust. According to [24] further demonstrated how blockchain smart contracts can automate supply chain agreements, reporting explicit transaction costs across agricultural IoT scenarios. Collectively, these works highlight that semantic architectures and multi-criteria frameworks provide conceptual clarity, but cost-efficient blockchain execution remains the most urgent bottleneck for real-world adoption.

Table 2 highlights the core contributions of each work in terms of architecture, algorithms, and outcomes, showing how researchers have leveraged blockchain to ensure confidentiality, integrity, and secure sharing of agricultural IoT data.

Table 2: Comparative summary of Theme 2 papers.

Paper (no.)	Methods & architecture	Algorithms / techniques	Key results
[22] Aliyu & Liu (2023)	ESP32 IoT nodes → AWS cloud (IoT Core + Lambda) → Ethereum (Rinkeby); smart contracts automate responses	Edge threshold/rule detection; Solidity smart contracts; on-chain logging	Observed transaction counts ≈ 109k–291k avg network latency ≈ 0.11 s
[29] Wang et al. (2025)	Human-Cyber-Physical System combining IoT, remote sensing, AI, semantic blockchain layer	Semantic data integration; H-CPS architecture (conceptual)	Qualitative improvements in traceability and cost-efficiency reported
[25] Almazmomi (2025)	4-layer framework: data acquisition, AI layer, security layer, blockchain layer	Binary SMA for feature selection; Bi-LSTM, GRU for prediction; blockchain for integrity	Yield accuracy: 95.8% (Bi-LSTM) 94.6% (GRU); F1 ≈ 0.96/0.94; anomaly detection precision 0.93, recall 0.92; blockchain integrity ↑ ≈97%
[28] Hossain et al. (2023)	IoT sensors + cloud + mobile UI + blockchain for integrity; energy harvesting for sensors	ML recommendation model (unspecified) for irrigation/fertilizer; blockchain for logging	ML model accuracy ≈ **89.5%** in their experiments; system supports remote control and energy harvesting
[30] Atalla et al. (2023)	WSN simulation (COOJA) with 6LoWPAN + RPL; scenarios: fixed-node (olive farm) and mobile nodes (stable)	RPL routing; Random Waypoint mobility model; COOJA simulation	Fixed-node: more stable connectivity and lower power consumption; mobile-node: higher radio duty cycle and connectivity fluctuation
[27] Manoj et al. (2025)	Federated learning orchestration + blockchain ledger (DIDs, VCs) for authentication & provenance	CNN-LSTM, ResNet-16/28, CNN-DNN as models; DP-FL variants; smart contracts for metadata logging	Centralized CNN-LSTM: MSE ≈ 22.07, RMSE ≈ 4.70, R^2 ≈ 0.84 (2018); DP-FL (3 clients IID): MSE ≈ 26.50, RMSE ≈ 5.15, R^2 ≈ 0.77;
[31] Awan et al. (2021)	3-layer IoT architecture with clustering protocol + blockchain logging	Custom energy-efficient clustering protocol (LEACH-variant)	Compared to LEACH: +23% network stability, −68% energy consumption, +112% network lifetime
[32] Chaudhari et al. (2025)	IoT data collection + blockchain for secure tracking; TOPSIS for barrier prioritization	TOPSIS multi-criteria decision method; IoT + blockchain architecture for GSCM	Ranked adoption barriers and proposed prioritized interventions
[23] Chaganti et al. (2022)	Arduino/ESP8266 sensors → AWS IoT Core + Lambda → Ethereum (Rinkeby) via Infura; Web3 UI	Threshold-based anomaly detection in Lambda; Solidity smart contracts for logging	IoT→cloud publish ≈ 2 s; Ethereum tx ≈ 7 s; end-to-end alert ≈ 9s
[26] Bakthavatchalam et al. (2022)	IoT sensors measuring N,P,K,pH,temp,humidity,rainfall; dataset (2,200 instances)	MLP, Jrip, Decision Table classifiers (WEKA)	MLP accuracy ≈ 98.23%, Jrip ≈ 96.23%, Decision Table ≈ 88.59%; ROC ≈ 0.991–0.997; model build times 0.15–10.56 s
[24] Pranto et al. (2021)	IoT sensors + Solidity smart contracts on Ethereum testbed; MQTT messaging; contract functions for storage/distribution	Solidity smart contracts (self-check/trigger functions), off-chain sensor input via MQTT	Gas usage per operation addSeed() transaction 168,402 gas (transaction) / 144,314 (execution); temperatureSelfCheck() 50,681 / 29,217 gas; retailSell() 91,464 / 69,808 gas

Source: Authors, (2026).

Overall, the reviewed studies show clear trends: (i) edge-assisted smart contracts can deliver real-time security but gas costs demand optimization; (ii) deep learning approaches achieve high prediction accuracy, while federated learning enables privacy-preserving collaboration at modest performance trade-offs; (iii) energy-aware clustering yields measurable IoT lifetime extensions, making it one of the most deployment-ready innovations; and (iv) semantic frameworks and barrier analyses advance conceptual supply chain trust, though empirical cost and latency data are still underreported.

The comparative evidence suggests that privacy-preserving deep learning and energy-optimized IoT protocols, tightly integrated with blockchain provenance, represent the most promising direction for next-generation precision agriculture ecosystems.

III.3 THEME 3: CROP BREEDING, GENOMICS & DATA MANAGEMENT

Theme 3 papers focus on the integration of blockchain, IoT, and advanced computational methods (ML, encryption, privacy-preserving frameworks) to address the growing challenges in crop breeding, genomics, and large-scale agricultural data management. The reviewed studies contribute solutions for high-throughput data storage, secure genomic management, breeding efficiency, and supply chain traceability, while also revealing gaps related to scalability, security-performance trade-offs, and integration of advanced analytics. Figure 5 demonstrates the role of IoT in collecting genomic and field data, with blockchain ensuring secure storage, provenance, and controlled sharing. This integration strengthens breeding programs, genomic research, and collaborative data management.

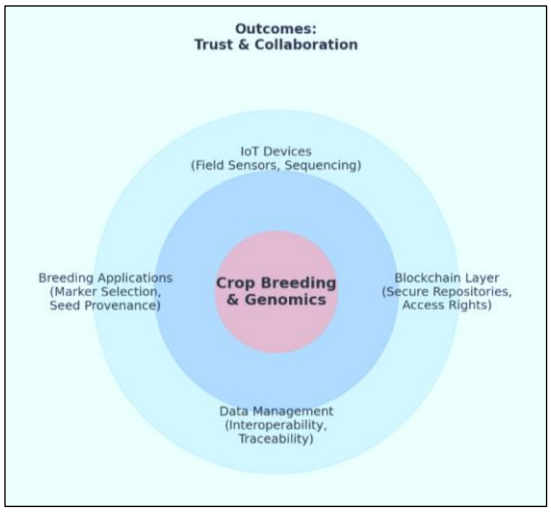

Figure 5: Framework of IoT and Blockchain in crop breeding, genomics, and data management.
Source: Authors, (2026).

III.3.1 Data Storage, Compression & Retrieval

According to [33] developed a spectral data pipeline within Breedbase, demonstrating 40% compression via differential computation and 50% faster retrieval with indexing, while PCA captured >85% variance for dimensionality reduction. However, robust blockchain-level security was absent. In contrast, [34] implemented multi-chain blockchain architecture with proxy encryption for GSBCP, which significantly improved system concurrency and secure storage of sensitive breeding data. Both works show how storage and retrieval challenges are addressed, but [33] emphasized efficiency while by [34] focused on security-performance trade-offs.

III.3.1.1 Breeding Information Management & Genealogy Tracking

According to [35] proposed a Hybrid Crop Breeding Information Management System (HCBIMS) with diallel crossing design, GCA/SCA analysis, and genealogy tracking, doubling efficiency in combining ability test analyses. This was further supported by compound genealogy tools, which enhanced lineage tracking. Similarly, [36] built a relational database-based breeding trait tracking system, enabling faster querying and visualization, with higher data accuracy than manual methods. While both improved breeder decision-making, neither incorporated blockchain security.

III.3.1.2 Secure Genomics & Privacy Preservation

According to [37] introduced a blockchain-based privacy-preserving genomic data system with Local Differential Privacy (LDP). It separated encrypted private storage for staff and irreversibly modified semi-private storage for external access, ensuring confidentiality, access control, and user monitoring. However, the study lacked ML-driven analytics for predictive genomics. Compared to [34], which emphasized proxy encryption and multi-chain performance, Park's contribution primarily addressed privacy and fine-grained access control.

III.3.1.3 Supply Chain Traceability & End-to-End Data Integrity

According to [38] extended blockchain applications beyond breeding to food grain traceability. By combining IoT sensors (temperature, humidity, GPS) with Ethereum blockchain, IPFS, and ML algorithms, the system enhanced scalability, throughput, and latency. Notably, it maintained strong confidentiality, integrity, availability, and non-repudiation guarantees. Unlike in [33], [35] works that focused on breeding data management, by [38] contribution highlighted how blockchain–IoT–ML convergence can secure the entire crop supply chain lifecycle. Table 3 presents a comparative overview of Theme 3 papers, highlighting their methods, algorithms, achieved results, and the specific agricultural challenges they addressed.

Table 3: Comparative summary of theme 3.

Paper	Methods / Techniques	Results / Performance	Challenges Addressed
Hershberger et al. (2021) [33]	Breedbase pipeline, differential compression, PCA	40% compression, 50% faster queries, >85% variance retained	Storage efficiency, retrieval speed
[34] Zhang et al. (2020)	Multi-chain blockchain, proxy encryption, GSBCP	Improved concurrency, secure storage with layered access	Data security, storage scalability
Han et al. (2020) [35]	HCBIMS, diallel crossing, GCA/SCA analysis, genealogy tool	Doubled efficiency in combining ability analysis, automated reports	Breeding efficiency, lineage tracking
Basheija et al. (2021) [36]	Relational DB, phenotype trait tracking, custom algorithm	Faster querying, higher accuracy than manual methods	Data organization, real-time decision support
[37] Park et al. (2021)	Blockchain + LDP, dual storage (private/semi-private)	Privacy-preserving genomic access control, staff & external data segregation	Data privacy, access monitoring
[38] Agarwal et al. (2024)	IoT sensors, Ethereum, IPFS, ML anomaly detection	High throughput, low latency, strong CIA+NR security	Transparency, anomaly detection, supply chain scalability

Source: Authors, (2026).

In synthesis, Theme 3 highlights how the triad of IoT, blockchain, and ML is not just an incremental enhancement of existing agricultural systems but rather a paradigm shift toward intelligent, decentralized, and resilient agri-ecosystems. The works reveal a trajectory where trust (blockchain), perception (IoT), and cognition (ML) are interwoven, pointing to a future in which agricultural decision-making is secure, explainable, and adaptive to uncertainties—a cornerstone for next-generation digital agriculture.

IV. CHALLENGES & FUTURE DIRECTIONS

- ✓ A major research gap lies in the integration of heterogeneous agricultural data sources, where IoT sensor streams, spectral datasets, blockchain transaction records, and genomic information remain fragmented, limiting holistic insights.
- ✓ Scalability challenges persist as most proposed systems have been validated on limited datasets or small-scale pilots, restricting their applicability to high-throughput crop breeding pipelines or multi-stakeholder agricultural supply chains.
- ✓ Interoperability issues continue to hinder progress, with the absence of standardized frameworks preventing seamless cross-platform data exchange between IoT–Blockchain–ML ecosystems and breeding information systems.
- ✓ Security and privacy concerns remain inadequately addressed, particularly for sensitive genomic and phenotypic data, where existing blockchain mechanisms ensure transparency but fail to provide fine-grained confidentiality.
- ✓ User-centric limitations emerge as farmer usability, cost-effective deployment, and real-time decision support features are often overlooked, reducing the practical adoption of these advanced technologies in resource-constrained environments.
- ✓ Energy and cost constraints are evident, as blockchain and IoT-driven solutions demand significant computational and communication resources, posing barriers for sustainable agricultural implementation.

❖ Future directions

- ✓ Future directions point towards the deployment of federated and edge AI frameworks that enable scalable, privacy-preserving analytics without centralized data pooling.
- ✓ Hybrid blockchain models that integrate lightweight consensus mechanisms with sharding are needed to balance transparency, efficiency, and real-world feasibility in agricultural contexts.
- ✓ The development of interoperable standards for multi-source agricultural data exchange will be critical in bridging the gap between phenotyping, breeding, and supply chain systems.
- ✓ The incorporation of explainable AI and XAI frameworks is essential to ensure interpretability and trust in decision support for breeding, disease detection, and traceability tasks.
- ✓ Sustainable computing paradigms, including green blockchain and energy-efficient IoT deployments, are required to mitigate the environmental and economic costs of digital agriculture.
- ✓ Farmer-centric innovations such as mobile-based decision support, fuzzy reasoning mechanisms, and multilingual interfaces will play a vital role in democratizing access to advanced IoT–Blockchain–ML solutions in agriculture.

V. CONCLUSIONS

This review critically analyzed the integration of IoT, blockchain, and AI/ML technologies across three thematic dimensions: agricultural supply chain traceability, smart farming with predictive intelligence, and breeding/genomic data management. The findings highlight that blockchain ensures transparency, immutability, and trust, IoT enables real-time monitoring of agricultural processes, and AI/ML enhances predictive accuracy and intelligent decision-making. In Theme 1, blockchain–IoT frameworks improved traceability and security across food supply chains, though issues of interoperability and scalability remain unresolved. Theme 2 emphasized predictive modeling for crop health and resource optimization, where hybrid deep learning models such as CNN-LSTM and Bi-LSTM achieved high accuracy (up to 96%) and improved efficiency, yet challenges of energy consumption and cost persist. Theme 3 demonstrated blockchain's role in securely managing high-throughput breeding and genomic data, supported by lightweight architectures and proxy encryption, though concerns around system sustainability and farmer usability continue.

Overall, while significant progress has been made, critical gaps remain in scalability, standardization, and user-centric design. Future research must focus on interoperable, explainable, and sustainable frameworks that combine technological robustness with accessibility for diverse stakeholders. Addressing these gaps will enable IoT–Blockchain–AI ecosystems to evolve into a resilient foundation for next-generation smart agriculture.

ABSTRACT

The rapid expansion of the big data in cloud facilities has posed immense challenges in terms of storage efficiency, privacy as well as security. To address these issues, this study proposes a Fractal Coding-based Privacy-Preserving Framework with a dynamic trusted authentication architecture to handle big data in cloud systems safely. First the framework divides raw information into blocks and encodes them to small fractal codes minimizing overhead of storage and transmission yet preserving the structure of the information. Then the privacy levels of each blocks are determined by the sensitivity allocation mechanism and much protection is guaranteed on highly sensitive data through assigning the privacy level to the respective divided block. Finally, to strengthen confidentiality, Triple Data Encryption Standard (TDES)-Dynamic Intelligent Multiple Access (DIMA) module added which engages extended TDES encryption together with dynamic authentication to withhold brute force attack and unauthenticated access. The combination of these design balances compression efficiency, the preservation of privacy, and cloud security. Experimental analysis shows that the proposed framework provides a faster decryption, a high transmission efficiency, high data confidentiality of 95% and minimum CPU consumption of 24%.

I. INTRODUCTION

Cloud storage has become the default storage and processing location to hold and operate large datasets due to its easy scaling and reduced initial cost of infrastructure. With the shift of the routine reporting to sophisticated analytics, Machine Learning (ML), and real-time decision systems, the amount and diversity of information stored on clouds had to increase manifold as sensor streams and medical records gave way to multimedia and transaction logs [1], [2]. These expansions put new strains on the manner in which data are stored, accessed and secured necessitating to reconsider the efficiency of storage, privacy guarantees and end to end protection in the clouds [3], [4]. To efficiently store large scale data in the cloud, it is needed to deploy algorithmic compression, smart redundancy, and storage aware data placement together [5]. Conventional ways like deduplication, erasure coding and sharding are predominant in minimizing physical footprint and enhancing durability, but it interacts badly with privacy controls and introduces nontrivial computational and network overhead in the event it operates at web scale. The recent work thus explored more adaptive redundancy mechanisms and erasure-code optimizations to reduce storage overheads without impacting on availability and repairability [6]. Privacy and security are now first-class issues instead of subsequently considered. End-to-end data encryption preserves confidentiality but complicates analytics and deduplication; fully homomorphic cryptographic techniques have been proposed to perform computations on ciphertexts, yet are too expensive to scale with large deployments [7]; and lightweight or certificateless cryptographic designs have been suggested to provide a secure IoT-to-cloud pipeline, but are too expensive to scale to large deployments.

The literature of recent times [8] provides a clear picture of these trade-offs between confidentiality, computability, and the usage of resources and inspire hybrid solutions that decouple data utility and secrecy. The latest optimization and adaptive partitioning techniques have rendered the fractal and self-similarity-based schemes feasible in large heterogeneous data sets [9], and exhibited encouraging enhancement in the ratio of compression and encode/decode performance on real data. These advances indicate that fractal coding can be considered an effective part of a privacy-aware storage pipeline together with an effective parameter encoding and targeted fidelity control. Several recent studies tackled secure cloud storage holistically by some combined homomorphic or searchable encryption with storage verification primitives; others proposed dynamic access control or lightweight authenticators to support data dynamics and audits with low preprocessing costs [10]. These works highlighted the need for storage designs that are simultaneously compression-aware, privacy-driven, and verifiable at scale. Despite these advances, important gaps remain. Many storage schemes either prioritize compression and efficiency at the expense of adaptive privacy controls. Recent redundancy and erasure-code optimizations addressed availability, but did not simultaneously solve sensitivity-aware compression and efficient key management across distributed cloud nodes. Motivated by this gap, the proposed model combines three major concepts: (1) fractal compression (2) a sensitivity allocation layer and (3) TDES-DIMA security layer that provides robust, session-bound access control and layered encryption for high-sensitivity content. At the time of data request dynamic authentication, preventing brute-force attacks and unauthorized access. The contribution of the proposed framework was:

- To remove anomalies, redundancy, and noises in the data, the proposed model uses the partitioning and preprocessing step that maximizes the uniformity of the data, which increases the efficiency of compression and general computational performance.
- To improve storage efficiency without reducing the reconstruction quality the proposed model combines the fractal geometric transformations to achieve the efficient data compression the use of the self-similarity.
- To offer the adaptive privacy preservation, the model under consideration allocates varying levels of sensitivity to data that are based on the contextual and content-specific features of data.
- To resolve both confidentiality of data and user authentication, a new privacy-preserving model based on TDES-DIMA was created to allow big data storage and retrieval in clouds securely.
- To improve scalability, redundancy, and consistency without compromising access controls and efficient retrieval, the proposed model uses distributed cloud storage.

The rest of this paper was arranged in the following way: Section 2 is a review of the privacy preservation methods existing in big data in cloud infrastructures. Section 3 explains the proposed TDES-DIMA framework in great detail and is followed by Section 4 which explains the performance evaluation of the proposed model. Lastly, the study is concluded and the future research directions are outlined in the Section 5.

II. LITERATURE REVIEW

In [11], a partition-based distributed big data model to store personnel information in a cloud environment was proposed, which incorporates ChaCha20 encryption, Dual Stage Data Partitioning (DSDP), and k-anonymization to increase the privacy and confidentiality of the information. The model spreads data through several cloud nodes by using the hash of SHA-512 which is more secure, efficient and fault tolerant than the traditional methods. Nevertheless, it did not have dynamic trust negotiation and adaptive anonymization protocols to deal with various data sensitivity and decentralized key management. The Hierarchical Federated Learning (HFL) approach is suggested by the author of [12] to enhance the scalability, computational efficiency, and privacy of healthcare data analysis. Tests on real and artificial medical data revealed that the HFL framework attained an accuracy of 97% of the model with the minimized privacy leakage. However, limitations variations in performance with data characteristics, and increased computational costs were identified. A SecPri-BGMPOP (Security and Privacy of BoostGraph Convolutional Network-Pinpointing-Optimization Performance), a multi-step architecture that was constructed in [13] to improve the security and privacy of cloud-based big data systems. The model integrated BG Convolutional Network Clustering (BGCNC) to minimize computational complexity and employed pinpointing-based encryption to mitigate key leakage risks. Also, the optimization algorithm was used to optimize the generation of encryption keys to enhance better accuracy and efficiency. The model, however, should be able to speed encryption and decryption to enable its use in large applications. One of the studies [14] suggested a scalable method of big data multidimensional anonymization through MapReduce. The main concept was to break down the dataset recursively into small portions using MapReduce until all the partitions had fit in the memory of a computing node. It came up with a tree indexing structure so that it could compute recursively. Moreover, the analysis revealed the relevance of the method to differential privacy.

The experimental findings demonstrated that the suggested approach enhanced the scalability significantly. The study [15] suggested the lightweight matrix factorization framework or personalized recommendations, in which shard gradient training on user IoT device facilitated the local learning of the model without data exposure. A two-phase design guaranteed the security of the data and dimensionality reduction and a stabilization mechanism was used to reduce the gradient perturbation. In experimental assessments, there was greater accuracy, efficiency and privacy than the existing measures. On the same note, the authors of [16] presented a user-customized model of differential privacy based on the level of trust among the users, which is measured by the density of the community and implemented by controlled randomized noise. A noise correlation decoupling mechanism based on Markov and a blockchain-powered community modeling further avoided linkage and poisoning attacks and ensured a better privacy protection. The research [17] offered the TDES technique to ensure high-security levels in the analysis of extensive data. Implementation of TDES improved security of data transmission and storage to avoid the unauthorized access and data leakage. It was able to trade off the strength of encryption with the complexity of computations by using simulation-based tests on large datasets. The study [18], has also put forward an effective and dynamic verification scheme on cloud based Industrial Internet platform (IIP). It was designed using a homomorphic authenticator that was very lightweight and an authenticator accumulator and reduced the computational overhead during preprocessing of the data.

The accumulator of the authenticator was enhanced with dynamic information so that it can make safe changes and updates in the data. In [19], a Two-Step Authentication Inner Product Functional Encryption (TSA-IPFE) scheme was suggested to a three-tier cloud-edge-smart device architecture. The model allowed the dynamic management of authorizations by a two-step mechanism of identity-matching and the efficient revocation of the computational authorizations of migration during device migration. The semantic security, anonymity, and increased efficiency of the simulation proved the superiority over the current algorithms. In [20] presented a TDES-based approach to improve the confidentiality and integrity of the large healthcare information stored in the cloud. The above cloud storage was offered a secured read-write operation and was not susceptible to unauthorized access because it encrypted patient-related data before cloud storage. Its effectiveness in protecting healthcare data was validated with the help of the experiment. The model however had a problem of long computational time.

II 1 RESEARCH GAP

The literature review indicates that there are still unresolved issues in guaranteeing efficient, secure and privacy-conscious big data management in cloud setups. The currently available models including partition-based storage [11], HFL [12], and multi-stage encryptions frameworks [13] have enhanced confidentiality, scale and computation efficiency but remain to be characterized with significant weaknesses. These are lack of dynamically negotiated trust, adaptive anonymization and decentralized key management schemes alongside larger computational and encryption costs of large-scale or heterogeneous data. Further, the conventional encryption schemes [20] are still computationally demanding which implies that there is a necessity of a less heavyweight, more adaptable and distributed security system to balance privacy, efficiency and scalability of the various cloud-based big data uses.

III. PROPOSED FRAMEWORK OVERVIEW

In this section the proposed model Fractal Coding, TDES-DIMA based framework of the big data in cloud is presented. The first step of the model splits the raw heterogeneous data into smaller blocks in order to be preprocessed and normalized. The blocks are then coded using fractal coding method, which takes advantage of the self-similarity of data in order to obtain a high compression with minimum loss. The sensitivity allocation mechanism is built in to allocate levels of privacy depending on the importance of the data. In order to maintain confidentiality, the TDES-DIMA module uses extended TDES encryption and dynamic authentication in order to ensure access and avoid illegal use. Lastly, the stored and encrypted information is retrieved and stored on distributed cloud systems.

Phase 1: Data Ingestion

In order to make the simulation closer to real-world a huge heterogeneous data were simulated in the form of a dataset, which recreates multi source data properties such as time-series sensor measurements, medical imaging data fragments and enterprise transaction data. This is a simulated data that makes it scalable and also variable so as to accommodate both structured and unstructured data. The ingested dataset is represented as:

$$D = \{d_1, d_2, d_3, \ldots d_i\} \tag{1}$$

Here d_i is a raw data that has values obtained by a specific source. The heterogeneous data is prepared to further handle the framework.

Phase 2: Partitioning and Preprocessing

After the ingestion of the dataset into the cloud gateway, it passes through the stage of partitioning and preprocessing to be analyzed further. The large data D is broken into smaller data blocks that can be managed in terms of source type, data format, or sampling rate. The metadata linked to every block is Source ID S_i, Timestamp T_i, and Consent Flag C_i as presented in the Figure 1. This association is expressed as follows:

$$M_i = \{S_i, T_i, C_i\} \tag{2}$$

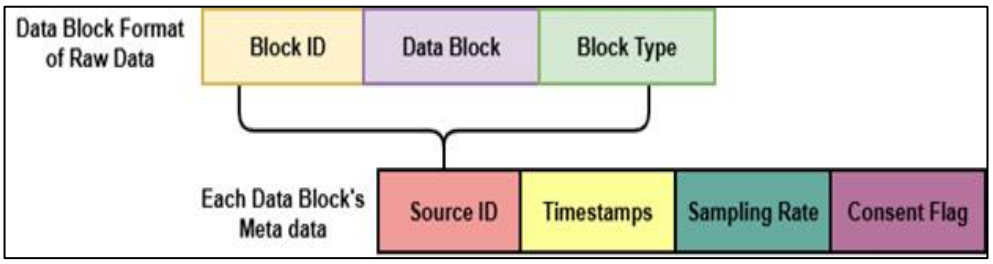

Figure 1: Data Block Format.
Source: Authors, (2026).

The cleaning, normalization and noise removal processes of each block b_i are performed:

$$b_i = f_{norm}(f_{clean}(d_i)) \tag{3}$$

In order to ensure the consistency of the heterogeneous data, z-score normalization is used:

$$x' = \frac{x-\mu}{\sigma} \tag{4}$$

In this case, x is the raw value, μ is the mean, and σ is the standard deviation of the data set. In preprocessing, unnecessary, corrupt, or missing records may be eliminated and the data are normalized so that, it is consistent across various modalities including images, waveforms, tabular records and text blocks. This makes each block of data structurally coherent, and also makes metadata integrity.

Phase 3: Fractal Coding

Here, the processed and segmented data blocks are broken down into fractal coded blocks, which is a mathematical compression algorithm which exploits the self-similarity in data to reduce redundancy and realize high compression efficiency. The main aim of this stage is to symbolize every data block in terms of fractal transformations, which result in a small size of storage, but do not compromise any important structural and statistical data. All preprocessed blocks b_i are subdivided into two categories, range blocks (r) and domain blocks (db). The process identifies a transformation T_i that best maps a domain block db_j to a range block r_i through geometric and intensity adjustments. This mapping relation is stated to be:

$$r_i = T_i(db_j) \tag{5}$$

The transformation T_i uses an affine transformation, scale and offset of the intensity levels of the data block to provide optimal similarity. Mathematically, this is expressed as:

$$T_i(x) = \alpha_i x + \beta_i \tag{6}$$

In this case, the scaling factor of contrast, α_i, and the offset of a data block, β_i. These two values are computed by minimizing the reconstruction error between the original and transformed block in terms of Mean Squared Error (MSE) criterion:

$$E = \min_{T_i} \sum_{x \in r_i} (r_i(x) - T_i(db_j(x)))^2 \tag{7}$$

When the optimum transformation parameters have been generated, it gets stored as a fractal code that represents the block of data. The parameters in each of the codes are: α_i, β_i the domain block ID db_j and E the corresponding error metric.

$$f_i = \{\alpha_i, \beta_i, db_j, E\} \tag{8}$$

These space-efficient fractal codes are stored instead of the original data, and this helps to save a lot of storage space since only these compact codes are stored.

Phase 4: Sensitivity Allocation

At this stage, the fractal-coded blocks that were extracted in the step above are processed and categorized according to their sensitivity level in order to create a privacy-conscious dataset. The objective of this stage is to make sure that data blocks that entail sensitive data are given more robust protection mechanisms. The f_i fractal-coded block is rated according to its sensitivity level (sl_i) which, depending on the metadata and sensitivity of the content of the context (e.g., medical identifiers, financial information):

$$sl_i = f_{priv}(S_i, C_i, D_i) \tag{9}$$

Depending on the calculated sl_i, the fractal-coded block is classified into one of three categories:

- High-sensitive (H)- Blocks of data that include critical or personally identifiable information (e.g. medical identifiers, financial attributes). These blocks need high level of encryption and high-fidelity reconstruction to maintain the integrity of data.
- Medium-sensitive (M) – Medium significance blocks that are the subject of balanced protection with mild compression that can be accepted without intrusion to privacy.
- Low-sensitive (L) – Blocks that hold non-crucial data that can be stored or recreated roughly, so that lossy compression can be used to achieve best storage and computational efficiency.

After identifying the sensitivity class of a given block, all the fractal-coded blocks are labeled with the sensitivity level, creating privacy-aware representation of:

$$tag_i = \{f_i, sl_i\} \tag{10}$$

The sensitivity-based tagging tag_i brings about a change in encryption and reconstruction fidelity during later stages.

Phase 5: Security with TDES-DIMA and Storing in Cloud

This stage is used to make sure that data confidentiality and integrity is upheld especially when dealing with high-sensitive fractal-coded blocks detected in the former stage. The stage involves combination of Triple DES and DIMA mechanism to ensure protection of sensitive data against unauthorized access and identity spoofing at the same time maintaining efficient retrieval and verification. All highly sensitive block f_i are encrypted by TDES algorithm that uses three consecutive encryptions and decryptions with different keys (k_1, k_2, k_3). The ciphertext block c_i is obtained by encrypting the plaintext block p_i using the following format:

$$c_i = e_{k_3}(d_{k_2}\left(e_{k_1}(p_i)\right)) \tag{11}$$

Here e and d denote encryption and decryption operations, respectively. This multiple level encryption provides high levels of cryptographic robustness because exploiting one key will not give the whole dataset. The process of decryption restores the transformation to retrieve the original plaintext which is defined as:

$$p_i = d_{k_1}(e_{k_2}\left(d_{k_3}(c_i)\right)) \tag{12}$$

The DIMA mechanism presents a dynamic authentication mechanism which identifies users and devices on a session basis. Each access attempt is authenticated with a representation of the formulation based on hash: a session-specific authentication token is produced.

$$A_{token} = h(Id_u \oplus T_s \oplus R_n) \tag{13}$$

In this case, the identity of the unique user or device, a timestamp to verify freshness of the session, and a random nonce to prevent predictability are denoted as Id_u, T_s and R_n respectively. The $h(.)$ is a safe hash function that generates a special token on each access instance, and therefore offers time-limited and identity-based access control. This is done to stop replaying and impersonation attacks through this mechanism of continuously updating the session tokens with time and random variations. The general structure of the proposed model is presented in figure 2.

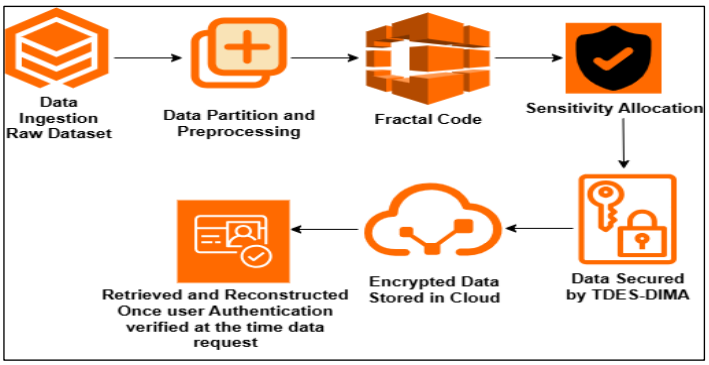

Figure 2: Overall Architecture Diagram of Suggested TDES-DIMA.
Source: Authors, (2026).

The privacy-tagged and securely encrypted data is sent to the distributed cloud storage facility of scalable hosting, high availability, as well as fault tolerance. The distributed architecture also provides greater reliability and redundancy of the data stored in the system such that, when a node fails, the data can be retrieved out of the replicas. The redundancy and reliability (R_d) of the stored dataset is given as:

$$R_d = \frac{n_{rep}}{n_{tot}} \tag{14}$$

Here n_{rep} is the replication of data blocks and n_{tot} is the sum of all the stored blocks. This makes sure that an adequate data replication feature is replicated at the cloud infrastructure. As a result, the distributed storage system has a secure, scalable, and fault-tolerant data management.

Phase 6: Retrieval & Reconstruction

At this last stage, the retrieval and reconstruction procedures will start with a legitimate user placing a data access request to the cloud system. First, DIMA mechanism authenticates the user by session based authentication tokens to confirm authorized access. The system then verifies that the content is correct and then decrypts the sensitive blocks of data with the help of the TDES decryption routine as previously described and gets the original encrypted data. The blocks of the fractal-coded data are then decrypted and reassembled using inverse fractal transformations, restoring the dataset with fidelity levels matching the sensitivity tag of each block, a high sensitive block is reassembled with its full precision whereas a low sensitive block can be reassembled with approximations to achieve more efficiency. The general reconstruction procedure can be formulated as:

$$\hat{d} = f_{recon}(d_{dec}, sl_i) \tag{15}$$

Here $\hat{d}$ denotes the reconstructed dataset, d_{dec} represents the decrypted fractal-coded blocks, and sl_i indicates the sensitivity level of each block guiding the reconstruction fidelity. This phase ensures that the final output is a securely reconstructed dataset, preserving both data privacy and analytical integrity. Where $\hat{d}$ signifies the reconstructed data, d_{dec} signifies decrypted fractal-coded blocks, and sl_i signifies the sensitivity degree of every block that determines the reconstruction fidelity. In this stage, the data is securely reconstructed and both data privacy and data analytical integrity are maintained in the final output.

IV. RESULTS AND DISCUSSIONS

The proposed model enhances security of big data on a cloud environment with Python software in a system with 6GB of a graphics card, 16GB of RAM, i7 core processor, and windows 10 OS. This section describes the comparison of the proposed method and the existing methods. The proposed TDES-DIMA model was compared with throughput of the current SecPri-BGMPOP [13] and Standard TDES as Figure 3. The proposed model showed that in 75 blocks, it had 105 ms, which was above the SecPri-BGMPOP (45 ms), and Standard TDES (80 ms).

With the block count of 300, the throughput was 118 ms, which was 84% and 36% higher than the SecPri-BGMPOP (64 ms) and Standard TDES (87 ms), respectively. The proposed model had a better performance at the highest block size, 525, with 140 ms, which is 72.8% better than SecPri-BGMPOP (81 ms) and 12 times better than Standard TDES (125 ms).

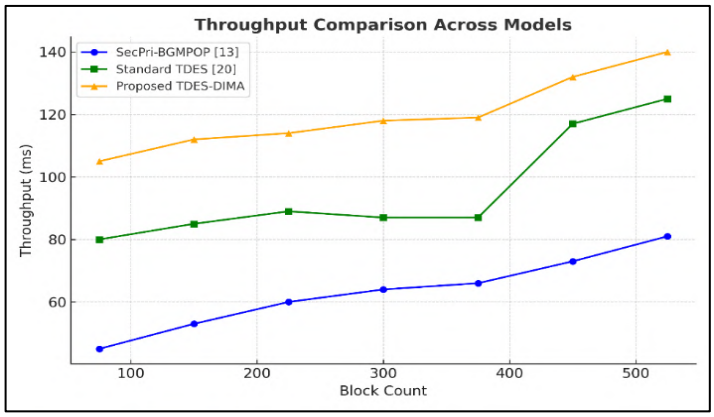

Figure 3: Throughput Analysis.
Source: Authors, (2026).

SecPri-BGMPOP model despite being effective in preserving privacy had disadvantages in that it was slow when encrypting and decrypting large data thus its application was limited in scaling. On the same note, the Standard TDES method had considerable delays because of its abundance of computational time. On the contrary, the proposed model of TDES-DIMA has addressed these disadvantages by incorporating DIMA which made it simpler to access and minimize key usage when encrypting. This mechanism minimized redundant calculations and thus enhance data processing efficiency and hence increase in throughput especially during heavy work loads.

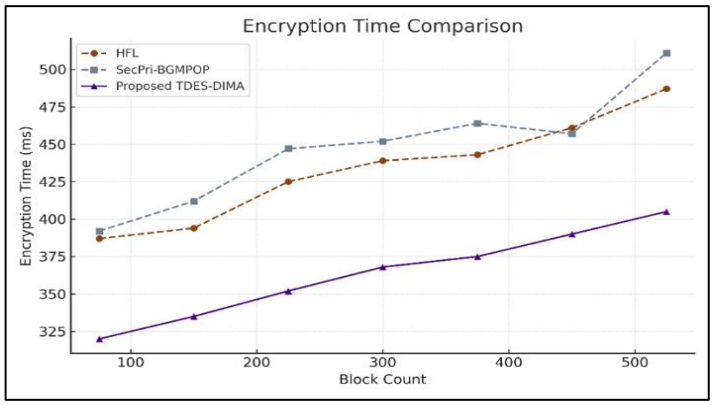

Figure 4: Encryption Time.
Source: Authors, (2026).

It is evident in the comparative analysis between encryption and decryption time that HFL [12], SecPri-BGMPOP, and the proposed model of TDES-DIMA have different differences in computational efficiency. Based on the Figure 4 the HFL framework showed moderate encryption performance, with a base of 387 ms and 487 ms at 75 and 525 blocks, respectively, and is mainly caused by the hierarchical data aggregation process which, although enhances scalability and privacy, introduces latency as a result of the multiple communication layers.

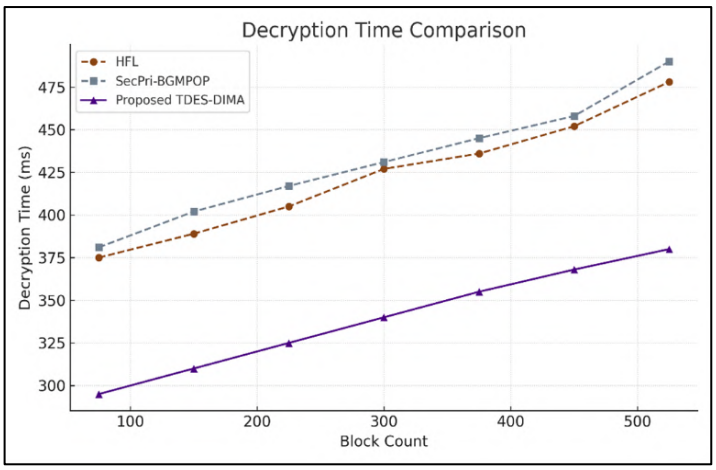

Figure 5: Decryption Time.
Source: Authors, (2026).

Equally, the SecPri-BGMPOP model had a slightly longer encryption time, with a range of 392 ms to 511 ms since the multi-stage encryption events combined with pinpointing-based key generation incurred some extra overhead. This is consistent with its well-established weakness of taking acceleration to encrypt and decrypt messages. By contrast, the proposed TDES-DIMA had a more stable encryption time, ranging between 318 and 409 ms, and decryption time, between 298 and 379, as shown in the Figure 5. This was achieved because of the effective management of sensitivity-based data prioritization that allows faster encryption and decryption of large data without reducing the security and proves the suggested model to be a good balance in the computational workload and privacy conservation where the previous framework had a struggle to balance the increased latency and resource utilization. Figure 6 shows the latency test of the proposed model when compared to the current frameworks. The latency was found to be between 260 ms and 350ms with increasing block count in the HFL model, largely due to its data aggregation layering and federation coordination schemes where frequent synchronization across the distributed nodes was necessary leading to communication bottlenecks. Equally, the model SecPri-BGMPOP had latency levels of between 245 ms and 340 ms which is largely attributed to its sequential encryption and clustering algorithm and pinpointing based optimization; which added more computational burden to the process of intermediate data exchanges.

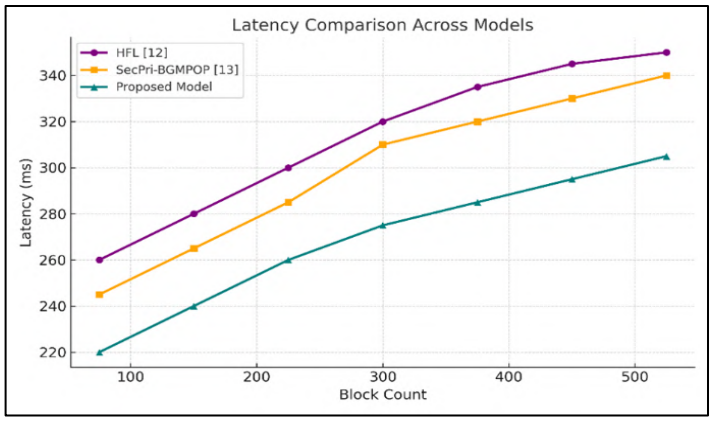

Figure 6: Latency Analysis.
Source: Authors, (2026).

Conversely, the proposed model recorded lower latency of 220 ms to 305 ms with the encapsulated data fractal-based encoding and streamlined block handling system which reduced the overhead of repetitive computation and data transfer. This integration also created a faster response time as the adaptive processing flow was integrated and capable of supporting the high-volume operations of data in cloud-based systems and with minimal delays. Figure 7 presents the relative comparison of data confidentiality and CPU use of DSDP [11], HFL, and the proposed model. The DSDP model had a confidentially rate of 81% and a CPU usage of 32 and this was mainly attributed to its fixed anonymization and lack of dynamically negotiated trust which restricted its versatility in negotiating heterogeneous and sensitivity-varying data. HFL framework increased the confidentiality to 89% with a minor decrease of CPU usage to 29% but the performance of HFL varied with changes in data distribution and feature complexity resulting in varying privacy levels between datasets.

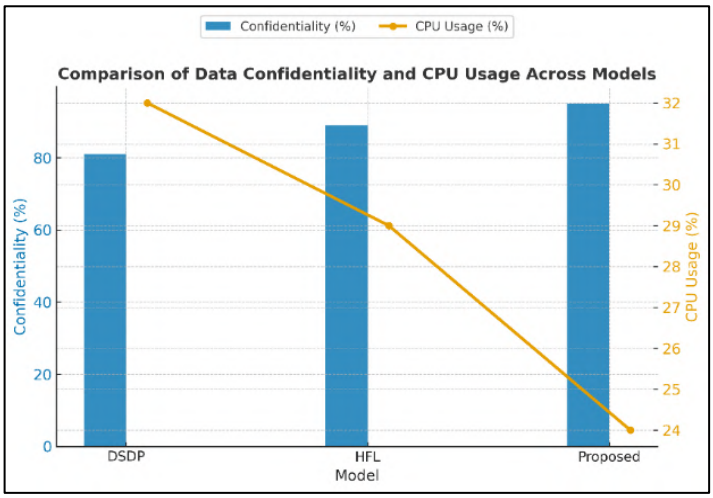

Figure 7: Confidentiality Analysis.
Source: Authors, (2026).

By contrast, the proposed TDES-DIMA framework reached the highest confidentiality of 95% and the lowest CPU consumption of 24% which is 17.3% improvement in confidentiality and 25% decrease in CPU consumption as compared to DSDP. The suggested model had minimal CPU consumption because of optimized fractal coding mechanism that compresses and encodes blocks of data efficiently which minimizes redundant calculations when encryption and retrieval is taking place. The secrecy was due to the dynamic trusted authentication process which highly verifies user identities prior to providing access so that only authorized users can decrypt and manipulate sensitive data.

V. CONCLUSIONS

This study proposed a Fractal Coding based Privacy- Preserving Framework to manage big data safely and efficiently in cloud computing. The framework was useful to minimize the computational cost, in addition to enhancing data confidentiality and security, through fractal coding of compact data representation, sensitivity-based privacy distribution, and TDES-DIMA module of dynamic encryption and authentication. The experimental findings attested that the proposed model attained the best confidentiality of 95% and lowest CPU consumption of 24% indicating the best performance among existing methods. Fractal based compression strategies and sensitivity-based encryption strategies also helped to enhance throughput, latency and better use of storage. To work with hybrid cloud-edge environments in the future, the framework could be expanded to address the latency reduction even more and increase the scalability. The inclusion of quantum-resistant cryptography and AI-assisted adaptive trust should also result in increased resilience to new cyber-threats.

ABSTRACT

Audio deepfakes generated by modern text-to-speech and voice conversion systems pose serious threats to security, privacy, and trust in digital communication. This study proposes a multi-domain feature fusion framework for robust deepfake audio detection under realistic, in-the-wild conditions. A large-scale dataset comprising 31,780 audio samples, evenly split between genuine and synthetic speech and covering diverse speakers, languages, and recording environments, is utilized. Acoustic, compression-related, emotional, phase-based, prosodic, and statistical–spectral features are extracted and fused, and classification is performed using a lightweight fully connected neural network evaluated via stratified five-fold cross-validation. The proposed system achieves an average validation accuracy of 98.03% and an AUC of 0.998, demonstrating strong and stable discriminative performance. Ablation experiments and SHAP-based analysis highlight the critical role of compression-related features in enhancing robustness when combined with other feature domains. While the study focuses on audio-only detection and does not address adversarial or multimodal scenarios, the results indicate that multi-domain feature fusion offers a practical and generalizable solution for real-world deepfake audio detection, particularly in environments involving diverse codecs and synthesis techniques.

I. INTRODUCTION

The evident growth of generative models shows significant transformation in the field of synthetic media, leading to the creation of hyper-realistic audio content commonly referred to as deepfake audio. These deepfake audios or artificially manipulated speech signals convincingly create a replica of the voice, tone, and prosody of the target speaker, even with minimal input data. Such advancement, even with certain legitimate applications in entertainment and personalized user interface, poses serious threats to privacy, security, and information integrity. In particular, the capacity of audio deepfakes to convincingly impersonate individuals has opened avenues for misinformation campaigns, identity theft, and high-stakes fraud [1]. Audio deepfakes are predominantly produced using neural architectures such as text-to-speech (TTS) synthesis, voice conversion (VC), and end-to-end speech generation using generative adversarial networks (GANs), variational autoencoders (VAEs), or transformers [2], [3], [4]. To capture the intricate patterns of human speech, large-scale datasets and complex acoustic modelling are being used. Near-human naturalness in synthesized speech and significant narrowing of the perceptual gap between real and fake audio have been demonstrated by recent TTS systems like VITS [5] and StyleTTS [6]. Consequently, the state-of-the-art automatic speaker verification (ASV) systems are vulnerable to adversarial exploitation. The threats associated with the audio deepfakes are not merely hypothetical but have posed real issues to society. These threats force the need to develop a reliable and explainable detection mechanism capable of performing under an adversarial environment, and real-world, noisy data [7]. Even with the evident increased attention towards audio deepfakes, this field remains under-explored compared to visual deepfakes.

The significant problems for the audio deepfake detection include the diversity of generative models and synthesis techniques, the lack of comprehensive and generalized datasets, and the difficulty of identifying consistent acoustic artifacts across variable conditions [8]. The state-of-the-art detection methods generally rely on spectral anomalies, prosodic irregularities, or embeddings learnt through deep neural networks. However, these models fail to be accurate beyond the specific conditions of the dataset under which they were developed, limiting their practical usage [9], [10]. This fast development of audio deepfake technology is a major challenge, which demands the advancement of robust detection methods that are capable of addressing both the technical and ethical implications of these manipulations [11], [12]. Through the application of a multi-domain feature fusion strategy utilizing acoustic, compression, emotional, phase, prosodic, and spectral features, this paper addresses these problems. The system aims at high accuracy and generalization in a wide range of conditions with a robust and interpretable deep neural network architecture. A large, in-the-wild dataset that has been carefully curated to reflect the conditions in the real world is employed for the study. The efficacy and interpretability of the proposed method are established through multiple experiments, setting a new benchmark for reliable audio deepfake detection [13]. In the subsequent sections, a comprehensive literature review is discussed in Section 2, the proposed methodology is described in detail in Section 3, experimental setup and findings are given in Section 4, key findings and future work are elaborated in Section 5, and a list of contributions is summarized in Section 6.

II. LITERATURE REVIEW:

Prior research in deepfake audio detection has evolved through distinct methodological paradigms, from spectral feature analysis to advanced temporal modeling and generalization strategies. This section synthesizes key advancements, highlighting their contributions, limitations, and persistent challenges in achieving robust, generalizable detection across diverse synthesis techniques and real-world conditions.

II.1 SPECTRAL FEATURE DOMINANCE:

A work on generalization in audio deepfake detection investigates CNN-based models trained on log-Mel spectrograms using the ASVspoof 2019 Logical Access corpus. The model is well-performing on familiar vocoders with an Equal Error Rate (EER) of around 1.4%, but there was a significant dip in performance around 18% EER when tested with unfamiliar vocoders. This is one of the biggest challenges of generalization since the models tend to overfit on spoof types [14]. A study employed MFCCs along with basic classifiers such as k-NN, SVM, and decision trees to identify deepfake TTS-synthesized speech. With 85–88% accuracy on the dataset it created, the paper demonstrated that although MFCCs offer a good baseline, they fall short in detecting more sophisticated or novel manipulations. This study thus benchmarks simple features and models for the detection of deepfakes [15]. A benchmark study on deep learning compared CNN, CRNN, LSTM, and Transformer architectures with spectrogram input. CRNN models showed optimal trade-off between accuracy and efficiency with EERs of around 3–4%, whereas Transformers demonstrated better generalization. Scalability and performance with real-time usage was the primary emphasis of this research with utilizing ASVspoof 2019 and WaveFake datasets [16]. SpecViT used a Vision Transformer on log-Mel spectrogram patches and included speaker embeddings. Outperforming CNNs with an EER of roughly 1.8%, SpecViT showed good generalization to out-of-dataset data. This method brought ViT-style token learning to time-frequency modeling for deepfake detection from datasets such as WaveFake and ASVspoof LA [2].

II.2 TEMPORAL AND MULTI-SCALE DYNAMICS:

A two-branch CNN-BiGRU model combined spectral and temporal evidence through cross-attention. With an EER below 2% on ASVspoof LA and DFDC-Audio, this technique emulated human perception processes by combining features dynamically in a multiscale manner. It offered an effective architecture for identifying varied audio deepfakes [17]. Another research emphasized voiced and unvoiced region analysis, demonstrating that fake cues are more prominent in voiced parts of speech. Through the evaluation of energy, zero-crossing rate, and variation of pitch in these parts, the research attained 91% accuracy with straightforward models. It presented a new outlook for localized temporal analysis for better detection efficiency [18]. A work utilized direct and reverberant forms of audio signals to enhance robustness in deepfake detection. By training a dual-branch model on both channels jointly with contrastive loss, it learned subtle cues from the reverberation and improved generalizability. Tested on LA and DF-TIMIT datasets, the model achieved an EER of 5.4%, better than single-channel methods and demonstrating the contribution of acoustic realism to fake audio detection [19]. Wave-spectrogram fusion was introduced in an attempt to better handle audio deepfake detection with improved generalizability. The WaveSpec model simultaneously processes raw waveform and spectrogram features with the help of multi-scale fusion and cross-modal alignment, which allows it to better identify out-of-domain forgeries. It obtained state-of-the-art results on ASVspoof2021 and In-The-Wild datasets, demonstrating improved resistance against diverse manipulation methods [20].

II.3 GENERALIZATION AND ROBUSTNESS STRATEGIES:

A study introduced a GAN-based anomaly detection technique trained on only real audio. Assuming counterfeited audio as an anomaly, the model had about 92% detection accuracy with generator loss as an anomaly score. The unsupervised technique prevents overfitting to a certain type of spoof and promises better generalization. The system was tested on the ASVspoof LA dataset [21]. A refinement strategy for the latent space coupled with manifold mixup augmentation was introduced to enhance generalizability in audio deepfake detection. Aligning the latent features and increasing training diversity, the technique minimized overfitting to individual deepfake generators. Evaluated on ASVspoof and FakeAVCeleb, the technique registered a 10–15% decrease in EER on novel attack types, highlighting the strength of feature-space regularization [22]. An incremental learning system for unsupervised domain adaptation was introduced in a paper to prevent performance degradation in dynamic audio scenarios. By employing a memory-light domain discriminator and contrastive learning, the model learns to adapt incrementally without access to target labels.

Cross-domain performance improved by up to 30% on ASVspoof and In-the-Wild datasets during evaluation, making its real-world deployment without retraining from scratch prominent [23]. A study proposed a two-branch adversarial training paradigm that localizes partial deepfake segments in audio through feature gradient refinement. The method improves contrast between real and artificial speech segments with a gradient-guided loss and sharpening in feature space. Evaluated on the Fake-or-Real and Partial-Fake datasets, it recorded more than 80% EER gain over baselines, which indicates its robustness in localizing partial manipulations in speech [24].

II.4 SPECIALIZED AND SURVEY PERSPECTIVES:

A study resolved the specific problem of identifying deepfakes in singing voices. Based on MFCC, pitch, jitter, and shimmer features, a traditional combination of random forest and MLP models attained 89% accuracy on a proprietary singing dataset. The study emphasized how voice distortions affect prosody differently in singing, thus prosodic features being more effective [25]. FakeSound study presented a deepfake general audio detection task and a highly realistic fake audio dataset. The dataset uses inpainting with AudioLDM and AudioSR, featuring spliced, regenerated, and partially manipulated audio. A benchmark model trained on the dataset outperformed human detection accuracy (<60%) and previous SOTA on ADD 2023, particularly on challenging half-truth samples and zero-shotot situations [26]. A survey presented an in-depth overview of audio deepfake detection approaches, categorizing them as feature-based, model-based, and hybrid. The survey did not present experiments, but noted important gaps in the research. Certain gaps highlighted in the paper included cross-language generalization, low-resource manipulation, and interpretability. The ASVspoof and FakeAVCeleb datasets were noted as benchmarks ofof the field [16]. Although targeting visual deepfakes, this review offers cross-domain insights that can be applied to audio. It grouped detection techniques into frequency-based, biological signal-based, and transformer models, and highlighted challenges such as generalizability and real-time deployment.

The review offered hybrid multimodal architectures merging audio-visual cues for next-generation detection, hinting at cross-modal prospects for audio deepfake research [27]. A research centered on algorithm attribution for synthetic audio detection. It proposed a two-stage network incorporating attention-guided attribution maps and contrastive loss to distinguish synthesis methods. Based on datasets such as ASVspoof and In-the-Wild, the model yielded above 90% accuracy in recognizing the source algorithm, highlighting the significance of interpretability and fine-grained attribution in generalized detection environments [28]. Confidence calibration in deepfake audio detection was investigated when a calibration layer was added to CNN outputs. This had better reliability with domain shifts and reached an AUC of approximately 94%. The authors highlighted the need for calibrated confidence scores for deployment in real-world applications, utilizing the FakeAVCeleb dataset [29]. A new multi-stage approach based on contrastive learning and GAN-based data augmentation was proposed to make deepfake detection resilient for audio. Through the integration of pre-trained models (such as Wav2Vec2), HiFi-GAN for generating spoofed samples, and contrastive loss, this technique enhanced generalization against fine manipulations and novel spoof types. The proposed framework was compared against conventional PTM-based systems over ASVSpoof 2019, In-The-Wild, and DECRO corpora and achieved better performance [30].

II.5 RESEARCH GAPS:

One of the most persistent and unsolved issues in audio deepfake detection is low generalizability to unknown spoofing techniques, particularly vocoders and synthesis pipelines not included in the training set. Most models work flawlessly on datasets such as ASVspoof 2019 if tested in-domain but suffer hugely when tested on out-of-distribution data or novel generation methods. This exposes a central flaw in constructing strong, universal detectors that can generalize over a wide range of manipulations. The area is missing techniques that abstract away from overfitting to dataset-specific signals and instead aim to capture deep, modality-invariant properties of natural speech. With the advent of strong speech representation models such as BERT, Wav2Vec2.0, and ECAPA, their incorporation into deepfake detection pipelines is still under-researched or under-optimized [31], [32], [33]. A limited number of papers work on semantic, emotional, or prosodic inconsistencies, which tend to be subtle but indicative of synthesis. Yet few models actually combine linguistic comprehension with acoustic modeling, leaving it to holistic, context-sensitive detection mechanisms. Furthermore, emotional regularization and pragmatic content (tone, irony, stress) are areas where deepfakes often fail, but these remain underutilized in detection systems. Most recent research draws upon ASVspoof, WaveFake, or other prominent though comparatively narrow datasets. There is an urgent need for more multilingual, cross-domain, and variable-spoken language, accent, codec, emotional, and realistic audio noise environments datasets. Very few research efforts are devoted to language transferability or speaker accent variation, which are essential for global usage.

Besides, experiment frameworks are mostly static and fail to mimic adaptive attackers or live generation conditions. Therefore, there is an increasing demand for dynamic, changing benchmark suites and ongoing learning evaluation tests. Interpretability is another indispensable but insufficiently addressed gap. Most deep models act as black boxes, providing outputs without explaining why a sample is counterfeit. This is undesirable in forensics, legal testimony, and high-stakes settings. A few works start to leverage tools such as Grad-CAM or saliency maps, but systematic human-understandable explanations are mostly missing. Moreover, uncertainty modeling and calibration of confidence are usually overlooked despite being essential for identifying whether a sample should be accepted, checked, or rejected. The research community does not have effective tools to quantify, visualize, and describe model behavior on difficult inputs. Overall, the surveyed literature reveals a clear methodological evolution from early spectral and MFCC-based baselines toward spectro-temporal fusion, anomaly-based learning, confidence calibration, and domain-generalizable training pipelines. While existing systems achieve strong in-domain performance on benchmarks such as ASVspoof, WaveFake, Fake-or-Real, FakeAVCeleb, and the recently introduced FakeSound, consistent gaps remain in cross-corpus robustness, low-resource and cross-lingual settings, and interpretable, deployment-ready detectors. To contextualize the above discussion, Table 1 provides a summary of prior works in audio deepfake detection.

Table 1: Summary of Prior Research Done.

Sr. No.	Paper Title	Methodology	Features Used	Dataset	Findings
1	[28]	CNN-based classifier on log-Mel spectrograms	Spectral (contrast, roll-off)	ASVspoof 2019	1.4% EER (in-domain) but 18% EER on unseen vocoders due to spoof-type overfitting
2	[15]	Classical ML (SVM, k-NN)	MFCC (spectral), ZCR	Custom voice dataset	85–88% accuracy; MFCCs good baseline but limited on sophisticated TTS
3	[34]	Taxonomy of fake gen. + detection	Broad coverage (not experimental)	Multiple (overview)	Identified gaps: cross-language, low-resource, interpretability
4	[23]	Benchmark: CNN, RNN, CRNN, Transformer	Spectrograms (statistical)	ASVspoof, WaveFake	CRNN optimal at 3–4% EER; Transformers better generalization
5	[26]	Feature extraction + SVM	ZCR, Spectral (entropy), Prosody (pitch)	FakeSound (proposed)	Outperformed human accuracy (<60%) and ADD 2023 SOTA
6	[21]	GAN trained on real audio only	Time-domain (RMS), Environment (artifacts)	ASVspoof 2019 (LA)	92% accuracy using generator loss; prevents spoof-specific overfitting
7	[25]	Feature extraction + ensemble (RF, MLP)	MFCC, Jitter, Shimmer, Pitch	Custom singing dataset	89% accuracy; prosodic features effective for singing deepfakes
8	[18]	Voiced vs. unvoiced region splitting + stats	ZCR, Pitch, Energy, Jitter	LA ASVspoof	91% accuracy; fake cues prominent in voiced regions
9	[2]	ViT on spectrogram patches	Spectral (token-level) + Speaker awareness	WaveFake, ASVspoof LA	1.8% EER; superior out-of-dataset generalization
10	[17]	Dual-branch CNN-RNN + fusion	Spectrogram (multi-scale), Temporal variation	LA, DFDC-Audio	<2% EER; emulates multiscale human perception

III.2 MULTI-DOMAIN FEATURE REPRESENTATION:

The authenticity of speech manifests across multiple interdependent acoustic and temporal dimensions. Deepfake generation techniques, despite remarkable progress, still fail to reproduce the complete hierarchy of correlations present in human speech — from micro-level spectral variations to macro-level prosodic flow. To capture these complementary cues, the proposed system constructs a multi-domain feature representation that integrates six distinct yet interconnected families of descriptors: acoustic, compression-related, emotional, phase-based, prosodic, and statistical/spectral features. Each family encapsulates a specific physical or perceptual aspect of speech production, and their fusion provides a discriminative basis for differentiating genuine and synthetic audio. Figure 1 presents an overview of this multi-branch feature-extraction pipeline.

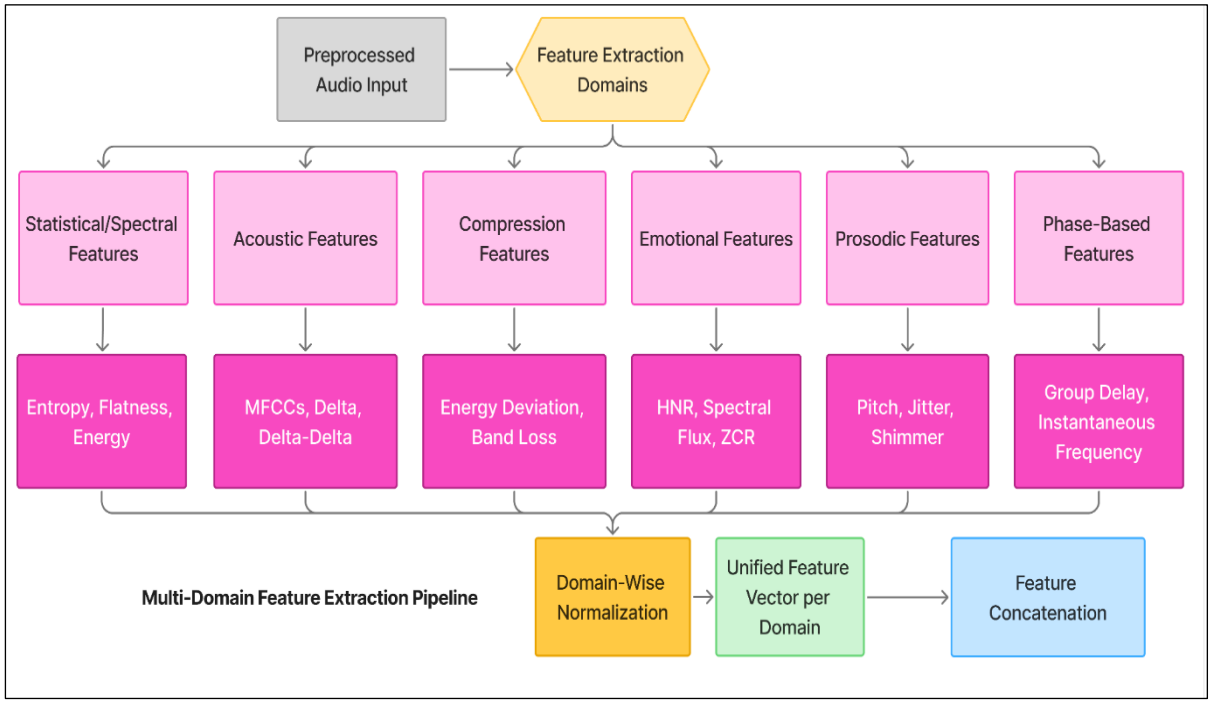

Figure 1: Multi-Domain Feature Extraction Pipeline.
Source: Authors, (2026).

III.2.1 Materials and Methods

Acoustic descriptors capture the spectral envelope and short-term resonance structure of the human vocal tract. Genuine speech exhibits smooth transitions in its spectral shape as the articulators move continuously; conversely, deepfake audio often suffers from vocoder-induced over-smoothing or discontinuous formant trajectories. To model these differences, we extract Mel-Frequency Cepstral Coefficients (MFCCs) using the Librosa library [35]. The waveform is divided into 25 ms Hamming-windowed frames with 10 ms overlap, and a 512-point Fast Fourier Transform (FFT) is applied to obtain the magnitude spectrum. The power spectrum is then filtered through 40 Mel-spaced triangular filters to approximate the human auditory frequency response. The logarithm of the filter-bank energies is decorrelated using a discrete cosine transform to produce 13 cepstral coefficients per frame.

Equation 1.

$$c_n(t) = \sum_{k=1}^{K} \quad log\ E_k(t)\ cos\left[\frac{\Pi n}{K}(k - \frac{1}{2})\right] \tag{1}$$

Here, $E_k(t)$ denotes the Mel filter-bank energy in the k-th band at frame t, K is the total number of Mel filters, $c_n(t)$ is the n-th cepstral coefficient at frame t, and N_c is the number of retained MFCCs. To capture spectral dynamics, first- and second-order temporal derivatives (Δ and Δ² MFCCs) are computed, resulting in a 39-dimensional acoustic feature vector per frame. Frame-wise mean and variance statistics are finally pooled to obtain an utterance-level representation. This process emphasizes subtle spectral variations suppressed in synthetic speech. In natural recordings, the MFCC trajectory demonstrates smooth formant motion, while deepfake samples reveal reduced variance and abrupt spectral transitions due to neural vocoder quantization.

III.2.2 Compression-Related Features:

Deepfake audio often undergoes digital post-processing distinct from that of real recordings. Genuine recordings, captured through physical microphones, naturally preserve micro-level noise and non-linearities that interact predictably with audio codecs. Synthetic audio, generated numerically, exhibits different quantization behavior when compressed. To exploit this difference, compression-related features are computed by measuring how perceptual and spectral statistics vary before and after standard compression–decompression. Each audio signal is encoded using MP3 at 128 kbps, decoded back to waveform, and both versions are analyzed for spectral distortion, log-energy loss, and band-energy ratio differences. For every Mel band k, the energy deviation is defined as

Equation 2.

$$\Delta_k = \frac{E_k^{orig} - E_k^{comp}}{E_k^{orig}} \tag{2}$$

Where E_k^{orig} and E_k^{comp} denote Mel-band energies before and after compression. The mean, variance, and skewness of Δ_k across bands constitute the compression feature vector. In real audio, this deviation follows a smooth decay pattern; synthetic samples show irregular distortions because vocoder-generated signals lack the micro-redundancy that codecs exploit for efficient encoding.

III.2.3 Emotional Features:

Human speech carries rich emotional prosody resulting from complex coordination between vocal-fold vibration, subglottal pressure, and articulatory movement. Deepfake systems typically generate emotion using averaged style embeddings or prosody templates, which fail to reproduce the spontaneous micro-variations in tone and energy that characterize genuine affect. The openSMILE toolkit, configured with the emobase parameter set, is employed to extract emotional descriptors comprising a series of low-level descriptors (LLDs), including the harmonic-to-noise ratio (HNR), zero-crossing rate (ZCR), spectral flux, spectral centroid, and pitch-related functionals. For each LLD, a set of statistical functionals—namely mean, standard deviation, skewness, and kurtosis—is computed over the entire utterance, resulting in a consolidated emotional feature vector for subsequent analysis. HNR quantifies the ratio of periodic to aperiodic energy, reflecting voice quality and stability [36]. Synthetic voices often exhibit unnaturally high HNR due to vocoder smoothing, while real speech displays subtle irregularities associated with breathiness or emotional tension. Spectral flux and centroid, representing the rate of spectral change and the "brightness" of the signal respectively, further differentiate dynamic natural expressions from their flattened synthetic counterparts.

III.2.4 Phase-Based Features:

The phase spectrum encodes the fine temporal alignment of harmonics and reveals source–filter coherence in human phonation. While most speech synthesis methods accurately reconstruct magnitude spectra, they frequently neglect phase continuity, leading to temporal incoherence and phase jumps across frames. Phase information is extracted from the short-time Fourier transform (STFT) of the waveform. For each frequency bin f and time frame t, the instantaneous phase $\phi(f,t)$ is computed as the arctangent of the complex STFT components. From this, we derive the group delay and instantaneous frequency statistics:

Equation 3.

$$\tau_g(f,t) = -\frac{\partial\phi(f,t)}{\partial f}, \quad \omega_{inst}(f,t) = \frac{\partial\phi(f,t)}{\partial t} \tag{3}$$

Frame-level averages, standard deviations, and entropy of these quantities are then calculated over the spectral domain. Real speech shows consistent, smoothly varying group-delay trajectories governed by physiological glottal excitation, whereas deepfake audio demonstrates discontinuities or flattened phase patterns due to imperfect reconstruction. Capturing these discrepancies provides strong discriminative evidence of synthesis artifacts.

III.2.5 Prosodic Features:

Prosody encompasses intonation, loudness, rhythm, and temporal structure — the higher-level organization of speech beyond individual phonemes. It is a crucial indicator of naturalness, reflecting cognitive and emotional states. Synthetic voices often display uniform rhythm, quantized pitch patterns, and limited expressive range. Prosodic analysis is performed by computing fundamental frequency (F_0) contours, intensity, and temporal-rhythm descriptors. The F_0 contour is extracted via autocorrelation using Librosa's piptrack function. Local perturbations in pitch and amplitude are summarized using jitter and shimmer metrics:

Equation 4.

$$Jitter = \frac{1}{N-1}\sum_{i=1}^{N-1} \frac{|T_i - T_{i+1}|}{T} \tag{4}$$

Equation 5.

$$Shimmer = \frac{1}{N-1}\sum_{i=1}^{N-1} \frac{|A_i - A_{i+1}|}{A} \tag{5}$$

Where T_i and A_i represent the period and amplitude of successive cycles. Aggregate descriptors such as mean F_0, standard deviation, range, energy variance, and voiced/unvoiced ratio are also computed. Genuine recordings exhibit natural fluctuations in F_0 and intensity driven by respiratory control, while deepfake speech tends to produce smoother, less variable contours, revealing synthetic regularity in rhythm and stress.

III.2.6 Statistical and Spectral Features:

In addition to domain-specific attributes, global statistical and spectral summaries offer compact yet powerful characterization of the signal's overall distribution. These metrics assess the entropy, randomness, and harmonic structure of the waveform, complementing the localized descriptors described above [37], [38]. We compute short-time energy (STE), spectral entropy (H_s), and spectral flatness (SF) from the STFT magnitude spectrum.

Equation 6.

$$H_s(t) = -\sum_f \; p(f,t)\, log\, p(f,t) \tag{6}$$

Equation 7.

$$p(f,t) = \frac{|S(f,t)|^2}{\sum_f \; |S(f,t)|^2} \tag{7}$$

Equation 8.

$$SF(t) = \frac{\left(\Pi_f |S(f,t)|^2\right)^{1/F}}{\frac{1}{F}\sum_f \; |S(f,t)|^2} \tag{8}$$

STE measures temporal energy variation; spectral entropy quantifies the uniformity of energy distribution; and spectral flatness captures the balance between tonal and noise-like components. Real speech, characterized by quasi-periodicity, exhibits low SF and moderate H_s values, while synthetic speech often yields higher flatness and entropy due to excessive smoothing and lack of micro-harmonic detail [39]. The multi-domain design provides a comprehensive view of both physiological and algorithmic aspects of speech production. Acoustic features capture vocal-tract behavior, prosodic and emotional cues reflect cognitive and expressive intent, phase-based features encode fine-grained temporal coherence, compression features exploit codec-sensitivity differentials, and statistical measures summarize global spectral organization [40]. By combining these complementary cues, the proposed representation detects inconsistencies that remain imperceptible in any single domain. This holistic integration is essential for countering the rapid evolution of generative speech models, many of which may correct one type of artifact while still revealing another. Consequently, the multi-domain representation forms a robust, interpretable foundation for the deepfake detection framework that follows.

III.2 MODEL ARCHITECTURE:

The fused multi-domain representation is used as input to a fully connected neural network optimized for binary deepfake classification. The network architecture is deliberately lightweight to emphasize interpretability and generalization while avoiding the over-parameterization that commonly affects high-dimensional feature sets. Figure 1 illustrates the overall network design.

III.3.1 Architectural Design

The classifier consists of three layers: an input layer, a single hidden layer of 128 neurons, and an output layer that produces posterior probabilities for the two target classes—genuine and synthetic audio. Each hidden unit employs the Rectified Linear Unit (ReLU) activation function to introduce non-linearity and enhance feature discrimination. To mitigate overfitting and encourage generalization, a dropout layer with a probability of 0.3 is applied after the hidden layer, randomly deactivating a subset of neurons during training. The final layer uses a softmax activation, transforming the linear output into normalized probabilities:

Equation 9.

$$\hat{y} = softmax(W_2 F_{fused} + b_1) \tag{9}$$

Where $h_1 = ReLU(W_2 F_{fused} + b_1)$ denotes the hidden representation of the fused feature vector F_{fused} , and W_i , b_i are the trainable parameters of the network. This shallow structure is intentionally chosen: it provides sufficient representational capacity to model non-linear relationships among features while remaining interpretable and computationally efficient.

III.3.2 Training Objective and Optimization:

Training is performed using the cross-entropy loss function, defined for a binary problem as

Equation 10.

$$L = -\frac{1}{N}\sum_{i=1}^{N} [y_i \, log(\hat{y}_i) + (1 - y_i) log(1 - y_i) \tag{10}$$

Where y_i represents the ground-truth label and $\hat{y}_i$ the predicted probability of the sample being genuine. This loss encourages the model to maximize the likelihood of correct classification while penalizing confident mispredictions. Optimization is conducted with the Adam optimizer (learning rate = 1×10^{-3}, $\beta_1 = 0.9$, $\beta_2 = 0.999$). To facilitate smooth convergence and adaptive exploration of the parameter space, a cosine-annealing learning-rate scheduler with warm restarts is applied, gradually reducing the learning rate within each epoch cycle. This scheduling approach prevents premature convergence and helps the model escape shallow local minima. The network is trained for up to 15 epochs with early stopping activated if the validation loss does not improve for five consecutive epochs. The early-stopping criterion ensures optimal trade-off between bias and variance, effectively halting training before overfitting begins.

III.3.3 Batching and Data Handling:

Training is conducted with a batch size of 128, using stratified batching to maintain class balance within every mini-batch. This prevents gradient bias arising from unequal class representation and ensures stable optimization. All inputs are standardized before training and shuffled at the start of each epoch to improve randomness and reduce dependency on sample ordering. To ensure deterministic reproducibility, all random seeds across Python, NumPy, and PyTorch environments are fixed. This guarantees consistent results across multiple runs—a crucial requirement for forensic and reproducible AI research. Figure 2 illustrates the end-to-end workflow. The normalized and fused features are loaded into mini-batches, propagated through the dense network, and optimized via back-propagation. Validation accuracy and loss are monitored at each epoch; the model achieving the lowest validation loss is retained for testing. This disciplined training regimen—combining early stopping, stratified data handling, and adaptive learning rates—ensures a stable and reproducible optimization process. The trained model subsequently undergoes evaluation.

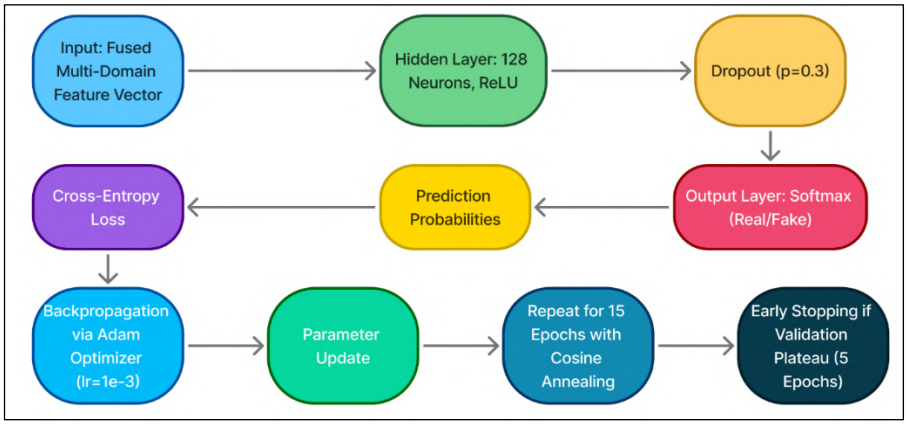

Figure 2: Neural Network Architecture and Training Workflow.

IV. EXPERIMENTAL SETUP, IMPLEMENTATION, AND RESULTS

This section presents a detailed description of the experimental setup, implementation workflow, and evaluation results of the proposed multi-domain deepfake audio detection framework. The discussion is structured to ensure methodological clarity and reproducibility, beginning with dataset handling and preprocessing, followed by model configuration and training strategy, and finally presenting quantitative results and analytical observations. All experiments were conducted using a stratified five-fold cross-validation protocol to ensure robustness and statistical reliability of the reported performance.

IV.1 DATASET LOADING AND EXPERIMENTAL PARTITIONING:

The experiments were conducted on a large-scale in-the-wild audio dataset comprising a total of 31,780 audio samples, evenly divided between genuine (real) and synthetic (fake) speech. The dataset was curated to reflect realistic deployment conditions, incorporating diverse speakers, languages, recording environments, and multiple deepfake generation techniques. The balanced class distribution was intentionally maintained to prevent classification bias and to enable fair evaluation of both false acceptance and false rejection behavior. For experimental evaluation, the dataset was organized into two primary directories corresponding to real and fake audio classes. A stratified five-fold cross-validation strategy was employed, ensuring that each fold preserved the original class distribution. In each iteration, four folds were used for training while the remaining fold served as the validation set. This procedure was repeated until all folds were used once for validation, and the final performance was reported as the average across all folds. Such a validation strategy provides a robust estimate of generalization performance while reducing the dependency on any single data split.

IV.2 PREPROCESSING PIPELINE:

Prior to feature extraction and model training, all audio samples underwent a standardized preprocessing pipeline designed to minimize irrelevant variability while preserving speech-specific characteristics critical for deepfake detection. Voice Activity Detection (VAD) was applied using the Silero VAD model to remove silent and non-informative regions from the recordings. This step ensured that subsequent feature extraction focused solely on speech-bearing segments. All processed audio signals were resampled to a uniform sampling rate of 16 kHz to standardize temporal resolution across samples. Given the natural variability in recording durations, each audio clip was either zero-padded or truncated to a fixed duration of five seconds. This uniform length constraint enabled consistent batch processing and ensured compatibility with the feature extraction and classification pipeline. The preprocessing stage was optimized for large-scale execution using GPU acceleration and mixed-precision computation, allowing efficient handling of the dataset without altering signal fidelity.

IV.3 FEATURE EXTRACTION AND REPRESENTATION

Following preprocessing, each audio sample was transformed into a comprehensive multi-domain feature representation as described in Section 3. Feature extraction was performed independently for each domain, and utterance-level representations were constructed using statistical pooling. The extracted features included acoustic descriptors, compression-related features, emotional features obtained via openSMILE, phase-based features derived from the short-time Fourier transform, prosodic attributes such as pitch and perturbation measures, and global statistical and spectral descriptors. All extracted features were concatenated to form a unified fused feature vector representing each audio sample. Before classification, the feature vectors were standardized to zero mean and unit variance to ensure stable optimization and prevent dominance of any single feature domain. This fused representation served as the sole input to the neural classifier, allowing the model to jointly exploit complementary cues arising from multiple aspects of speech production and synthesis artifacts.

IV.4 MODEL ARCHITECTURE AND TRAINING CONFIGURATION

The classification model employed in this study is a lightweight fully connected neural network specifically designed to balance discriminative capacity with interpretability and computational efficiency. The network accepts the fused multi-domain feature vector as input, followed by a single hidden layer consisting of 128 neurons activated using the Rectified Linear Unit (ReLU) function.

A dropout layer with a probability of 0.3 is applied to the hidden layer during training to mitigate overfitting and enhance generalization. The output layer consists of two neurons corresponding to the genuine and synthetic classes, with softmax activation producing normalized posterior probabilities. The input layer receives a fused multi-domain feature vector of fixed dimensionality, formed by concatenating all extracted feature streams. Model training was performed using the cross-entropy loss function optimized via the Adam optimizer with a learning rate of 1×10^{-3}. A cosine annealing learning-rate scheduler with warm restarts was employed to promote stable convergence and avoid premature stagnation. Training was conducted for a maximum of 15 epochs, with early stopping activated if the validation loss failed to improve for five consecutive epochs. Mini-batches of size 128 were used, and stratified batching ensured balanced class representation within each batch. All experiments were implemented in PyTorch and executed on Google Colab Pro using an NVIDIA Tesla T4 GPU.

IV.5 OVERALL QUANTITATIVE PERFORMANCE

The model achieved consistently high performance across all five validation folds, with accuracies ranging from 97.79% to 98.28%, yielding an average validation accuracy of 98.03% (±0.18). The mean Area Under the ROC Curve (AUC) was 0.998, indicating near-perfect separability between genuine and synthetic audio samples. Table 2 summarizes the fold-wise results for Accuracy and Loss. The narrow range of variation across folds demonstrates the model's stability and reproducibility—a result of stratified partitioning, balanced batch training, and early stopping strategies. The high AUC value confirms that the model maintains discriminative strength across multiple threshold values, suggesting that it does not rely on a narrow confidence range to identify synthetic speech. The F1-score averaged 0.981, reflecting a balanced trade-off between detection rate and false-alarm control. Together, these results confirm that the proposed architecture—despite being shallow and computationally efficient—achieves state-of-the-art performance on a complex, real-world dataset.

Table 2: Validation Accuracy and Loss during each fold.

Folds	Validation Accuracy	Validation Loss
1.	0.9807	0.006125
2.	0.9828	0.005840
3.	0.9812	0.005390
4.	0.9779	0.005600
5.	0.9807	0.006200
FINAL	0.9806	0.005831

IV.6 EVALUATION METRICS AND PERFORMANCE CRITERIA

To thoroughly assess the performance of the suggested deepfake audio detection system, a wide range of complementary metrics was utilized. These metrics offer subtle aspects of the system's discriminative ability, calibration, and class-specificity that are critical to evaluating robustness and reliability in real-life forensic and security applications. Accuracy is a baseline metric, measuring the proportion of correctly classified samples out of all predictions. Informative as this metric is, it can hide class-wise imbalances or trade-offs in errors, especially in light of the high-stakes application of deepfake detection. To better handle this, precision and recall metrics were calculated independently for every class.

Precision describes the ratio of correctly recognized positive instances to all positives predicted—quantifying the false positive control—whereas recall (sensitivity) takes note of the model's capacity to identify all actual positive instances, quantifying false negative rates. The F1-score, a harmonic mean between precision and recall, offers a balanced individual score of classification performance for each class. Given the approximately balanced dataset, macro-averaged (treating each class equally) and weighted-averaged (accounting for class sample sizes) versions of these statistics were also calculated to help summarize the class-level performance comprehensively. In addition to these point statistics, Receiver Operating Characteristic (ROC) curve and summary statistic Area Under the Curve (AUC-ROC) were used to analyze model separability at different classification thresholds. The model performed an average AUC close to 0.998, which presents almost perfect discrimination between original and manipulated audio samples. Complementarily, the Precision-Recall curve was also examined, which is especially relevant in security scenarios where false positive (false alarm) and false negative (forgery missed) costs are asymmetric. The PR curve again verified that high precision holds even at nearly complete levels of recall, highlighting practical application.

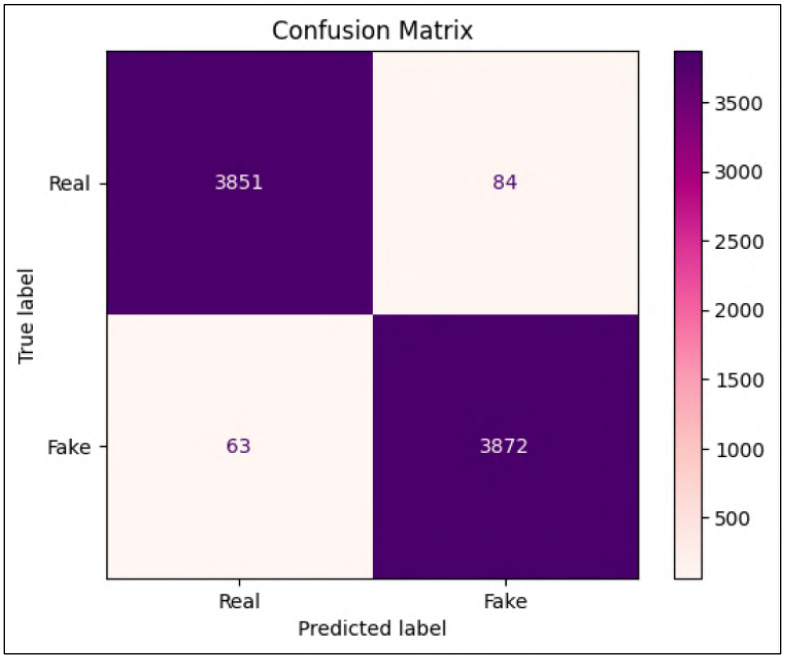

Figure 4: Confusion Matrix for the Validation Dataset.
Source: Authors, (2026).

Confusion matrices were constructed to provide an intuitive representation of the distribution of correct and incorrect predictions between classes, emphasizing the low but non-zero misclassification rates, which were mostly localized on difficult or borderline samples. Finally, predicted probability distributions and confidence margins were analyzed, illustrating excellent calibration of output probabilities and allowing reliable interpretations necessary for deployment environments calling for graded risk judgments. In combination, this set of performance metrics stringently confirms the accuracy, balance, and reliability of the detection framework. This complementary nature of the metrics, from baseline accuracy to advanced ROC-AUC and calibration, guarantees a rigorous and transparent performance estimation.

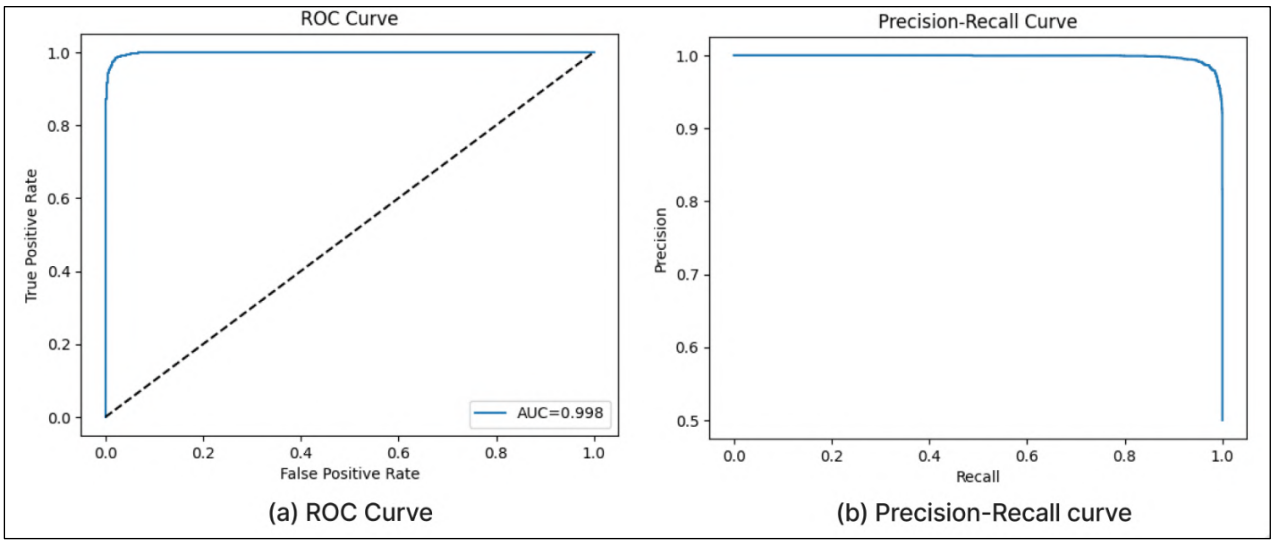

Figure 5: (a) Receiver Operating Characteristic (ROC) curve b) Precision-Recall.
Source: Authors, (2026).

ROC Curve of the suggested deepfake audio detection model averaged across five stratified folds. The excellent AUC value of 0.998 displays superb class separability. Precision-Recall curve indicating strong detection precision for varying recall levels, essential in forensic accuracy. To further examine the discriminative structure of the proposed multi-domain feature representation, a t-distributed Stochastic Neighbor Embedding (t-SNE) visualization was employed. While quantitative metrics such as accuracy and AUC provide aggregate performance evaluation, t-SNE offers an intuitive low-dimensional view of how genuine and synthetic audio samples are distributed in the learned feature space prior to classification. The t-SNE projection was generated using the fused multi-domain feature vectors extracted from the validation data. All samples were reduced from the original high-dimensional feature space into two dimensions using a fixed random seed to ensure reproducibility. No class information was provided to the dimensionality reduction algorithm, allowing the visualization to reflect the intrinsic structure of the learned representations rather than supervised separation. As shown in Figure 6, the t-SNE plot reveals a clear tendency toward class-wise clustering, with a substantial proportion of genuine and synthetic samples forming distinct regions in the projected space. However, partial overlap between the two classes is also observed, particularly in boundary regions. This overlap is expected given the use of real-world, in-the-wild audio data, where recording conditions, speaker variability, and high-quality synthesis techniques can reduce the prominence of individual artifact cues. Importantly, the presence of overlap does not contradict the strong classification performance reported earlier. Instead, it highlights the role of the proposed classifier in learning non-linear decision boundaries that effectively separate samples even when low-dimensional projections appear ambiguous. The high AUC and consistent fold-wise accuracy indicate that the classifier successfully exploits subtle multi-domain feature interactions that are not fully preserved in two-dimensional embeddings. Overall, the t-SNE visualization supports the quantitative findings by demonstrating that the fused feature space captures meaningful structure between genuine and synthetic audio, while also reflecting the inherent difficulty of the detection task under realistic conditions. This further validates the necessity of multi-domain feature fusion and supervised learning for robust deepfake audio detection.

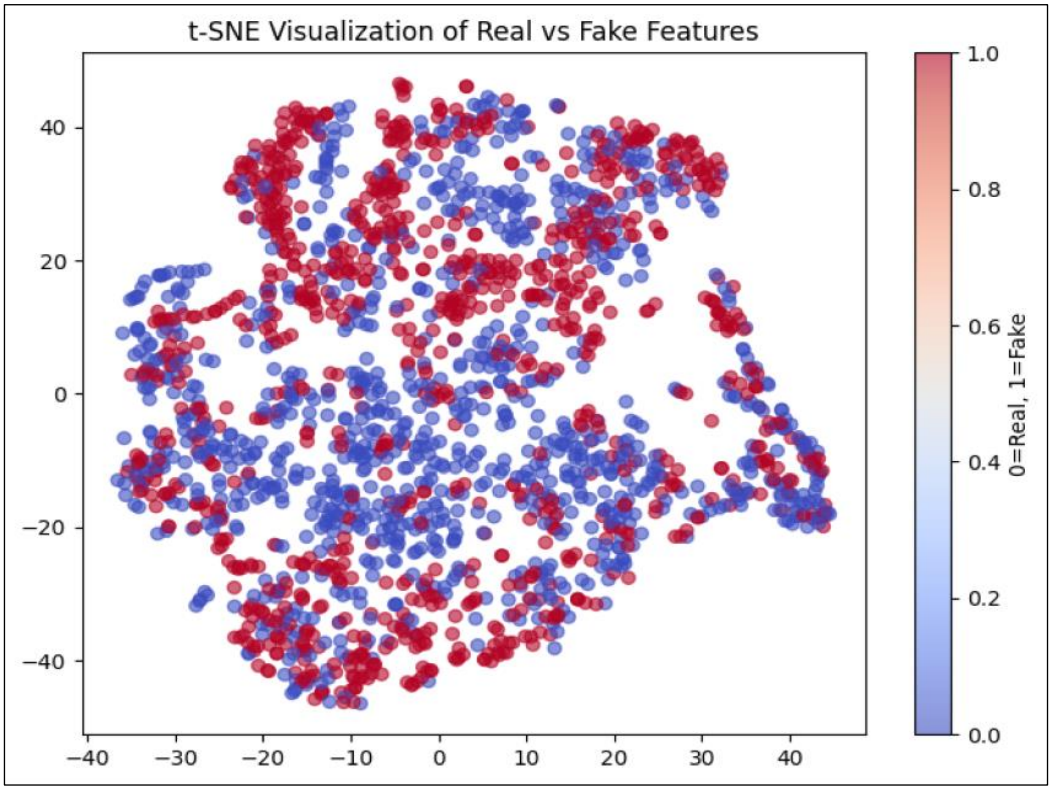

Figure 6: t-SNE visualization of fused multi-domain feature representations.
Source: Authors, (2026).

IV.7 ABLATION STUDY- IMPACT OF COMPRESSION ARTIFACTS:

To assess the unique contribution of compression artifact features to the detection system, an ablation study of their individual and combined effects was performed. Compression artifacts represent signal anomalies introduced through the encoding and transmission stages of audio, commonly challenging synthetic generation pipelines to replicate accurately. The objective was to learn how such features affect model performance both in isolation and as components of a fused multi-feature representation. The models were trained in three different settings: (i) baseline model trained on the complete fused feature set with all the feature domains, (ii) model trained only on compression artifact features, and (iii) model trained on fused features but not including the compression domain. All models were tested using stratified 5-fold cross-validation to maintain data split consistency and preprocessing. The performance in Table 3 illustrates evident performance differences between configurations. Significantly, the model that was trained on the combination of compression and acoustic features attained an optimal validation accuracy of 93.59%, with precision and recall balanced to a high extent on both real and fake classes. The classification report is as stated below:

Table 3: Classification Report on the Combination of Compression Artifacts Features and Acoustic features.

Class	Precision	Recall	F1-score	Support
0	0.9573	0.9126	0.9344	2357
1	0.9165	0.9593	0.9374	2357
Accuracy			**0.9359**	**4714**

Source: Authors, (2026).

Conversely, the model trained using only compression artifact features performed much lower—with the average accuracy at 56.43%. Precision and recall values for the two classes were moderate, but the F1-scores (0.6219 for class 0 and 0.4860 for class 1) reflect poor discriminatory ability when using only these features:

Table 4: Classification Report for only Compression Artifact Features.

Class	Precision	Recall	F1-score	Support
0	0.5493	0.7166	0.6219	2357
1	0.5924	0.4120	0.4860	2357
Accuracy			**0.5643**	**4714**

Source: Authors, (2026).

These results emphasize the subtle contribution of compression artifacts: although individually inadequate to induce high detection rates, when combined with other feature domains, notably acoustic features, they greatly improve model robustness. This interaction is likely to arise from compression features detecting peculiar encoding discrepancies inaudible to purely acoustic or prosodic descriptors. By and large, the ablation study affirmatively underscores the need for multi-domain feature fusion, with compression artifacts serving a catalytic yet supporting function towards building a stable and generalizable deepfake detection system, especially in adversarial or codec-variant real-world scenarios.

IV.8 CLASSIFICATION PERFORMANCE ANALYSIS:

The efficacy of the designed deepfake audio detection system was critically tested using stratified 5-fold cross-validation on the entire fused multi-domain feature space. On all folds, the model showed uniformly high accuracy, affirming its robust capability to generalize across a wide range of speaker profiles, recording conditions, and spoofing methods included in the large-scale dataset. Table 5 collates the classification metrics for all folds and shows impressively consistent and balanced results. The accuracy varied between 97.79% and 98.28%, with average precision, recall, and F1-scores closely bunched up around 98% for both "real" and "fake" classes. Such performance indicates the ability of the model to classify authentic robustly and manipulated audio samples and suppress false positives and false negatives—the very feature needed for real-world security and forensic applications.

Table 5: Evaluation Report for each Fold.

Fold	Accuracy	Precision (Real)	Recall (Real)	F1-Score (Real)	Precision (Fake)	Recall (Fake)	F1-Score (Fake)
1	98.07%	0.9856	0.9756	0.9806	0.9758	0.9858	0.9808
2	98.28%	0.9835	0.9822	0.9828	0.9822	0.9835	0.9829
3	98.12%	0.9788	0.9837	0.9812	0.9836	0.9786	0.9811
4	97.79%	0.9798	0.9759	0.9778	0.9760	0.9799	0.9779
5	98.07%	0.9874	0.9738	0.9805	0.9742	0.9875	0.9808

Source: Authors, (2026).

The robustness of these measures between folds and the well-balanced support sizes of roughly 3,935 samples per class per fold further emphasizes the model's consistent predictive performance irrespective of data splits. Receiver Operating Characteristic (ROC) curves generated for each fold also illustrate strong separability between authentic and manipulated audio classes. Mean Area Under the Curve (AUC) asymptotically reached values of approximately 0.99, indicating near-perfect discriminative ability. Counterpart confusion matrices indicated that misclassification was largely relegated to noisy or slight samples where acoustic cues may be partially masked or synthetic speech perfectly mimicked natural voicings. Furthermore, the forecasted probability distributions for both classes showed clear margins, with the majority of samples categorized firmly—reflecting well-calibrated outputs that can guide trust decisions in high-stakes deployment situations. These strong findings confirm the effectiveness of combining heterogeneous feature domains—specifically compression artifacts, prosodic dynamics, and phase information—in the development of a model able to cope with the sophisticated, multilateral nature of real-world deepfake audio detection. Together, the combined validation performance constitutes a robust empirical basis that not only demonstrates leading-edge detection precision but also underpins the downstream interpretability analyses and subsequent refinements specific to adaptive and dynamic deepfake generation processes.

IV.9 SHAP-BASED FEATURE CONTRIBUTION ANALYSIS:

To further examine the internal decision behavior of the proposed multi-domain deepfake audio detection framework, a SHAP (SHapley Additive exPlanations) analysis was conducted on the trained classifier [6], [41]. The objective of this analysis was not to reinterpret the model as inherently explainable, but rather to validate whether the learned feature importance patterns align with the empirical observations obtained from the ablation studies presented earlier in this section. SHAP values were computed on the fused feature space using a representative subset of the validation data. Feature contributions were aggregated at the domain level by grouping individual feature dimensions into their corresponding categories, namely acoustic, compression-related, prosodic, phase-based, emotional, and statistical–spectral features.

This grouping allows for a coherent interpretation of how different feature families contribute to the model's predictions, without overemphasizing individual low-level dimensions. Figure 7 presents the resulting SHAP summary plot, illustrating the relative importance of each feature domain in influencing the classification outcome. A clear dominance of compression-related features is observed, indicating that variations introduced through codec-induced distortions play a significant role in distinguishing genuine audio from synthetic speech. This observation is consistent with the ablation results reported in Section 4.7, where the exclusion of compression features led to a noticeable degradation in performance, while their integration with acoustic features yielded substantial gains. Acoustic and prosodic features also exhibit strong contributions, reflecting the model's reliance on spectral structure and temporal speech dynamics. In contrast, emotional and statistical–spectral features demonstrate comparatively moderate but non-negligible influence, suggesting that they act as complementary cues rather than primary discriminators. Phase-based features contribute more subtly, reinforcing the notion that fine-grained temporal coherence differences, while difficult to isolate independently, enhance robustness when fused with other domains. Overall, the SHAP analysis corroborates the central design hypothesis of this work: no single feature domain is sufficient in isolation, but the joint exploitation of complementary cues—particularly compression artifacts in conjunction with acoustic information—enables stable and high-performing deepfake audio detection. Importantly, this analysis serves as a consistency check between the learned model behavior and the experimental findings, strengthening the methodological justification of the proposed multi-domain fusion framework rather than introducing new assumptions. The plot highlights the dominant influence of compression-related features, followed by acoustic and prosodic domains, supporting the conclusions drawn from the ablation study.

V. DISCUSSION:

The findings gathered throughout our comprehensive experimental analysis provide rich insights into the strengths and weaknesses of the suggested deepfake audio detection model. This section explains these results in the framework of feature significance, ablation experiments, comparisons with existing literature, and concerns regarding strong generalization. Collected together, these analyses help disentangle the reasons behind the success of the model, reveal areas where existing methods might weaken, and illustrate opportunities for future enhancement. All experiments are performed on Google Colab Pro utilizing an NVIDIA Tesla T4 GPU with mixed-precision acceleration. The implementation is carried out entirely in PyTorch, and all model checkpoints, training losses, and validation metrics are logged during training. The computational footprint of the model remains modest due to its shallow architecture, allowing real-time inference on consumer-grade hardware and facilitating scalability for large-scale deployments.

V.1 COMPARATIVE ANALYSIS:

To put our suggested multi-domain fusion framework's performance and contribution into context, we contrast it with some of the state-of-the-art deepfake audio detection techniques in recent research. The comparison emphasizes the way our method contributes to advancement in detection accuracy, robustness, explainability, and the ability to work with real-world, in-the-wild datasets. Table 6 gives an overview of exemplar previous work compared to ours, highlighting feature sets, model structures, training data, and performance metrics claimed. Most previous approaches mostly utilize spectral or prosodic features in CNN, RNN, or combined architectures [42], [43], [44]. Such models have decent in-domain performance on ASVspoof or WaveFake datasets but tend to lack generalizability to additional real-world situations. Our fusion system, through the combination of acoustic, compression, prosodic, and phase information, achieves a mean accuracy of around 98% with an AUC of close to 0.998 on a very large-scale, "in-the-wild" collection, outperforming standard benchmarks (e.g., EERs ranging from 1.8–4%) published on benchmark corpora. Of particular interest, the addition of compression artifacts—a relatively neglected feature space—greatly increases detection resilience, as indicated by our ablation experiments. This differentiates our method from earlier research that either omits compression features or merges information only at later model phases. By leveraging dataset diversity, multi-domain feature fusion, and interpretability all at once, our research advances the state of the art in deepfake audio detection overssss comparable systems that target more limited or less explainable approaches.

Table 6: Comparative Summary of Deepfake Audio Detection Methods.

Paper / Method	Dataset(s)	Accuracy / EER / AUC	Notable Contributions
Proposed Work	**Large "In-the-Wild" dataset**	**Accuracy ~98%, AUC 0.998**	**Multi-domain early fusion, interpretability, robustness**
[2]	WaveFake, ASVspoof	EER ~1.8%	Token-level spectral modeling
[42]	ASVspoof, WaveFake	EER ~3–4%	Efficiency-accuracy tradeoff
[21]	ASVspoof Logical Access (LA)	Accuracy ~92%	Unsupervised anomaly detectionion
[15]	Custom voice dataset	Accuracy ~85–88%	Baseline for comparison
[17]	ASVspoof LA, DFDC-Audio	EER < 2%	Multi-scale dynamic feature fusion

VI. CONCLUSION AND FUTURE SCOPE

This work presents a robust and systematic framework for deepfake audio detection based on multi-domain feature fusion and lightweight neural classification. The proposed approach is evaluated on a large-scale, in-the-wild dataset comprising 31,780 audio samples evenly distributed between genuine and synthetic speech. By incorporating diverse speakers, languages, recording conditions, and synthesis techniques, the dataset closely reflects real-world deployment scenarios and provides a strong empirical foundation for evaluating generalization and robustness. A carefully designed preprocessing pipeline ensures standardized input quality, enabling consistent feature extraction and stable model training. The core methodological contribution of this study lies in the integration of complementary feature domains that capture both physical and algorithmic characteristics of speech production. Acoustic features model vocal-tract behavior, prosodic descriptors reflect higher-level speech dynamics, phase-based features capture fine-grained temporal coherence, emotional features characterize expressive variability, compression-related features expose codec-sensitive artifacts, and statistical spectral measures summarize global signal distributions. Rather than relying on a single representation, the fusion of these domains enables the detector to identify subtle inconsistencies that persist even when modern synthesis systems successfully mimic surface-level spectral patterns. The fused feature representation is classified using a lightweight fully connected neural network, which achieves strong discriminative performance while remaining computationally efficient and stable across validation folds. A key outcome of the experimental evaluation is the consistently high classification performance observed under stratified five-fold cross-validation, with minimal variation across folds. The results demonstrate that the proposed framework effectively separates genuine and synthetic audio across diverse conditions, supporting its suitability for real-world forensic and security applications. Importantly, the ablation study highlights that while individual feature groups, such as compression artifacts, are insufficient in isolation, their inclusion within a multi-domain fusion strategy significantly enhances robustness. This finding explains why the proposed system outperforms approaches that rely solely on spectral or prosodic cues and supports the central design choice of early, heterogeneous feature integration. When compared with existing deepfake audio detection methods reported in the literature, the proposed framework offers several practical advantages.

Many prior works achieve strong in-domain performance but rely heavily on deep spectro-temporal models trained on constrained benchmark datasets, often suffering performance degradation when exposed to unseen synthesis techniques or real-world distortions. In contrast, the present approach leverages domain-diverse features that are less tightly coupled to specific vocoders or architectures, allowing it to generalize more effectively across synthesis pipelines and recording environments. The inclusion of compression-related and phase-based cues, which are often underexplored in earlier studies, provides additional discriminatory evidence that remains difficult for generative models to reproduce consistently. These factors collectively explain the strong empirical results observed in this study. Despite the encouraging performance, several directions remain open for future investigation. While the current dataset is large and diverse, further evaluation under extreme acoustic conditions, adversarial perturbations, and emerging synthesis paradigms would strengthen confidence in long-term robustness. Extending the framework to incorporate linguistic or semantic representations may further enhance detection capability, particularly for emotionally neutral or low-variance speech. Additionally, adaptive or continual learning strategies could be explored to allow the model to update efficiently as new spoofing techniques emerge, without requiring full retraining. Finally, integrating the proposed audio-based system with complementary modalities, such as visual or behavioral cues, represents a promising avenue for constructing more comprehensive multimodal deepfake detection pipelines. In summary, this work establishes a strong and extensible foundation for deepfake audio detection by demonstrating that carefully designed multi-domain feature fusion, combined with an efficient classification model, can achieve reliable and generalizable performance under realistic conditions. The insights gained from feature ablation and comparative analysis provide clear justification for the proposed methodology and offer valuable guidance for future research aimed at countering the rapidly evolving threat of synthetic speech.

Keywords:
Multi-SKU forecasting,
FP-Growth,
Echo State Network,
LSTM.

ABSTRACT

This study examines whether cross-product signals derived from market-basket transactions can enhance multi-SKU retail sales forecasting when embedded as auxiliary features in global sequence models. Retail transaction records from January 2024 to November 2025 were utilized. Frequent itemsets and association rules were mined using FP-Growth, and the resulting co-purchase structure was transformed into forecasting features. Daily sales were aggregated into weekly multivariate series and normalized using Min–Max scaling. Two feature-augmented forecasting architectures were evaluated: an Echo State Network (ESN+FP) and a Long Short-Term Memory network (LSTM+FP). Hyperparameters were tuned with Optuna (30 trials) using validation sMAPE, and per-SKU performance was assessed using MAE and sMAPE. Across 43 Food & Beverage SKUs, the lowest sMAPE was obtained by ESN+FP for 28 SKUs, whereas LSTM+FP performed best for 15 SKUs, indicating substantial heterogeneity in demand dynamics. Although slightly lower average errors were achieved by LSTM+FP, ESN+FP yielded superior results for several volatile yet repetitive series, while more stable trend patterns were better captured by LSTM+FP. An adaptive, per-SKU model selection strategy is therefore supported.

I. INTRODUCTION

Digital transformation in the retail sector has intensified the need for accurate demand forecasting and inventory control. In highly competitive markets with large product portfolios and rapidly evolving consumer behavior, forecasting errors directly increase holding costs, raise stockout risk, and reduce revenue. These challenges are amplified in multi-SKU settings because operational decisions are often made at the item level while demand across products can be interdependent. Transaction data frequently exhibit complementary and substitution relationships, making cross-product signals valuable for more stable and generalizable forecasts. A wide range of demand-forecasting methods has been applied in retail and supply chains, from statistical baselines to regression-based machine-learning models, largely due to their operational simplicity and competitive short-horizon performance. Comparative studies on industrial demand forecasting also show that the choice of algorithm and modeling strategy (e.g., global vs. local) affects the accuracy and consistency of cross-item/series performance [1], while comparative studies in the context of data-driven logistics confirm the common practice of comparing statistical methods with ML for time series [2]. In recent years, deep learning (e.g., LSTM/RNN variants) has been increasingly adopted to capture nonlinear dynamics in demand forecasting, including in e-retail and industry/food data-based demand forecasting [3], [4], [5].

However, in practice, many approaches still emphasize item-specific temporal pattern learning or rely on implicit cross-series learning (e.g., through global/local strategies or multivariate modeling), without explicit and measurable mechanisms to represent co-purchase/shopping basket structures. This challenge is compounded by heterogeneous SKU-level dynamics and disruptions such as outliers and calendar effects, which can destabilize model selection and generalization [1], [6]. Additionally, the intermittent demand characteristics of some retail products have been explicitly reported and require special attention in feature design, modeling strategies, and evaluation [7]. Association-rule mining provides an explicit mechanism for extracting cross-product signals from transaction data. Algorithms such as Apriori and FP-Growth have been widely used to extract frequent itemsets and association rules that represent co-purchase tendencies, and support cross-selling analysis and bundling promotion design [8]. However, the use of association analysis outputs as predictive features in time series forecasting is still relatively limited; many studies stop at descriptive findings (co-purchase patterns) without systematically integrating them into quantitative forecasting frameworks trained and evaluated at the SKU level. This limitation leaves clear room for research: can the co-purchase structures mined from transactions be transformed into features that enrich multi-SKU forecasting models and provide consistent improvements for specific SKUs, especially for volatile or infrequent series? Beyond LSTM as a widely used sequence-learning approach, Echo State Networks (ESN) offer a computationally efficient RNN alternative.

Unlike LSTM, which trains network weights end-to-end, ESN uses a reservoir with fixed weights and only optimizes output weights, making its training relatively lightweight and practical when applied to multi-SKU scenarios that require model/configuration maintenance across multiple outputs [9]. Comparative studies on dynamic systems also show that reservoir computing can be a competitive alternative to LSTMs for certain prediction tasks, while providing perspective on the accuracy–efficiency trade-off between fully-trained and reservoir-based approaches [10]. These characteristics are relevant to retail needs: useful prediction solutions must be accurate, but also feasible to run efficiently on large data and periodic model updates. Based on this gap, this study proposes a multi-SKU retail sales forecasting framework that integrates FP-Growth-based cross-product features with two different sequence forecasting architectures, namely ESN and LSTM. FP-Growth is used to extract inter-product correlation patterns from transactions and distill them into features/feature selections that represent co-purchase structures, so that the model learns not only from the historical temporal patterns of each SKU, but also from the cross-SKU relationships that emerge in shopping baskets. Furthermore, this study evaluates two global model variants—LSTM+FP and ESN+FP—on a like-for-like basis with consistent tuning procedures and per-SKU evaluation using MAE and sMAPE on weekly time series. Using transaction data from January 2024 to November 2025 filtered to the Food & Beverage category, the experiments focused on 43 SKUs that met the weekly history eligibility criteria.

II. RELATED WORK

Multi-item retail forecasting studies commonly retain classical baselines (e.g., ARIMA, exponential smoothing) and regression-style ML models due to their training efficiency, competitive short-horizon accuracy, and ease of deployment. In the context of grocery retail, Liashenko and Yakymchuk emphasize model selection as a practical decision under exogenous shocks (e.g., pandemics) and interpretability requirements; they discuss comparisons of classical time series methods with ML regression and additive approaches that support covariates (e.g., the Prophet family) to capture trends, seasonality, holidays, and external variables [11]. This direction is consistent with the literature's practice of demanding a robust and easily explainable baseline before proposing more complex architectures, especially when the study's goal is not just accuracy but also applicability and transparency of assumptions [11]. As data complexity increases and the need to capture non-linearities grows, the demand/time-series forecasting literature increasingly highlights deep learning designs that combine temporal memory (LSTM/GRU) with feature extractors (CNN/TCN) or attention mechanisms to model both local patterns and longer dependencies. In retail sales, Moraes et al. proposed a hybrid CNN–LSTM variant (stacked and parallel) that uses LSTM for temporal dynamics and convolutional modules to extract multivariate/exogenous information, and they reported improved performance over simpler neural architectures and autoregressive baselines on multivariate retail data [12]. In other time series domains, similar hybrid designs are widely used to combine linear/non-linear structures and balance feature representation needs against training load; for example, Nandigam et al. explore CNN–LSTM for large-scale energy consumption forecasting as an example where complex patterns and covariates drive the use of hybrid models [13]. Conceptually, these results reinforce the argument that "sequence memory + feature extraction" becomes the dominant design pattern when series are multivariate, influenced by external factors, and have variable structures.

Beyond hybrid CNN–RNN, two other relevant lines of research are (i) modeling multivariate dependencies and long contexts through attention/Transformer and (ii) improving robust forecasting for long horizons. Cheng et al. introduced SeriesNet as a conditional forecasting architecture that combines a causal CNN component with an RNN and then adds attention to improve temporal feature learning without uncontrolled parameter growth [14]. For contexts demanding long dependencies and complex covariates, the Transformer approach—e.g., Temporal Fusion Transformer (TFT)—is also frequently chosen; Alorf and Khan position TFT as a framework for capturing long-term dependencies in complex meteorological time series (with decomposition) [15]. On the robust long-horizon forecasting side, Zhou et al. propose TreeDRNet (based on arXiv) as an example of a deep approach targeting robustness in long-term predictions [16]. Furthermore, cross-dataset comparative studies are also commonly conducted to avoid single claims based on one dataset; Altıparmak and Aksu exemplify the practice of comparing several deep learning approaches for installed capacity forecasting, showing that "state-of-the-art" assessments often depend on evaluation protocols and data characteristics [17]. Overall, the deep forecasting literature tends to move in two directions: enriching mechanisms for capturing cross-variable dependencies (attention/Transformer) and strengthening robust generalization for long horizons, while still demanding rigorous comparison and replication on diverse datasets [14], [15], [16], [17]. However, in the representative works above, cross-product dependencies in retail are generally handled implicitly through multivariate inputs, convolutional modules, or attention—not through signals derived directly from the "market-basket" transaction structure. In fact, classical association-rule mining is designed to extract cross-item co-purchase patterns from large-scale transaction data, with Apriori as the initial foundation of association rules [18] and FP-Growth as an efficient method without candidate generation for frequent pattern mining [19].

The absence of an explicit path from "basket → rules → predictive features" in retail deep forecasting studies (e.g., retail CNN–LSTM [12]) leaves clear room for feature engineering that injects co-purchase structures as more interpretable cross-SKU signals, especially when the target is global multi-SKU forecasting and per-SKU evaluation. On the alternative architecture side, reservoir computing such as Echo State Networks (ESN) is often considered for its training efficiency (only readouts are trained, reservoir remains fixed), making it attractive for multiple series/tuning experiment scenarios. The foundational ESN literature emphasizes the importance of the "echo state property" condition and performance sensitivity to reservoir design/dynamics [20], [21], [22]. However, neat and direct comparative evidence for ESN vs. LSTM in the context of multi-SKU retail—with aligned features and per-SKU evaluation—is still much less common than comparisons between deep network variants (e.g., CNN–LSTM vs. other approaches) or cross-architecture benchmark studies [12], [17]. Therefore, this study is positioned as a focused empirical contribution: testing ESN and LSTM as global models with aligned FP-Growth features, then interpreting their trade-offs based on per-SKU performance.

III. MATERIALS AND METHODS

III.1 DATA

The data used in this study were obtained from retail sales transactions at Retail Ayu Nadi covering January 2024 to November 2025. The initial dataset consists of 2,097,150 rows and 27 attributes representing transaction information at the receipt level, including transaction time, invoice number, product identity, quantity, and other sales-related attributes. In the initial stage, attributes that were originally only recognized by column index were relabeled. The five key attributes used were date_time (transaction timestamp), invoice_number, item_name, quantity, and item_category. Transaction data from 2024 and 2025 were combined into a single integrated data frame. Furthermore, the scope of the study was limited to the Food & Beverage category to maintain relevance to daily consumer goods; other categories were excluded. After this filtering process, the number of transactions was reduced to 1,026,524 rows. From all Food & Beverage products, a set of items that appeared in the FP-Growth association rule results and also had a long weekly sales history was selected. This process resulted in 43 SKUs that became the focus of multi-SKU modeling at the forecasting stage.

III.2 DATA PREPROCESSING

Preprocessing followed two parallel pipelines: association extraction and time-series construction, which subsequently served as inputs to ESN+FP and LSTM+FP. The complete diagram of the FP-Growth flow integrated with ESN and LSTM modeling is shown in Figure 1 and Figure 2. For association extraction, transactions were converted into shopping baskets using the invoice identifier (no_nota). The FP-Growth algorithm is used to perform frequent itemset mining with a certain minimum support threshold. This method extracts combinations of products that frequently appear together in a transaction. Association rules were derived from frequent itemsets, with confidence computed as shown in following equation [23]:

$$Support\ (X) = \frac{Transactions\ Contains\ With\ X}{Total\ Transactions}$$

$$Confidence\ (A \rightarrow B) = \frac{Support(A \cup B)}{Support\ (A)}$$

The resulting rules were evaluated using lift, and only rules with lift > 1 and support/confidence above the specified thresholds were retained to preserve statistically meaningful relationships [24]. The items involved in the selected association rules are reintegrated into the transaction dataset. Only transactions containing these products are used in modeling, so that the model focuses on products that have clear transactional relevance. This step also functions as association-based feature selection and reduces noise from irrelevant items [25]. For time-series construction, daily transactions were aggregated into weekly series by summing item-level sales over Monday–Sunday intervals. Weekly aggregation is chosen to reduce daily stochastic fluctuations and sparsity issues (many zero values) that are common in daily retail data, while maintaining trend and seasonal patterns that are relevant for decision making [26]. The aggregation results are then pivoted to obtain a multivariate time series matrix, with rows representing weeks and columns representing items. Missing values that arise due to pivoting are filled with zeros. Finally, all weekly sales values are normalized using Min–Max scaling to the range [0, 1]. This normalization is important to stabilize the learning process in both the ESN reservoir and the LSTM network, which are sensitive to differences in scale between variables. This scaled multivariate time series matrix becomes the database for the multi-SKU experiment in the next stage.

III.3 ESN+FP MODEL ARCHITECTURE AND TRAINING

The Echo State Network architecture with FP-Growth association features (ESN+FP) is designed as a global multi-SKU model that utilizes dynamic reservoir representations to predict weekly sales. The complete flow of FP-Growth and ESN integration is shown in Figure 1.

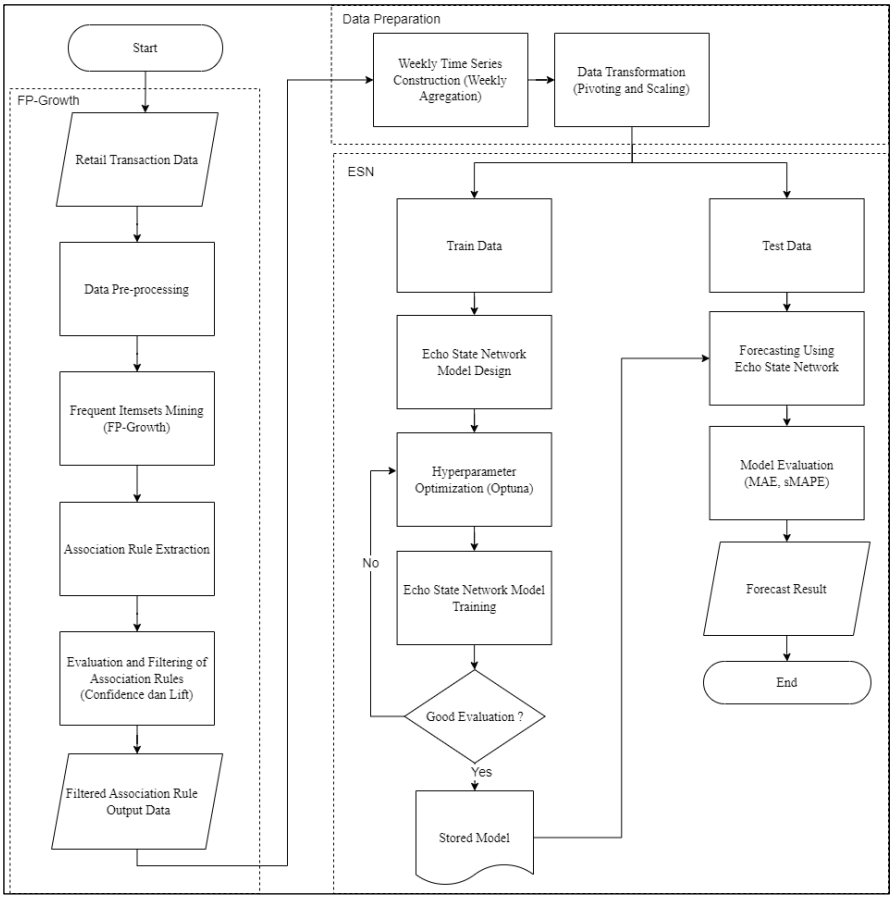

Figure 1: ESN+FP workflow for multi-SKU weekly sales forecasting.
Source: Authors, (2026).

Structurally, ESN consists of three main components: an input layer, a reservoir with random recursive weights, and an output layer (readout) [27]. The input and reservoir weights (Win and$W$) are randomly initialized with controlled sparsity and spectral radius to satisfy the Echo State Property, thereby keeping the reservoir dynamics stable [28]. At each weekly time step, the input vector contains scaled sales for all relevant SKUs along with additional features from FP-Growth (e.g., membership indicators or association intensity). The reservoir projects this input into a high-dimensional, nonlinear state space. Unlike conventional RNNs, the ESN training phase only optimizes the output weights$Wout$, whileWin and$W$ remain fixed. The training process begins with state harvesting, which involves feeding the training time series into the reservoir and recording the internal state matrix$H$ [29] [30]. The first few steps are ignored as a washout period to eliminate the effects of initial conditions. The output weights are then calculated using ridge regression.

$$W_{out} = Y_{target} H^T (HH^T + \lambda I)^{-1}$$

whereY_{target} is the sales target matrix,λ is the regularization coefficient, and$I$ is the identity matrix. Because ESN performance is sensitive to reservoir configuration, Optuna was used for hyperparameter optimization using the TPE sampler over reservoir size, spectral radius, leak rate, and ridge coefficient. This process utilizes the Tree-structured Parzen Estimator (TPE) algorithm to explore combinations of parameters such as reservoir size, spectral radius, leak rate, and regularization coefficient [31]. A total of 30 trials were run to minimize the sMAPE value on the validation data. The best hyperparameters were then used to train the final ESN+FP model on the training data. All model components, including the scaler and pivot structure, were stored in a serialized format to ensure consistency when performing inference on new data.

III.4 LSTM+FP MODEL ARCHITECTURE AND TRAINING

The second model is Long Short-Term Memory with FP-Growth association features (LSTM+FP), which is also configured as a global multi-SKU model. The integration flow diagram of FP-Growth and LSTM is shown in Figure 2.

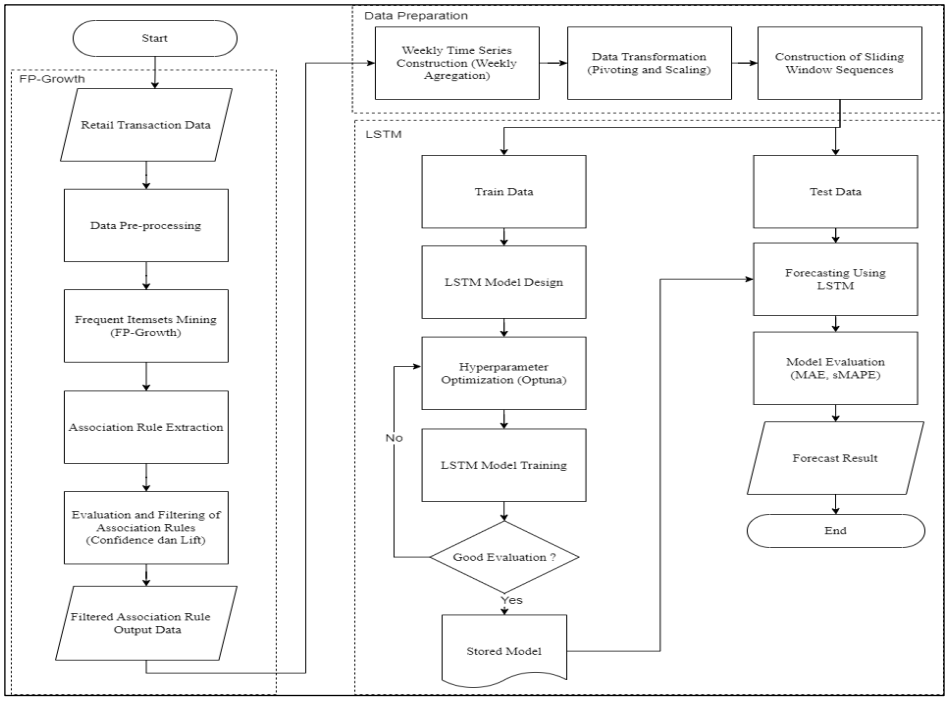

Figure 2: LSTM+FP workflow for multi-SKU weekly sales forecasting.
Source: Authors, (2026).

In contrast to ESN, LSTM employs gated memory cells (input, forget, and output gates) to learn long-range temporal dependencies. After the weekly aggregation and normalization stages, the multivariate time series matrix is converted into a fixed sequence using the sliding window approach[32]. Each window contains historical observations spanning L weeks for all SKUs, while the target is the next week's sales vector. This transformation allows LSTM to learn temporal patterns across multiple time steps[32]. The network architecture consists of one or more LSTM layers followed by a fully connected layer that produces multivariate predictions. All network weights are trained through backpropagation through time[33]. As in ESN, the LSTM configuration is tuned using Optuna with 30 trials to minimize sMAPE on the validation data. The optimized hyperparameters include the number of LSTM units, sequence length, learning rate, batch size, number of epochs, and dropout rate[33]. The training process was carried out with the Adam optimizer and an error-based loss function (e.g., MSE), with several epochs until convergence. The model that performed best on the validation data was selected as the final model. As with ESN+FP, the LSTM+FP model along with the pre-processing components (scaler, pivot structure, and window configuration) were saved for use in the forecasting and evaluation stages.

III.5 EXPERIMENTAL DESIGN AND EVALUATION

The experiment was designed to compare the capabilities of ESN+FP and LSTM+FP in the context of multi-SKU sales forecasting. Given the sequential nature of time series, the training and test data were separated chronologically. Several train–test ratio scenarios (60:40, 70:30, and 80:20) were evaluated to test the robustness of the model against variations in training data length, with the final model selected based on the best performance in the scenario considered most representative. In each scenario, both models were trained as global models using the same multivariate time series matrix, which had been enriched with FP-Growth association features. The evaluation was performed per SKU, so that for each item a pair of error values was obtained for ESN+FP and LSTM+FP. Two main metrics were used, namely Mean Absolute Error (MAE) and Symmetric Mean Absolute Percentage Error (sMAPE). MAE measures the average absolute deviation between actual and predicted values, while sMAPE provides a measure of relative error normalized to the average of actual and predicted values, making it easier to compare SKUs with different sales scales.

IV. RESULT AND DISCUSSION

IV.1 COMPARATIVE PERFORMANCE RESULTS

In this study, one global ESN model enriched with FP-Growth association features (ESN+FP) and one global LSTM model with FP-Growth (LSTM+FP) were trained simultaneously using the sales data of 43 SKUs. Both models share cross-product parameters, representing a real-world scenario in multi-SKU retail where practitioners tend to apply a centralized model. However, performance evaluation was conducted at the per-item (per SKU) level using MAE and sMAPE metrics, so that it could be observed how a single global architecture reacted to different sales time series characteristics. Table 1 presents the MAE and sMAPE values of ESN+FP and LSTM+FP for each SKU. Using the smallest sMAPE as the selection criterion, it can be seen that ESN+FP provides the lowest error in 28 of the 43 SKUs, while LSTM+FP performs better in 15 SKUs. For some products such as Chitato, Me Lewis, Sari Roti, and Boncabe, the sMAPE value of ESN+FP is very small (often below 5%), while LSTM+FP produces a larger error. Conversely, for products such as Madu, Indomie, and several dairy products, LSTM+FP produces a lower sMAPE than ESN+FP, indicating that the LSTM architecture is better able to follow the demand dynamics in these time series. There are also several SKUs with very high sMAPE for both models (e.g., ABC Mie and Kecap Ikan dan Inggris), indicating time series with highly irregular and unpredictable demand patterns.

Table 1: Comparison of per-SKU performance between ESN+FP and LSTM+FP based on MAE and sMAPE.

Item	ESN+FP Growth		LSTM+FP Growth	
	MAE	sMAPE (	MAE	sMAPE (%)
CHITATO	0.1	0.07	89.03	3.92
ME LEWIS	2.46	1.05	16.39	4.11

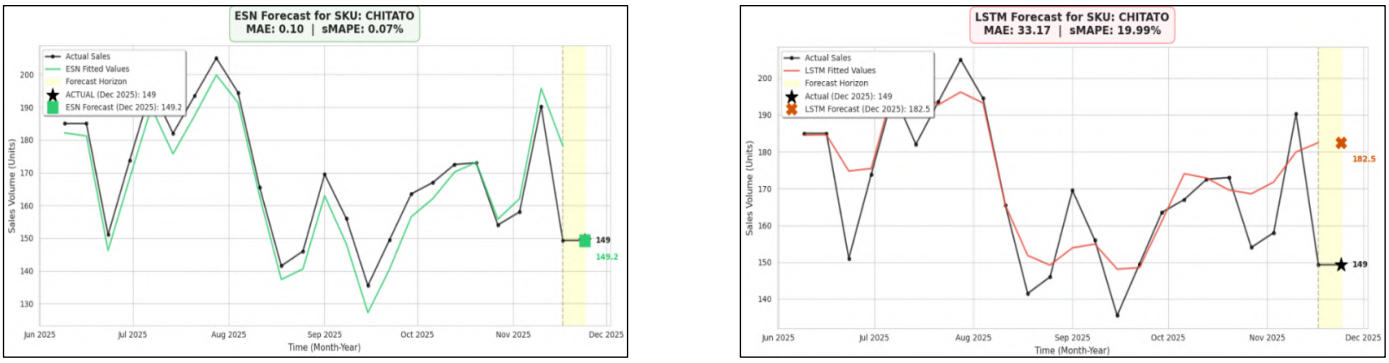
Average	**42.76**	**30.84**	**33.15**	**26.48**

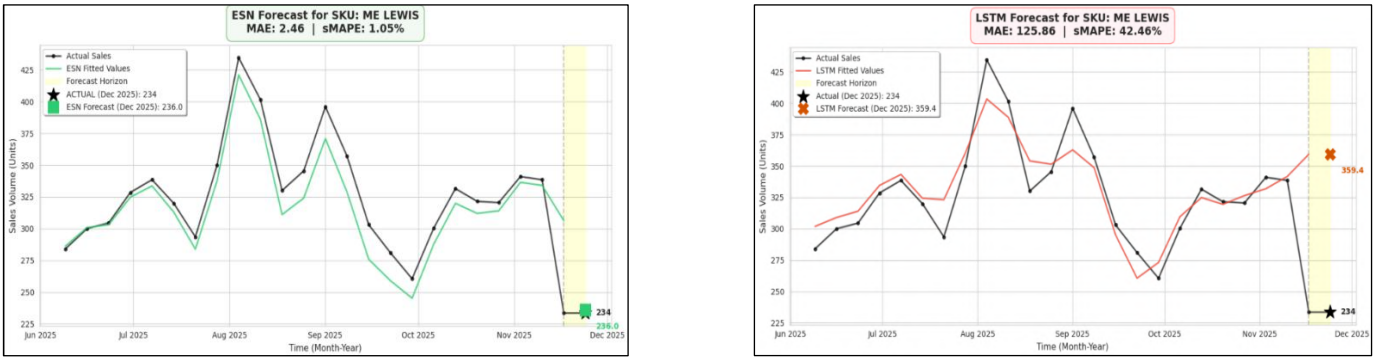


Source: Authors, (2026).

The pattern in Table 1 shows strong heterogeneity. For some items such as CHITATO, ME LEWIS, SARI ROTI, and BONCABE, ESN+FP achieved sMAPE below 5%, while LSTM+FP lagged significantly behind. This indicates that the combination of ESN reservoir with FP-Growth association features is very effective for the time series of these products. Conversely, there are other items such as MADU, ABC MIE, or several dairy products where LSTM+FP produces a lower sMAPE than ESN+FP, and ESN+FP tends to experience a significant under/over-prediction bias. There are also extreme cases such as ABC MIE and KECAP IKAN DAN INGGRIS where the sMAPE of ESN+FP is very high (up to around 200% and 150%), while LSTM+FP, although not good, remains within a more moderate error range. As shown in the Average row of Table 1, LSTM+FP achieves slightly lower mean MAE and sMAPE than ESN+FP. This indicates that, in aggregate across all SKUs, the global LSTM+FP model tends to produce smaller average errors. However, ESN+FP is more often the best model at the item level (28 SKUs), and its sMAPE value distribution is wider. This means that ESN+FP is very effective for certain SKU subsets but also shows high performance variation, while LSTM+FP is less often the best for a product, but its behavior is relatively more consistent and less likely to produce extreme errors. These item-level findings confirm that a single global model will not behave uniformly across all products, as it reacts differently to the time series characteristics of each SKU—ranging from volatility levels, trend patterns, to demand properties that are more continuous or sporadic—so performance evaluation should not rely solely on aggregate average values, but must always be reviewed at the SKU level.

In addition, the comparison results show that ESN+FP does indeed more often emerge as the model with the smallest sMAPE and is therefore worth considering as a global baseline, but LSTM+FP cannot be ignored because for some SKUs it actually provides more accurate predictions, so that in practice the combination of the two opens up opportunities for an adaptive model selection approach per product.

IV.2 ITEM FORECASTING RESULT ANALYSIS

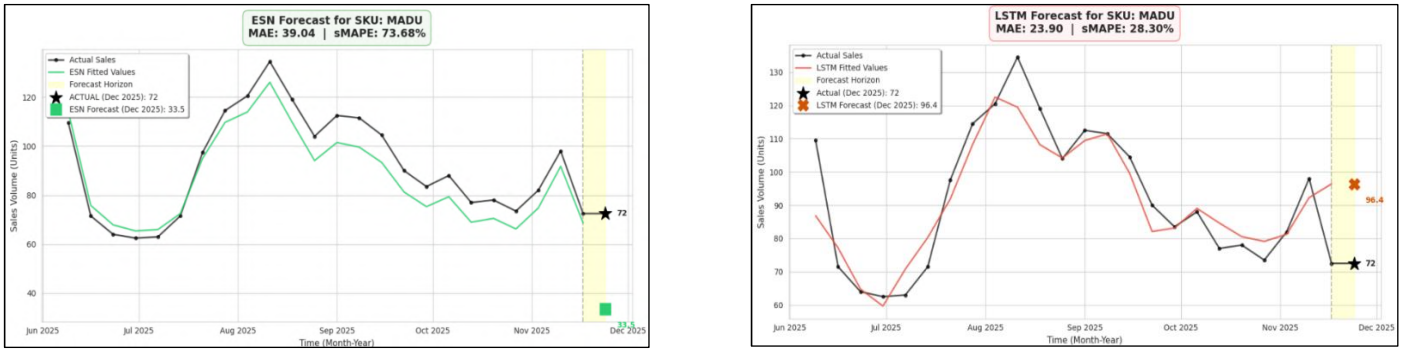


This subsection examines six representative SKUs selected to reflect diverse demand characteristics and compares models using both aggregate accuracy (MAE, sMAPE) and operational behavior at the final forecast point. The first lens is aggregate performance, which is measured by MAE and sMAPE throughout the test horizon. The second lens is operational performance, namely the behavior of the model at the last forecasting point and its suitability with the direction of demand change (up or down) towards the end of the period. The six pairs of graphs in Fig. 1–Fig. 6 were selected to represent three main patterns that emerged from the data: (i) cases where ESN+FP clearly outperformed LSTM+FP, (ii) cases where LSTM+FP was more accurate than ESN+FP, and (iii) cases where both models failed to represent demand dynamics (*hard-to-forecast series*). This dual-lens approach allows for a more balanced evaluation between average numerical accuracy and the practical usefulness of forecasting results at the item level.

(a) (b)

Figure 3: Comparison of CHITATO SKU sales forecast results between (a) ESN+FP and (b) LSTM+FP.
Source: Authors, (2026).

In Figure 3, both lenses consistently support the superiority of ESN+FP. From an aggregate perspective, ESN+FP produces an MAE of 0.10 and an sMAPE of 0.07%, which is much smaller than LSTM+FP, which has an MAE of 33.17 and an sMAPE of 19.99%. Operationally, the ESN+FP endpoint prediction in December 2025 closely matched the observed value (149 vs. 149.2) and captured short-term fluctuations. LSTM+FP tends to smooth out variations and slightly deviate from the actual line, resulting in less accurate form and value.



(a) (b)

Figure 4: Comparison of sales forecast results for SKU ME LEWIS between (a) ESN+FP and (b) LSTM+FP.
Source: Authors, (2026).

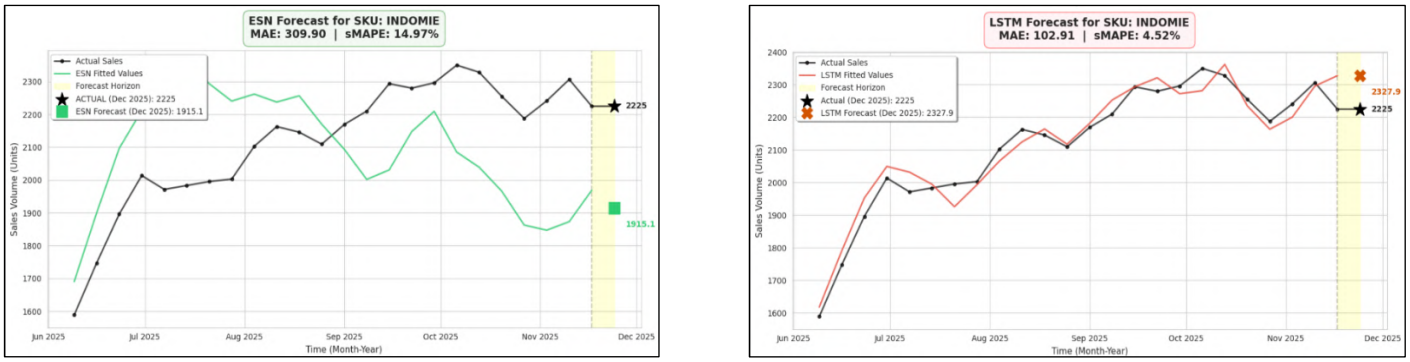


Figure 4 (SKU *ME LEWIS*) shows the same pattern. In aggregate, ESN+FP again excels with MAE of 2.46 and sMAPE of 1.05%, while LSTM+FP records MAE of 125.86 and sMAPE of 42.46%. From an operational perspective, ESN+FP provides a final prediction that is very close to the actual (234 vs. 236), with a curve shape that follows the ups and downs of sales. LSTM+FP not only has a large average error, but also predicts an overly high final level (359.4), making it unreliable for stock decision-making. These two examples illustrate the "fluctuating with clear local repetition" pattern group, where ESN+FP excels both in terms of metrics and final prediction behavior. The opposite is seen in Figure 5 and Figure 6, which represent series with relatively smooth trends and seasonality. In Figure 3 (HONEY SKU), from an aggregate perspective, LSTM+FP is clearly better with an MAE of 23.30 and sMAPE of 28.30%, compared to ESN+FP which has an MAE of 39.04 and sMAPE of 73.68%. Operationally, the final prediction of LSTM+FP (98.4) is still off from the actual 72, but its deviation ( ) is still smaller than that of ESN+FP, which predicted 33.5. The shape of the LSTM+FP curve is also more stable in following the downward trend in the latter half of the horizon, while ESN+FP shows a significant level bias.

In Figure 4 (INDOMIE SKU), the difference between the two models is even more apparent. LSTM+FP produced an MAE of 102.91 and an sMAPE of 4.52%, while ESN+FP recorded an MAE of 309.90 and an sMAPE of 14.97%. At the end point, the LSTM+FP prediction (2327.9) is much closer to the actual 2235 than ESN+FP (1915.1), and the LSTM+FP curve follows a relatively smooth upward trend, while ESN+FP fails to maintain its level. For a pattern like this—"smooth trend with weak seasonality"—both lenses point to LSTM+FP as the more suitable model.

(a) (b)

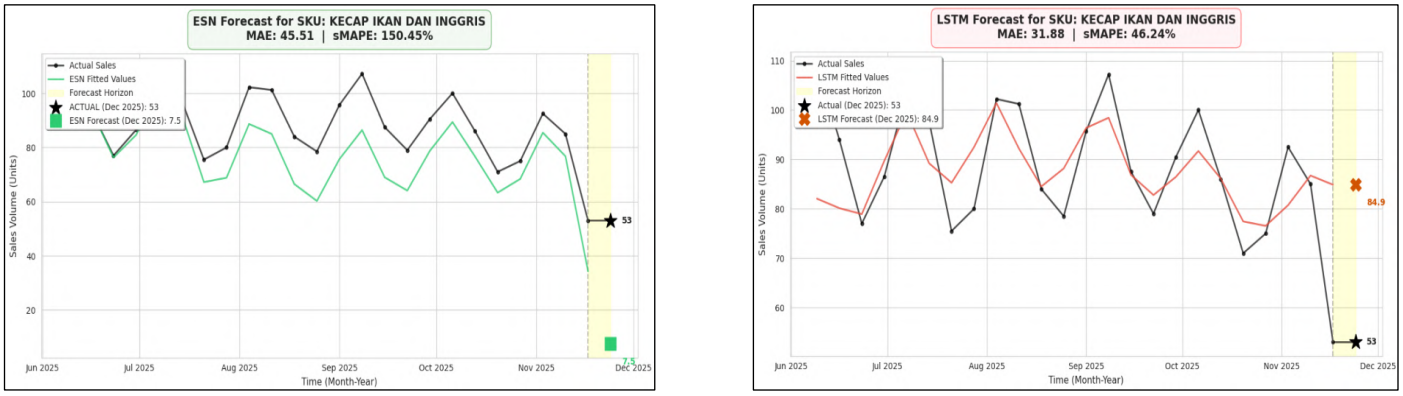

Figure 6: Comparison of sales forecast results for INDOMIE SKUs between (a) ESN+FP and (b) LSTM+FP.
Source: Authors, (2026).

Figure 7 (SKU ABC MIE) and Figure 8 (SKU KECAP IKAN DAN INGGRIS) illustrate series that can be categorized as hard-to-forecast series. In Figure 5, the ABC MIE series shows sharp changes and extreme declines at the end of the horizon. In aggregate, LSTM+FP performs better (MAE 22.78; sMAPE 69.26%) than ESN+FP (MAE 29.28; sMAPE 200.00%), but both sMAPE values are equally high. From an operational perspective, the final prediction of ESN+FP (7.8) is slightly closer to the actual 22 than LSTM+FP (44.3), but both are clearly off and misread the magnitude of the decline in demand. In Figure 6, the SKU KECAP IKAN DAN INGGRIS shows a sporadic demand pattern with fluctuating levels. LSTM+FP is better in aggregate (MAE 31.88; sMAPE 46.24%) than ESN+FP (MAE 45.51; sMAPE 150.45%), and also provides a relatively closer final prediction (84.9 vs. actual 53 compared to 7.5 for ESN+FP). However, from an operational perspective, both models remain inadequate because the deviation at the end point is still large and the direction of level changes is not captured well.

Figure 8: Comparison of sales forecast results for SKU KECAP IKAN DAN INGGRIS between (a) ESN+FP and (b) LSTM+FP. Source: Authors, (2026).

From the six examples in Figures 3–8, it can be concluded that the two assessment lenses provide complementary insights. For SKUs with **fluctuating but repeating** patterns, ESN+FP tends to excel in terms of both MAE/sMAPE and in replicating the shape and end point of the series. For SKUs with **smoother trends and seasonality**, LSTM+FP is more accurate, both in terms of aggregate error and the closeness of the final prediction to the actual value. Meanwhile, for series with **highly sporadic and unstructured demand**, both of these global models show limitations in terms of both numerical and operational aspects. This pattern-based insight confirms that an effective multi-SKU forecasting strategy needs to evaluate models from two perspectives—aggregate and operational—and encourages the use of an adaptive model selection approach tailored to the time series characteristics of each product group.

IV.3 RELATIONSHIP WITH TIME SERIES CHARACTERISTICS

The findings in Table 1 and the visual analysis in Figures 3–8 show that the performance of ESN+FP and LSTM+FP is greatly influenced by the time series characteristics of each SKU, not just by the model architecture used. Qualitatively, the sales time series of the 43 SKUs can be grouped into three main patterns: (i) a fluctuating pattern with clear local repetitions, (ii) a relatively smooth trend and seasonal pattern, and (iii) a highly sporadic and unstructured demand pattern. Each group exhibits different model tendencies in terms of aggregate performance (MAE/sMAPE) and operational behavior (final predictions and the direction of demand changes). In the first group, namely series with sharp but repetitive fluctuations (e.g., CHITATO, ME LEWIS, SARI ROTI, BONCABE), sales tend to oscillate around a certain level with several repeated spikes and declines over time. For these characteristics, ESN+FP generally provides the best performance: sMAPE values are in the very low range (often below 5%), and the ups and downs of the predictions closely follow the actual series. This indicates that the ESN reservoir effectively absorbs short-term dynamics and local variations, while the FP-Growth association feature helps add context to relevant inter-product relationships during periods of high demand. The second group includes series with long-term trends and subtle seasonality (such as MADU and INDOMIE). In these series, local fluctuations are relatively smaller than global trend changes, and there are no strong short-term pattern repetitions. Experiments show that LSTM+FP tends to be superior in this group: LSTM+FP produces lower MAE and sMAPE and is able to place the trend level and direction more accurately, while ESN+FP often experiences level bias that causes large vertical deviations even though the curve shape appears to follow the trend at first glance.

This is consistent with the character of LSTM, which is designed to capture long-term dependencies, making it more suitable for series with strong trend structures and gradual level changes. The third group consists of series with highly sporadic and unstructured demand, which is clearly seen in ABC MIE and KECAP IKAN DAN INGGRIS. Series in this group are characterized by sharp variations, high zero frequency, or sudden changes without seasonal patterns or stable trends. In this case, both global models show limitations: sMAPE reaches very high values and the final predictions are often far from the actual values. The FP-Growth association feature is also not very helpful, because the co-purchase patterns for these products tend to be unstable, making them difficult to use as additional signals. These series can be categorized as hard-to-forecast series that require a special approach beyond the ESN+FP and LSTM+FP configurations used in this study. In summary, the relationship between time series characteristics and the models that tend to excel can be summarized as follows: ESN+FP is suitable for SKUs with high but patterned volatility, LSTM+FP is more suitable for SKUs with smooth trends and seasonality, while SKUs with highly sporadic demand patterns are not suitable for modeling with only these two approaches. This pattern-based mapping forms the basis for model selection strategy recommendations in the multi-SKU context discussed in the next subsection.

IV.4 PRACTICAL IMPLICATIONS FOR MULTI-SKU RETAIL

From a practical perspective, findings from 43 SKUs indicate that applying a single global model to the entire product portfolio does not yield optimal results. Differences in demand pattern characteristics cause ESN+FP and LSTM+FP to be mutually superior in different SKU groups, and in a small portion of SKUs, both are equally inadequate. Therefore, forecasting strategies in a multi-SKU retail environment need to be designed as a step-by-step process that incorporates time series character diagnosis and adaptive model selection. First, before mass modeling, retailers are advised to conduct an initial diagnosis of the time series for each SKU based on simple indicators such as the volatility level (e.g., the ratio of standard deviation to average), the presence of trends and seasonality, and the level of intermittency (the proportion of periods with zero or very low demand).

This diagnosis can be used to group SKUs into three pattern types identified in Subsection IV.3: patterned-fluctuating, smooth-trending, and sporadic. Second, the results of the diagnosis can be mapped to model selection policies. For SKU groups with fluctuating but repeating patterns, ESN+FP can be used as the main baseline because it has proven to be superior in terms of both MAE/sMAPE and forecasting pattern suitability, especially when inter-product association information is relevant. For SKUs with smoother trends and seasonality, LSTM+FP is more appropriate to prioritize because it provides more accurate estimates of the level and direction of demand changes in aggregate. Meanwhile, SKUs with highly sporadic demand should not immediately rely on global ESN or LSTM models, but should consider using special methods for intermittent demand (e.g., Croston-based approaches) or be handled with more conservative stock policies until more suitable models are developed. Third, practical implementation in retail information systems can adopt a model selection framework per SKU. In this framework, the forecasting pipeline consists of: (i) a time series analysis module that periodically classifies SKUs, (ii) a model selection module that decides whether ESN+FP, LSTM+FP, or another method is used for a particular SKU, and (iii) a continuous evaluation module that monitors MAE/sMAPE and operational indicators such as bias level and accuracy of demand change direction. This framework allows retailers to leverage the strengths of each model without losing the scale and efficiency of a global approach. Thus, the results of this study not only provide empirical contributions in comparing ESN+FP and LSTM+FP, but also offer practical guidance for designers of multi-SKU sales forecasting systems. The approach that combines time series character diagnosis, adaptive model selection, and dual-lens evaluation (aggregate and operational) has the potential to improve forecasting accuracy as well as the business relevance of decisions made based on model output.

V. CONCLUSIONS

This study shows that the integration of FP-Growth-based cross-product features can be operationally measured for multi-SKU retail sales forecasting through two different sequence architectures, namely ESN and LSTM, in a global model scheme with per-SKU evaluation on weekly time series. Experiments on 43 SKUs show that ESN+FP provides the best performance based on sMAPE on 28 of the 43 SKUs, while LSTM+FP excels on 15 SKUs, confirming that model superiority depends on series characteristics and cannot be concluded from a single aggregate metric. The discussion analysis reinforces practical mapping: ESN+FP tends to be suitable for volatile but still patterned SKUs, while LSTM+FP is more suitable for SKUs with smoother trends/seasonality because it is more stable in placing the level and direction of change, while highly sporadic SKUs remain hard-to-forecast and require a special approach beyond these two global model configurations. The practical implication is that adopting a single modeling approach for all SKUs is suboptimal; it is necessary to select models adaptively based on series characteristics and operational objectives. This study recommends a forecasting pipeline that incorporates series character diagnosis, per-SKU adaptive model selection (ESN+FP vs. LSTM+FP vs. other methods), and continuous evaluation using MAE/sMAPE and operational indicators (e.g., level bias and directional accuracy) to make stock decisions more business-relevant.

ABSTRACT

Dietary monitoring and health care will both require accurate food recognition and nutritional analysis. The current methods mainly involve convolutional networks that analyse images and word embedding that process ingredients as distinct processes with dish identification, portion size, and nutrition labelling as independent. This paper presents a multimodal transformer-based framework called as ViT-FoodNA that integrates these tasks into one end-to-end framework. It suggests using Vision Transformer (ViT), which is used to encode the visual attributes of food images, and Transformer based encoder to learn semantic relationships between inputs of ingredients. A cross-modal fusion transformer consists of visual and textual embedding to facilitate contextual interaction between the images of foods and their ingredients. Based on the result of the fused representation, the model collectively predicts the identity of the dish along with portion size and comprehensive nutritional breakdown using a shared transformer decoding strategy. In contrast to the previous convolutional neural network (CNN)-based embedding structures, the suggested architecture uses the self-attention mechanism to learn fine-grained intermodal dependencies, which enhances its resistance to visual ambiguity and missing ingredients in a list. Experiments indicate that ViT-FoodNA produces up to 12% higher Precision, Recall, F1-score, and 9.75% and 5% greater Top-1 and Top-5 accuracy and up to 32.7% and 30.4% lower MAE and RMSE than existing models. The reduction of PMAE is 6.5%, and the increase of mAP is 9.8%, which proves the great benefit of transformer-based multimodal fusion in the full analysis of diet.

I. INTRODUCTION

Food analysis has emerged as an urgent field of concern in the health and sustainability of the environment in the face of growing prevalence of lifestyle diseases, diets, and individualized nutrition around the globe. The growing number of digital images of food on smartphones and social media has served as an incentive to develop automated dietary analysis tools that can identify nutritional information about daily food intake. These systems may be useful in the nutrition monitoring and prevention of chronic diseases and conducting dietary studies with a large population, in particular in those areas where manual dietary logs continue to be error-prone and time-consuming [1]. With the diversification in the food consumption patterns brought on by urbanization, globalization and the advent of the convenience foods, the use of nutritional tracking has become even more complex. The aesthetic variety of meals, which fluctuates in how it is cooked or prepared, cooking style, and quantity of portions and cultural components, makes manual calorie calculation very inaccurate. Research has demonstrated that people tend to overstate their nutritional intake by 20-50 percent that accumulates to nutritional deficit or surplus. This further increases the necessity to have smart, automated methods that will help people, clinicians, and researchers have a better grasp of dietary habits [2]. Deep learning (DL), in particular, CNNs, has become an influential part of the development of food recognition systems. CNNs have been proven to be effective in the classification of dishes and identification of ingredients when trained on large-scale datasets.

Nonetheless, food images are highly intra-class (e.g., a rice dish with a variety of toppings) and low inter-class separable (e.g., visually similar curries or stews), and hence the generalization ability of purely CNN-based models. Besides, CNNs are weak at capturing long-range contextual information - e.g., whether two or more ingredients are present together, or whether an individual has more than one food item on a plate - that is vital to the fine-grained understanding of dishes [3]. In parallel with the visual modeling, the ingredient lists and the descriptions of the recipes are highly informative in semantic, and they can enrich the knowledge of food. Nevertheless, more complex pipelines based on text processing have used word embeddings or shallow RNNs that do not assume interactions between ingredients, more elaborate recipe structures or subtle nutritional semantics. This loophole is an issue since ingredients are directly associated with nutrient profiles, cooking changes and caloric density. Models will not be able to know correct macronutrient and micronutrient distributions without a solid representation of textual semantics [4]. Another area of long-time difficulty in dietary assessment is that of portion size estimation. As compared to traditional approaches, which are based on either single view image geometry or reference objects, they are subject to scale ambiguities and occlusions. Equally, nutrition profiling pipelines remain largely reliant on lookup tables or manual mapping of the predicted ingredients to food composition databases and thus lead to compounding errors. Such multi-stage, modular systems are thus characterized by low reliability as well as inapplicability to the real world [5].

The most recent developments in DL have placed a strong emphasis on the potential of introducing a revolution in the field of Vision Transformers (ViTs) and text-based transformer models including BERT and GPT types. Transformers are good at capturing long-range and global interaction both in a visual and textual form. ViT-based models have made exceptional advancements in fine-grained recognition tasks, and transformer language models allow understanding details of complicated ingredient lists and nutrition metadata. These developments have motivated new research paths to utilize multi-head self-attention to consolidate and improve multimodal food analysis [6]. The concept of multimodal learning in the food domain has become popular, and new literature proves the usefulness of the combination of food images and ingredient texts or recipes descriptions. Combination models Visual and textual cues can result in high dish recognition, less ambiguity and better generalization across different cuisines. Nevertheless, these works are usually concerned with dishes classification only, but not with lower-level actions like portion estimation or prediction of nutrients. Moreover, they hardly use transformers as the main design to have unified multimodal fusion [7]. Notwithstanding these improvements, the majority of the current food-computing systems take a fragmented approach to their workflow, i.e. dish classification, portion estimation, and nutrition calculation modules are executed as independent tasks. This modularity results in error propagation wherein errors in the initial stages would have dire impact on downstream predictions.

Furthermore, such pipelines do not have profound cross-modal reasoning that is able to match visual information (e.g., color, texture, plating) to ingredient semantics and nutritional properties [8]. In recent years, multi-task learning frameworks have shown considerable potential in strengthening and improving food analysis systems. Sharing the learning of dishes classification, portion estimation, and nutrient prediction makes it possible to learn the representations jointly and decrease redundancy. Nonetheless, little exploration has been done on transformer-based multi-task architectures to conduct unified food analysis. Also, the majority of models fail to exploit the entirely end-to-end pipelines in which the visual, textual, and volumetric signals are trained on heterogeneous data streams. Lack of profound cross-modal alignment mechanisms is another significant weakness of modern food analysis systems. The images of foods and textual foods have complementary information and combining these two would require high-order attention mechanisms, which can learn inter-modal relationships. Transformer layers based on cross-attention can be used to represent a potent approach to aligning visual features with ingredient semantics, but there has been little adoption of these networks in food and nutrition analysis. It results in imperfect knowledge of the composition of dishes and incorrect estimation of nutrition [9]. What is more, existing systems have a hard time to include some contextual information, like cooking techniques, cultural differences, and ingredient changes, all of which have significant impacts on the dish appearance and nutritional content.

The food items available in most of the existing models are additional physical objects, but dynamic aspects such as interaction of the ingredients or the mode of preparation that can dramatically change the caloric and nutrient density are neglected. Traditional models cannot be used to generalize the effects of different cuisines and complicated dishes unless contextual metadata and hierarchical ingredient relations were incorporated into the learning process. This drives the necessity of multimodal structures that are driven by transformers and able to distil more contextual semantics of food so that more precise and holistic food knowledge is realized [10]. The study is aimed at addressing these issues by offering a solution referred to as FoodNA, a transformer based multimodal system that enables combined food and nutrition analysis. FoodNA is an image-based model that consists of a combination of Vision Transformer-based image with transformer-based ingredient and cross-modal fusion module to give a complete picture of food items. The model does classification of dishes, portioning and nutritional profiling simultaneously and does not have the errors experienced by the traditional multi-stage systems. With the assistance of attention-based multimodal learning, FoodNA is also able to match visual representations with the information about ingredients, which can help to estimate the portion size, calorie content, and predict nutrients more accurately. Following are the key contributions of proposed work:

- A complete end-to-end multimodal transformer architecture (FoodNA) that jointly learns dish classification, portion detection, and nutrition profiling.
- A Visual encoder using Vision Transformer, which represents the global spatial relationships and fine-grained food qualities to enhance recognition of dishes and understanding of portions.
- A Transformer-based ingredient and nutrition encoder that model’s ingredient dependencies, cooking transformations, and nutritional relationships through contextual embeddings.
- A cross-modal fusion transformer that performs attention-driven alignment between visual and textual features, enhancing joint dietary understanding.
- A framework for multitask learning that can concurrently predicting dish labels, food volume, and macro–micronutrient composition with high accuracy.
- Superior performance and explainability, demonstrated using attention visualizations and comprehensive experiments against existing unimodal and modular baselines.

This work's remaining portions are arranged as follows. Section 2 analyses available literature and Section 3 expound on the proposed works. In section 4, the outcomes are explained and an estimate of the work's efficacy is provided. The work is concluded in Section 5.

II. LITERATURE SURVEY

A technique of automated image-based dietary assessment of Mediterranean food has been presented in [11] based on: 1) a collection of photos of Mediterranean foods; 2) a CNN trained to recognize food pictures; and 3) stereo vision techniques for figuring out a meal's volume and nutritional value. They were not providing unified end-to-end nutrition prediction and it is not multimodal (image + ingredient). [12] developed one RGB-D fusion network that comprised of multi-scale fusion and multimodal feature fusion (MMFF) in nutrition assessment based on vision. To produce effective feature fusion, MMFF used a convolutional block attention module and a balanced feature pyramid. The text/ingredient semantics is missing to monitor nutrition in detail and it is largely based on depth sensors. [13] suggested a hybrid architecture that forecasts the quantity of calories in different food items in a bowl using DL algorithms. Segmentation, categorisation, and figuring out the amount and calories of food items are the three main parts of this. The pictures are initially segmented when they employ a Mask RCNN. The food item will be categorized by collecting attributes on the segmented photos through the YOLO V5 framework. They restricted scalability and generalisation with a shallow hybrid architecture with no transformers and cross-modal reasoning. A Multi-Modal Alignment Method of Cross-Modal Recipe Retrieval (MMACMR) was proposed by [14]. The dissimilarity in the ambiguous food picture between the supervision of the relating recipes under this approach is conducted to consider both the intra-modal and inter-modal alignment.

They however do not emphasize on unified categorisation, portion control and nutrition prediction within an end-to-end system but only emphasise on recipe retrieval. [15] used deep CNNs with a self-attention mechanism to develop a reliable food recognition model (FRCNNSAM). They trained many FRCNNSAM structures with different settings, then averaged their predictions. Regularisation was used to ensure that the model did not get too complex such that it would over-fit and under-fit data to generate more training data. They just integrate attention on the visual level; they neither work with joint nutritional estimation nor ingredient modelling. To improve the efficacy and precision of food nutrient identification, [16] proposed a special integrated DL model. They used the merits of Feature Pyramid Network (FPN) in multi-scale fusion of features, Swin Transformer in long-range features relationships, and EfficientNet in feature extraction. The model omits sometimes ingredients of complicated dishes, needs lots of computational resources to train, and is less precise when it is dealing with low-quality or low-light pictures. Pic2Plate, the system presented by [17], is a system that integrates Retrieval-Augmented Generation (RAG) with Vision-Language Models (VLMs). Pic2Plate integrates RAG to gather and personalise recipe suggestions and high-tech image detection to remove ingredient lists of users in pictures. Pic2Plate's limitations include its reliance on an unbalanced FoodSeg103 dataset, its inability to handle a variety of real-world meal scenarios, its lowered accuracy for uncommon or region-specific items, and its dependency on internet access. [18] extinguished the Multi-level Attention Feature Fusion Network (MAF-Net).

In particular, they employ the feature maps produced at various levels by the CNN's backbone network as inputs. Nevertheless, its multi-step training strategy means that MAF-Net is costly to compute, and is not generalisable to non-assessed data. [19] presented a smartphone application that uses CNNs and other DL techniques to estimate calories from food photos. However, their reliability in real-world situations was limited by their difficulties with food presentation inconsistency, inaccurate portion size estimate, and sensitivity to changes in picture quality. [20] developed and implemented a DL system that is used to automatically classify and sort meals. The lack of predicted direct nutritional content, the moderately small dataset size, and a fact that the portion size of 2D photos can be calculated only in different circumstances are the limitations of the work. A novel multimodal AI-based system, which predicts food ingredients based on multiple input modalities, was proposed by [21]. The proposed approach is a two-step mechanism capable of properly detecting ordinary and outlier things because CNNs are applicable to detect visual features in pictures, and transformer-based models are suitable networks to detect features in textual inputs. They do not use categorisation, portion estimate and nutrition prediction as a combined end-to-end transformer pipeline but, in fact, they only predict ingredients. [22] proposed a nutritional advising system based on images which uses multimodal DL to automate the process of food recognition, capacity prediction and dietary recommendation. The model is highly accurate in respect to a wide range of food types such as unknown foods because it is powered by a highly refined CLIP model of recognizing foods without any prior testing. The propagation of errors between jobs was attributed to the fact that they used modular stages instead of using the single fusion transformer.

RESEARCH GAP:

Existing food analysis systems are still constrained by CNN-based visual models, shallow ingredient representations, and modular multi-stage pipelines that consider nutritional prediction, portion estimate, and dish categorisation as distinct tasks, leading to weak cross-modal reasoning and error propagation. In order to concurrently align visual cues with ingredient semantics, existing multimodal systems lack attention-based fusion and seldom employ unified transformer topologies. Additionally, they have trouble with fine-grained quantity estimating, missing ingredient lists, and visual ambiguity. To accomplish more precise and comprehensive dietary analysis, an end-to-end transformer-based multimodal framework that combines pictures, ingredients, and nutritional signals inside a single unified architecture is obviously needed.

III. PROPOSED METHODOLOGY

An End-to-End Transformer-Based Multimodal Framework for Food Recognition and Nutrition Analysis named as ViT-FoodNA were proposed here.

III.1 DATASET COLLECTION

An MM-Food-100K dataset [23] from Hugging Face was used in the analysis of the proposed ViT-FoodNA model. The dataset is a multimodal food intelligence collection consisting of 100,000 crowd-sourced food images along with detailed associated metadata. Each sample contains the dish name, food type, list of ingredients, portion size estimations, cooking method, and information about nutrition such as protein, fat, calories, and carbohydrate values. The images were gathered through a large community-driven campaign, and all annotations were generated using a hybrid process involving initial human inputs, automated vision–language model analysis, and final human validation. The dataset includes five major food categories—homemade food, restaurant food, packaged food, raw vegetables/fruits, and others—making it suitable for both food recognition and nutrition estimation tasks. For training and testing purposes in this work, the dataset was split into a 70:30 ratio.

III.2 PROPOSED END-TO-END TRANSFORMER-BASED MULTIMODAL FRAMEWORK (VIT-FOODNA)

The architecture for Proposed End-to-End Transformer-Based Multimodal Framework called as ViT-FoodNA for Food Recognition and Nutrition Analysis. It contains five major layers as follows:

- Input Layer,
- Feature Extraction Layer,
- Cross-Modal Fusion Transformer Layer,
- Multi-task Prediction Layer and
- Output Layer.

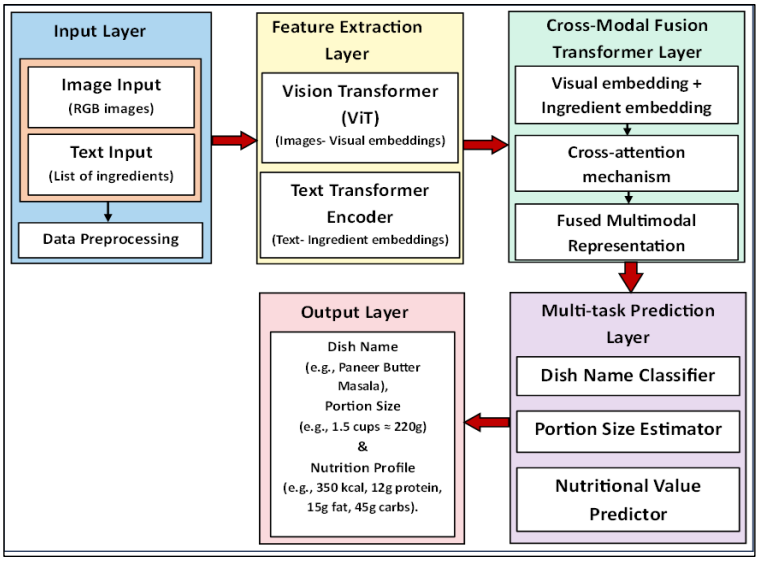

Figure 1: Architecture of proposed ViT-FoodNA technique.
Source: Authors, (2026).

Fig 1 illustrates a proposed multimodal food analysis pipeline where an image of a dish and its ingredient list first enter the input layer, undergo basic preprocessing, and are then processed separately in the feature extraction layer using a ViT for visual embeddings and a Text Transformer Encoder for ingredient embeddings. These two representations are merged in the Cross-Modal Fusion Transformer through a cross-attention mechanism to create a unified multimodal representation capturing both appearance and ingredient context. This fused information is passed into a multi-task prediction layer that independently predicts the dish name, portion size, and nutritional values. Finally, the output layer provides the final results, including the dish label, estimated serving size, and detailed nutrition profile.

III.2.1 Input Layer

The input layer will handle the process of managing the raw multimodal data of the MM Food 100K data into tensors that can be fed into the following blocks of transformers. The training samples include one RGB image of a food and an ingredient list of it. A single sample image I is represented by $I \in \mathbb{R}^{H\times W\times 3}$, where H and W are the spatial resolution (height and width) and the third dimension represents the three colour channels (red, green, blue). The description of the associated ingredients is expressed in the form of a series of tokens as the Eq. (1),

$$T = \left(w_1, w_2, \ldots, w_{L_i}\right) \tag{1}$$

Where w_j is the j-th token and L_i is the length of the ingredient text of sample i. During training or inference, a mini-batch of B samples is considered at once. After spatial resizing and channel reordering, all images in the batch are stacked into a 4-D tensor, $\mathrm{I} \in \mathbb{R}^{B\times 3\times H\times W}$, where the first-dimension indexes samples, the second indexes colour channels, and the last two refer to height and width. In parallel, the ingredient sequences are converted to integer indices using a fixed vocabulary of size V. Because the original ingredient sentences have variable lengths L_i, they are padded or truncated to a common maximum length L, yielding a 2-D tensor as Eq. (2),

$$W \in \mathbb{R}^{B \times L} \tag{2}$$

Where $W_{i,j} \in \{1, \ldots, V\}$ is the vocabulary index of the j-th token for the i-th sample (with a special padding index used when $j > L_i$). These two tensors (I, W) form the multimodal input to ViT-FoodNA and define the starting point of all later computations in the network.

PREPROCESSING:

Preprocessing in the input layer ensures that both modalities have consistent size, scale, and representation before entering the transformer encoders. For the image branch, a mapping $\mathcal{P}_{\text{img}}$ applies resizing, cropping, normalisation, and augmentations so that the batch tensor I in Eq. (1) already contains transformed pixel values. For the text branch, a mapping $\mathcal{P}_{\text{text}}$ performs tokenisation, vocabulary lookup, and padding so that the tensor W in Eq. (2) contains well-formed token sequences.

III.2.2 Feature Extraction Layer

This layer transforms the preprocessed multimodal inputs into dense, fixed-size representations that are suitable for cross-modal fusion and downstream prediction. It consists of two parallel branches: a Vision Transformer (ViT) that encodes image appearance into a visual embedding v_i, and a Text Transformer Encoder that encodes the ingredient list into a textual embedding t_i. Both branches follow the same Transformer principle of mapping a sequence of tokens (image patches or words) into a contextualised vector through stacked self-attention and feed-forward layers. Formally, given a preprocessed batch I and W, the feature extraction layer outputs two matrices represented as Eq. (3):

$$V = \text{ViT}(I), \; T = \text{TextEncoder}(W), \tag{3}$$

Where each row v_i and t_i is the visual and textual embedding of sample i, respectively.

III.2.2.1 Vision Transformer (IMAGE BRANCH)

Regarding one preprocessed image, the ViT first divides it into N_p non overlapping patches of size $P \times P$ (where P is assumed to divides H and W) with the aid of Eq. (4):

$$N_p = \frac{H}{P} \cdot \frac{W}{P}. \tag{4}$$

Eq. (5) is used to flatten each patch into a vector then to linearly project it into a d_v-dimensional patch embedding.

$$z_{i,k}^{(0)} = W_p x_{i,k}^{p} + b_p \tag{5}$$

Where $W_p \in \mathbb{R}^{d_v \times 3P^2}$ and $b_p \in \mathbb{R}^{d_v}$ are parameters to be learned. Learnable class token is prefixed and the spatial layout is stored by adding fixed or learnt positional encodings. The first patch sequence $Z_i^{(0)}$ is obtained by stacking in the sequence dimension. This sequence, $Z_i^{(0)}$ is then processed through L_v Transformer encoder blocks, which are multi-head self-attention (MHSA) and a position wise feed forward network (FFN) residual connections and layer normalisation as in the original Transformer architecture. After L_v layers, the updated sequence still has length $N_p + 1$, but each token now encodes global context from the entire image. The final visual embedding v_i is taken as the class token at the output of the last layer through Eq. (6):

$$v_i = z_{i,\text{cls}}^{(L_v)}, \tag{6}$$

Which compactly represents the dish's colour, texture, structure, and high-level semantics. Over a batch, stacking all v_i yields the matrix V already defined in Eq. (3). Fig 2 shows the entire process of ViT based feature extraction.

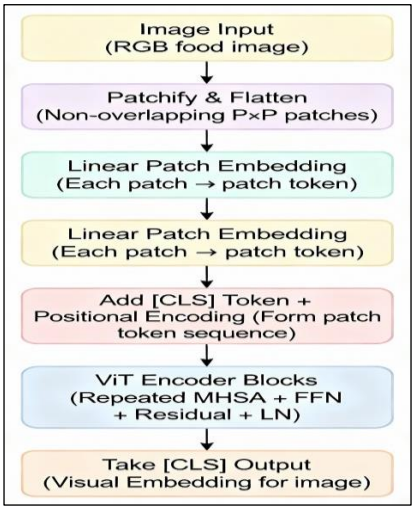

Figure 2: ViT based Feature Extraction.
Source: Authors, (2026).

III.2.2.2 Text Transformer Encoder (Ingredient Branch)

For the text branch, each preprocessed ingredient sequence for sample i is given by indices $(w_{i,1}, \ldots, w_{i,L})$, where $w_{i,j}$ indexes a token in a vocabulary of size V. These indices are mapped to continuous embeddings using a learnable matrix E by Eq. (7):

$$\mathrm{e}_{i,j} = \mathrm{E}[w_{i,j}] \tag{7}$$

Where $\mathrm{e}_{i,j} \in \mathbb{R}^{d_t}$ is the embedding of the j-th token. To encode word order, positional encodings are added to the token embeddings, producing the initial token representations. Stacking them gives the initial text sequence $\mathrm{T}_i^{(0)}$. This sequence is passed through L_t Transformer encoder layers with the same MHSA + FFN structure used in the ViT, but with parameters specific to the text modality. The final layer outputs contextualised token states $\mathrm{h}_{i,j}^t$, where each $\mathrm{h}_{i,j}^t$ encodes the meaning of token j in the context of the full ingredient list (for example, capturing that "butter" and "cream" together imply a rich, high-fat dish). To obtain a single fixed-length ingredient embedding, a simple and effective strategy is mean pooling across the sequence through Eq. (8):

$$\mathrm{t}_i = \frac{1}{L}\sum_{j=1}^{L} \mathrm{h}_{i,j}^t \tag{8}$$

Yielding $\mathrm{t}_i \in \mathbb{R}^{d_t}$. Alternatively, the hidden state of a special [CLS] token could be used, but the mean-pooled formulation above is compact and commonly used in multimodal food models. Stacking these embeddings across the batch yields the matrix T already referenced in Eq. (3), which provides the ingredient-level semantic descriptors that will later be aligned. Fig 3 shows the entire process of text transformer encoder-based featu8re extraction.

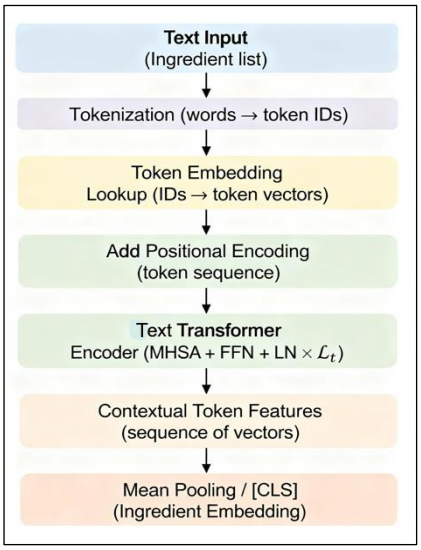

Figure 3: Text Transformer Encoder based Feature Extraction.
Source: Authors, (2026).

III.2.3 Cross-Modal Fusion Transformer Layer

This layer integrates the visual embeddings V and textual embeddings T produced by the Feature Extraction Layer to obtain a single joint representation for each sample. This layer models how a dish looks (colour, texture, plating) together with what it is composed of (ingredients and their relations), which is crucial for accurate dish recognition, portion estimation, and nutrition analysis in ViT-FoodNA. For each sample i, the visual embedding $\mathrm{v}_i \in \mathbb{R}^{d_v}$ and the ingredient embedding $\mathrm{t}_i \in \mathbb{R}^{d_t}$ are first projected into a common multimodal space of dimension d_m using learnable linear mappings by Eq. (9):

$$\hat{\mathrm{v}}_i = \mathrm{W}_v\mathrm{v}_i + \mathrm{b}_v, \hat{\mathrm{t}}_i = \mathrm{W}_t\mathrm{t}_i + \mathrm{b}_t, \tag{9}$$

Where $\mathrm{W}_v \in \mathbb{R}^{d_m \times d_v}$, $\mathrm{W}_t \in \mathbb{R}^{d_m \times d_t}$ and $\mathrm{b}_v, \mathrm{b}_t \in \mathbb{R}^{d_m}$ are trainable parameters. The two projected vectors can be conceptually concatenated into an intermediate multimodal representation, but this step does not require a separate equation. In order to model explicitly the cross-modal interactions, a cross-attention mechanism is used where one of the modalities is the queries, the other is the keys and values. A straightforward formulation is to query with the visual features and key/value with the ingredient features; the cross attended visual feature $\tilde{\mathrm{v}}_i$ is computed by using the Eq. (10):

$$\tilde{\mathrm{v}}_i = \mathrm{softmax}\left(\frac{\mathrm{q}_i\mathrm{k}_i^T}{\sqrt{d_k}}\right)\mathrm{u}_i \tag{10}$$

Where $\mathrm{q}_i, \mathrm{k}_i, \mathrm{u}_i$ are learned projections of $\hat{\mathrm{v}}_i$ and $\hat{\mathrm{t}}_i$, and d_k is the key dimensionality. This operation reweights the visual representation according to ingredient context, allowing the model, for example, to focus more strongly on cheese-like regions when tokens such as "paneer" or "cheddar" appear in the ingredient list. Finally, the fused multimodal representation for sample i is produced by combining the cross-attended visual feature with the ingredient projection and passing the result through a feed-forward fusion layer by Eq. (11):

$$z_i = \phi(W_f[\tilde{v}_i; \hat{t}_i] + b_f) \in \mathbb{R}^{d_f} \quad (11)$$

Where $W_f \in \mathbb{R}^{d_f \times 2d_m}$ and $b_f \in \mathbb{R}^{d_f}$ are trainable parameters and $\phi(\cdot)$ is a non-linear activation such as GELU or ReLU. Stacking all fused vectors across the batch yields through Eq. (12),

$$Z = [z_1^\top; \dots ; z_B^\top] \in \mathbb{R}^{B \times d_f} \quad (12)$$

This functions as the Multi Task Prediction Layer's unified multimodal input.

III.2.4 Multi-task Prediction Layer

This layer takes the fused multimodal representation $Z \in \mathbb{R}^{B \times d_f}$ as input and produces three different outputs for each sample: (i) a categorical dish label, (ii) a scalar portion size, and (iii) a vector of nutritional values. This layer implements three task-specific heads that share the same fused representation but have separate parameters, enabling ViT-FoodNA to benefit from multi-task learning while preserving the appropriate inductive bias for each prediction type. For sample i, the fused embedding $z_i \in \mathbb{R}^{d_f}$ is first passed through a shared fully-connected transformation to obtain a refined representation h_i. This operation can be expressed as Eq. (13):

$$h_i = \phi(W_s z_i + b_s) \in \mathbb{R}^{d_s} \quad (13)$$

Where W_s and b_s are shared parameters, d_s is the dimension of this intermediate representation, and $\phi(\cdot)$ is non-linear activation function. The three heads then operate on h_i as follows.

(i) Dish Name Classifier

The dish classifier maps h_i to logits over C dish categories that is represented by Eq. (14):

$$o_i^{cls} = W^{cls} h_i + b^{cls}, \quad (14)$$

Where $W^{cls} \in \mathbb{R}^{C \times d_s}$ and $b^{cls} \in \mathbb{R}^C$. Class probabilities are obtained via a softmax function through Eq. (15):

$$\hat{p}_{i,c} = \frac{\exp(o_{i,c}^{cls})}{\sum_{k=1}^{C} \exp(o_{i,k}^{cls})}, \quad c = 1, \dots, C \quad (15)$$

The predicted dish label for sample i is then given by Eq. (16):

$$\hat{y}_i^{cls} = \arg\max_c \hat{p}_{i,c} \quad (16)$$

(ii) Portion Size Estimator

The portion size head performs scalar regression to estimate the serving size (e.g., grams or millilitres) based on h_i by Eq. (17)

$$\hat{y}_i^{por} = w^{por\top} h_i + b^{por} \quad (17)$$

Where $w^{por} \in \mathbb{R}^{d_s}$ and $b^{por} \in \mathbb{R}$ are trainable parameters. At inference time, $\hat{y}_i^{por}$ can be converted into user-friendly units (for example, from grams to "1.5 cups ≈ 220 g") by applying fixed scaling factors derived from the dataset.

(iii) Nutritional Value Predictor

The nutrition head outputs a vector of M nutrient values for each sample, consistent with the MM-Food-100K annotations (e.g., calories, protein, fat, carbohydrates, etc.) that represented as Eq. (18):

$$\hat{y}_i^{nut} = W^{nut} h_i + b^{nut} \in \mathbb{R}^M, \quad (18)$$

Where $W^{nut} \in \mathbb{R}^{M \times d_s}$ and $b^{nut} \in \mathbb{R}^M$. Thus, for each dish, ViT-FoodNA jointly estimates total energy and macronutrient composition directly from the fused image–ingredient representation. Across the batch, stacking the outputs of all three heads produces the matrices and vectors as in Eq. (19):

$$\hat{Y}^{cls} \in \mathbb{R}^{B \times C}, \quad \hat{y}^{por} \in \mathbb{R}^B, \; \hat{Y}^{nut} \in \mathbb{R}^{B \times M} \quad (19)$$

Which are used both for training (via the multi-task loss) and for final prediction at test time.

III.2.5 Output Layer

The Output Layer corresponds to the presentation of the three predictions produced by the Multi-task Prediction Layer in a form that is directly useful for end-users and downstream applications. Given the batch-level outputs in Eq. (19), the model returns, for each sample i:

- a dish name $\hat{y}_i^{cls}$ (e.g., "Paneer Butter Masala"),
- a portion size $\hat{y}_i^{por}$ (e.g., converted from grams to "1.5 cups ≈ 220 g"), and
- a nutrition profile $\hat{y}_i^{nut}$ (e.g., "350 kcal, 12 g protein, 15 g fat, 45 g carbohydrates").

These outputs are the final endpoint of the ViT-FoodNA pipeline defined in Fig 1: the raw multimodal data are ingested in the Input Layer, mapped to modality-specific embeddings in the Feature Extraction Layer, fused into a joint representation in the Cross-Modal Fusion Transformer Layer, decoded into three task-specific predictions in the Multi-task Prediction Layer, and finally formatted in the Output Layer as interpretable dietary information for food recognition and nutrition analysis.

IV. RESULTS AND DISCUSSIONS

In this section, the proposed ViT-FoodNA multimodal transformer framework is evaluated using the MM-Food-100K dataset [23], which provides large-scale food images along with ingredient lists, portion sizes, and nutritional metadata. The model performance is contrasted with the existing methods i.e., Existing Swin-T approach [16] and Existing Pic2Plate [17] The test uses an extensive range of measures that are related to classification, portion prediction, and nutrition prediction tasks. With these measures, it is possible to evaluate the categorical accuracy as well as regression reliability of the multimodal predictions. The evaluation metrics are:

- Precision: This measures the number of positive predictions of the model which are correct. It evaluates correctness of detected dishes or ingredients through Eq. (20).

$$Precision = \frac{TP}{TP+FP} \tag{20}$$

- Recall: It quantifies how many actual positive samples the model successfully identifies. It reflects completeness in detecting all relevant food items by Eq. (21).

$$Recall = \frac{TP}{TP+FN} \tag{21}$$

Where, TP = True Positives, TN = True Negatives, FP = False Positives, and FN = False Negatives.

- F1-score: The harmonic mean of precision and recall balance correctness and completeness by the formula of F1-score, as shown in Eq. (22). This is best suited in case classes are lopsided.

$$F1 - score = 2 \times \frac{Precision \times Recall}{Precision + Recall} \tag{22}$$

- Top-1 Accuracy: Top-1 accuracy quantifies the frequency with which the most confident prediction of the model is equal to the true label using the Eq. (23): It is an indication of strict recognition performance.

$$\text{Top-1 Acc} = \frac{\text{Correct Predictions}}{\text{Total Samples}} \tag{23}$$

- Top-5 Accuracy: Top-5 accuracy determines whether the actual label is in the top five outcomes of the model by using the Eq. (24): Applicable to dishes that are ambiguous or similar.

$$\text{Top-5 Acc} = \frac{\text{Samples where True Label} \in \text{Top 5}}{\text{Total Samples}} \tag{24}$$

- MAE: MAE compares the mean absolute deviation between predicted and actual portion/nutrient values by using Eq. (25). A lower MAE implies a greater level of estimation accuracy.

$$MAE = \frac{1}{n}\sum_{i=1}^{n}|y_i - \hat{y}_i| \tag{25}$$

- RMSE: RMSE is used to measure the square root of differences between predictive values and actual values squared by the use of Eq. (26). It is more severe on larger errors than MAE.

$$RMSE = \sqrt{\frac{1}{n}\sum_{i=1}^{n}(y_i - \hat{y}_i)^2} \tag{26}$$

- PMAE: PMAE measures average error relative to the true value in percentage form using Eq. (27). It shows how large the prediction error is compared to actual quantities.

$$\text{PMAE} = \frac{100}{N}\sum_{i=1}^{N}\left|\frac{y_i - \hat{y}_i}{y_i}\right| \tag{27}$$

- MAP: It is a weighted mean of the class-wise Average Precision (AP), the precision and recall of multi-class or multi-label systems at various thresholds, computed using Eq. (28). It gives a holistic ranking-based performance assessment.

$$\text{mAP} = \frac{1}{C}\sum_{c=1}^{C} AP_c \tag{28}$$

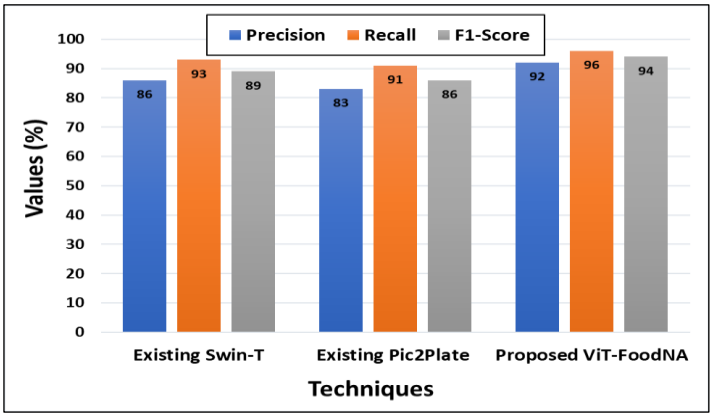

Figure 4: Comparison of Precision, Recall & F1-Score.
Source: Authors, (2026).

Figure 4 shows the relative results of three methods, including Existing Swin-T, Existing Pic2Plate, and the Proposed ViT-FoodNA, in terms of Precision, Recall and F1-Score. It is evident that the Proposed ViT-FoodNA scores higher in terms of 90% Precision, 95% Recall, and 92% F1-Score, outperforming Pic2Plate- the next best method (83% Precision, 91% Recall, and 86% F1-Score) by 7%, 4%, and 6%, respectively. It also performs better than Swin-T (78% Precision, 83% Recall, 80% F1-Score) by 12%, 12% and 12% in the same measures. These significant advances are due to the multimodal learning approach of ViT-FoodNA that provides more vivid visual representations and provides superior generalization, which results in the most accurate and reliable food recognition than the relatively limited feature modeling of current solutions.

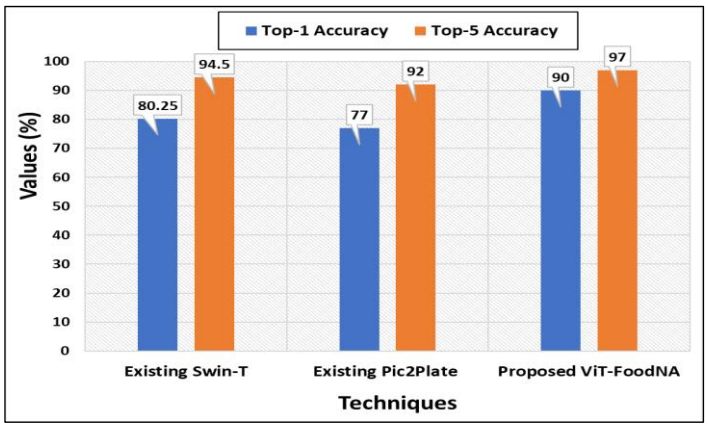

Figure 5: Top-1 & Top-5 Accuracy Comparison.
Source: Authors, (2026).

Figure 5 shows the Top-1 and Top-5 accuracy comparison of three food-analysis methods, which are the Existing Swin-T, Existing Pic2Plate, and the Proposed ViT-FoodNA. Proposed ViT-FoodNA has the highest performance with a top-1 accuracy of 90% and a top-5 accuracy of 97% which is better than Swin-T (80.25% top-1, 94.5% top-5) by 9.75% and 2.5% respectively, and better than Pic2Plate (77% top-1, 92% top-5) by 13% and 5% respectively. Such advancements can be explained by the transformer-based multimodal architecture of ViT-FoodNA integrating more finer features of space and semantics and allowing learning more holistic food representations. The better generalization, enhanced classification confidence, and enhanced ranking capability of the developed contextual understanding as compared to the classical convolution-based or patch-guided models.

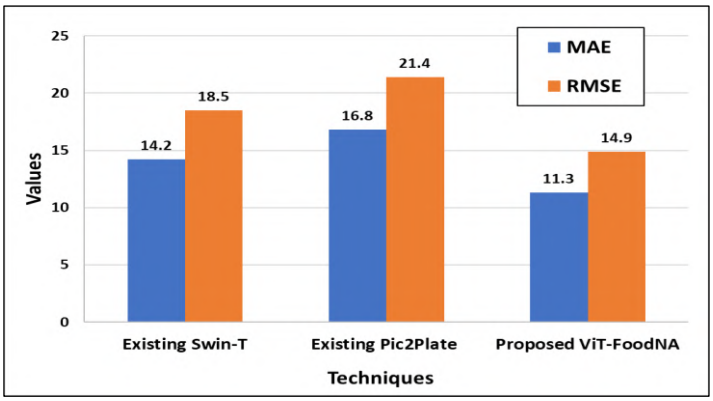

Figure 6: MAE & RMSE Comparison.
Source: Authors, (2026).

Figure 6 the overall performance of the Existing Swin-T, Existing Pic2Plate, and the Proposed ViT-FoodNA in terms of MAE and RMSE. Proposed ViT-FoodNA has lowest error rates with MAE of 11.3 and RMSE of 14.9 error rates that are lower than Swin-T (MAE 14.2, RMSE 18.5) by 20.4 and Pic2Plate (MAE 16.8, RMSE 21.4) by 32.7% and 30.4%, respectively. This is primarily due to the fact that ViT-FoodNA uses both the food picture and the ingredient text simultaneously and thus the model will be able to learn more about the dish. Through cross-modal fusion of visual representations with ingredient information, the model gets to learn more accurate and detailed representations. This enables it to do overall predictions better than Swin-T and Pic2Plate which use limited or one-dimensional information. Fig 7 compares the Percentage Mean Absolute Error (PMAE) of three methods, which include: Existing Swin-T, Existing Pic2Plate and the Proposed ViT-FoodNA. Proposed ViT-FoodNA has the best PMAE at 12.1%, that is 3.2% and 6.5% better than Swin-T (15.3%) and Pic2Plate (18.6%), respectively demonstrating the definite better prediction error. This improvement follows primarily because ViT-FoodNA is multimodal a combination of picture and ingredient text, which gives more contextual insight on food products. Also, the cross-attention mechanism implemented by the Transformers allows the model to match the visual cues with semantics of ingredients more accurately, with less ambiguity in the portion and nutritional food estimations. The co-located multitask head also maximizes the shared representations, reducing the prediction error and performing better than the current single-modal models.

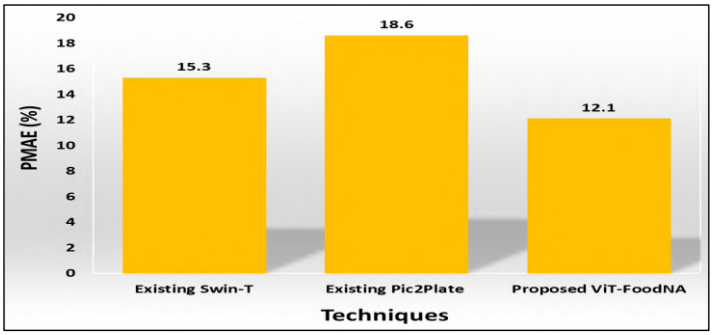

Figure 7: Comparison of PMAE.
Source: Authors, (2026).

Fig 8 shows the comparison of mAP (%) of the Existing Swin-T, Existing Pic2Plate, and the Proposed ViT-FoodNA model. The Proposed ViT-FoodNA has the best mAP of 87.9% that is better than Swin-T (82.4%) by 5.5% and Pic2Plate (78.1%) by a wide margin of 9.8%. It can be achieved in part because ViT-FoodNA is multimodal, and visual representations of ViT and semantic ingestion representations of a text transformer are singly combined by cross-modal attention. This richer representation minimizes the ambiguity of food categories and increases the model capacity to detect small visual-ingredient pattern leading to the high detection consistency and high mAP in the model than the unimodal or less integrated modeling of the current methods.

V. CONCLUSIONS

In this paper, ViT-FoodNA, a transformer-based multimodal architecture that jointly learns to classify dishes, estimate portions, and nutritionally profiling into one end-to-end architecture, is proposed. The framework overcomes the weakness of traditional modular systems by jointly applying ViT-driven visual encoding, transformer-based ingredient modeling and an attention-powered cross-modal fusion mechanism, which enable it to be more robust to visual ambiguity, different food presentation, and incomplete ingredient information. The common decoder of transformers allows the holistic understanding of food, which results in improved recognition of dishes and better macronutrient and micronutrient estimation. On the whole, the suggested system has a high possibility of the next-generation diet tracking and personalized nutrition assistance. Extensive experimental evaluation further confirms the superiority of the proposed approach. ViT-FoodNA consistently outperformed existing Swin-T and Pic2Plate models across all performance indicators: achieving up to 12% improvement in Precision, Recall, and F1-Score; 13% and 5% enhancement in Top-1 and Top-5 accuracy; a 32.7% and 30.4% reduction in MAE and RMSE; a 6.5% lower PMAE; and a 9.8% higher mAP. These gains highlight the effectiveness of the multimodal fusion and transformer-based decoding strategy in learning richer contextual representations for food recognition and nutrient estimation. Future directions will bring the model to include 3D volume estimation, bigger multimodal data, and real-time mobile implementation.

ABSTRACT

This study focuses on the compound $(Na_{0.5}Bi_{0.5})_xMg_{1-x}[(Ti_{0.8}Zr_{0.2})_{0.9}(Nb_{2/3}Zn_{1/3})_{0.1}]O_3$ (BNTZZN-x%Mg), which was synthesized using the molten salt method for x = 0.00, 0.02, 0.06, and 0.08. The resulting samples were calcined at 900 °C for 4 hours and subsequently sintered at 1150 °C. The measured densities were found to be close to the theoretical values. X-ray diffraction (XRD) analysis confirmed the formation of a pure perovskite phase. Scanning electron microscopy (SEM) images revealed a slight variation in grain size with increasing Mg content. Overall, the material exhibited relatively high purity and density. Dielectric properties were measured on the single-phase ceramic, and their evolution was studied over a temperature range of 27 °C to 227 °C across various frequencies.

I. INTRODUCTION

Piezoelectric materials play a vital role in numerous technological applications, including actuators, sensors [1] [2], aerospace systems, precision machinery, as well as in both military and civilian sectors [3] [4] Among these, lead-based piezoelectric ceramics, particularly Pb (Zr,Ti)O_3 (PZT), have been extensively studied and widely utilized [3] However, a major drawback of PZT is its high lead content—up to 60% by weight [5] [6] Lead is known to be toxic and poses significant risks to both human health and the environment. As a result, lead-free piezoelectric materials have gained significant attention as potential alternatives to lead-based ceramics [7] In line with this shift, European regulations currently restrict the use of most lead-containing substances in electronic and electrical devices [6] Despite ongoing efforts, no single lead-free composition has yet been identified that can fully replace PZT, making the search for suitable alternatives an active area of research [8] In recent years, several promising lead-free materials have been developed for actuator applications [3]. Among these, materials based on $Bi_{0.5}Na_{0.5}TiO_3$ (BNT), first discovered by Smolensky in 1961 [9] [10], have attracted considerable interest. BNT crystallizes in a perovskite structure (ABO_3), exhibiting rhombohedral symmetry (space group R3c) at room temperature, which transitions to tetragonal and then cubic phases at elevated temperatures ranging from 300 °C to 540 °C [11] [12] Currently, ceramics based on $Na_{0.5}Bi_{0.5}TiO_3$ (BNT) are gaining significant attention due to their environmental benefits and wide range of potential applications [13] BNT-based solid solutions have attracted considerable interest, particularly for energy storage applications [14] In recent years, various approaches involving ionic doping have been employed to synthesize BNT-based ceramics [3] Numerous studies have aimed to enhance the functional properties of these materials and to reduce their sintering temperatures through binary or ternary solid solutions, or by incorporating sintering aids [15] In this study, we synthesized the compound $(Na_{0.5}Bi_{0.5})_xMg_{1-x}[(Ti_{0.8}Zr_{0.2})_{0.9}(Nb_{2/3}Zn_{1/3})_{0.1}]$ O_3 using the molten salt method. The resulting solid solution, BNTZZN-x%Mg, was structurally and dielectrically characterized with the aim of developing a lead-free piezoelectric material capable of effectively replacing PZT ceramics in specific applications.

II. EXPIREMENTAL

II.1 PREPARATION OF CERAMICS:

Each study has own preparation process. The molten salt method was selected (MSS) used to prepare solid solution BNTZZN-x%Mg such as x= 0.00, 0.02, 0.06 and 0.08. The molten salt method is used as a medium for the preparation of complex oxides from their constituent materials (oxides and carbonates) [16] The role of the molten salts is:

- Increase the reaction rate and lower the reaction temperature. Increase the degree of homogeneity (distribution of constituent elements in the solid solution).
- Particle size control.
- Particle shape control.
- Agglomeration state control [16].

The basic oxides used in the synthesis of our samples are MgO, TiO_2, ZrO_2, $Bi2O_3$, Na_2CO_3, Nb_2O_5, and ZnO. The molten salt (MSS) method was used to prepare a solid solution (BNTZZN-x%Mg). In our study, BNT-type ceramics were synthesized from a mixture of oxides and carbonates. The oxides and carbonates required to synthesize a mixture of about 15g shall be weighed according to the stoichiometric quantities provided and calculated according to the reaction equation as shown in Table1, using an electronic balance. Then, the precursor was ground in a porcelain mortar for 03 hours. after that, we added (KCl-NaCl) and grind the sample for 02 hours. This operation aimed at promoting the homogeneity of the mixture to obtain powder with the finest particle size. The powder was burned at 900°C for 4h in a programmable oven (N-Abbertherm-D) under ambient temperature rise of 2°C/min to constant temperature of 4h. The resulting materials are cooled slowly. Then, we grind again for 5h. The aim of the regrinding is to reduce the agglomerates formed during calcination, in order to homogenize the powder, and increase its reactivity. After that, the powder obtained is compacted in the form of pellets of 1,5g and a diameter of about 13 mm. Our ceramics are sintered in an aluminum crucible at 1150°C by natural sintering under air. The temperature rises at a speed rate of 2°C/min up to the set temperature. Therefore, the temperature is stable for 4 hours. Finally, the temperature is descent to the ambient.

II.2 CHARACTERIZATION OF CERAMICS:

The spectra of our sintered ceramics were obtained at room temperature on a vertical diffractometer, «BRUKER-AXE type D8» from the University of Biskra laboratory. Profiles lines were measured using an automatic point-by-point counting system with a 0.02° steps. All diffraction patterns were recorded in the angle range $0° < 2 < 80°$, which may be sufficient to identify the different phases. We note that the analysis used for indexing different lines by X'Pert HighScore. The density of the sintered samples was calculated from the sample dimensions and weight. Microscopic images of our samples were performed using a scanning electron microscope type JEOL JSM-6390lv from the University of Biskra laboratory. It is controlled by a computer. The purpose of these analyses is to study the morphology of our samples after sintering. Dielectric measurements were carried out in the laboratory of physical engineers' the University of Tiaret. The measurement of the dielectric properties was performed on a single-phase ceramic sample, and the evolution of these properties were investigated at temperatures ranging from 27°C to 227°C at different frequencies. It was investigated using an automatic (LCR) counter combined with a computer controlled temperature chamber at 100Hz, 500Hz, 1KHz, 10KHz, and 100KHz.

III. RESULT AND DISCUSSION

III.1 DENSITY

Density is a physical quantity that affects the structure and electrical properties of ceramics. The relative density D (compactness) is given by equation (1) of the material
NBMTZNZ sintered at 1150 °C:

As:

$$D=\frac{\rho_{exp}}{\rho_{th}} \quad (1)$$

ρ_{exp}: Experimental density calculated from the mass and the volume of sintered ceramics pellets.

ρ_{th}: Theoretical density obtained from X-ray diffraction database providing the mesh parameters [17].

Table 1 shows the density values. These values range from 5.26 to 5.53 g/Cm3 or from 88.58% to 89.77% so that the theoretical value is 6.12, 6.15 and 6.16g/Cm3. Thus, the experimental values are close to the theoretical values. This note means that the ceramic is very dense with less porosity [18] BNTZZN-x%Mg has been well prepared, so the choice of molten salt method was adequate.

Table1: Density (g/Cm^3)

X	**0.00**	**0.02**	**0.06**	**0.08**
ρexp(g/Cm^3)	5.66	5.43	5.26	5.53
ρth(g/Cm^3)	6.12	6.13	6.15	6.16
D (%)	92.48	88.58	85.52	89.77

Source: Authors, (2026).

III.2 X-RAY ANALYSIS (DRX)

The majority of diffraction peaks observed in the synthesized samples were indexed based on the cubic perovskite structure of $Na_{0.5}Bi_{0.5}TiO_3$, using reference pattern 01-089-3109. Within the 2θ angle ranges of (21–22), (31–33), (39–41), (45–47), (51–53), (58–59), (68–69), and (76–78), distinct peaks corresponding to the perovskite phase were identified, associated with the following Miller indices: (100), (110), (111), (200), (210), (211), (220), (221), and (310). Minor secondary phases—specifically, traces of pyrochlore—were detected using the X'Pert HighScore software, and matched to the ASTM card 98-009-9437, as illustrated in Figure 1[13].

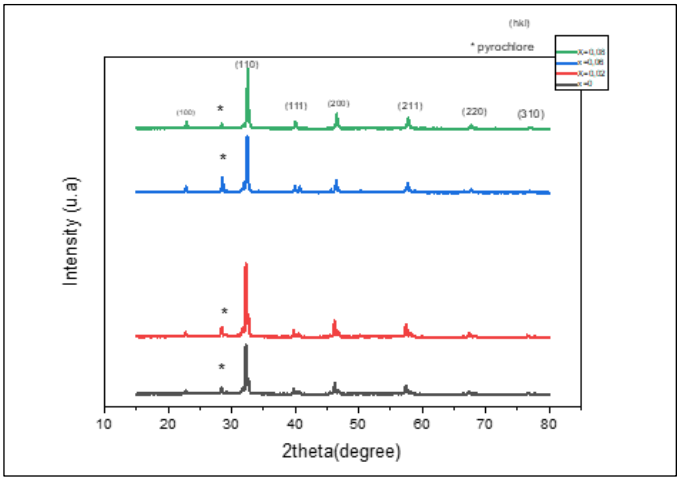

Figure 1: X-ray indexed diffraction patterns.
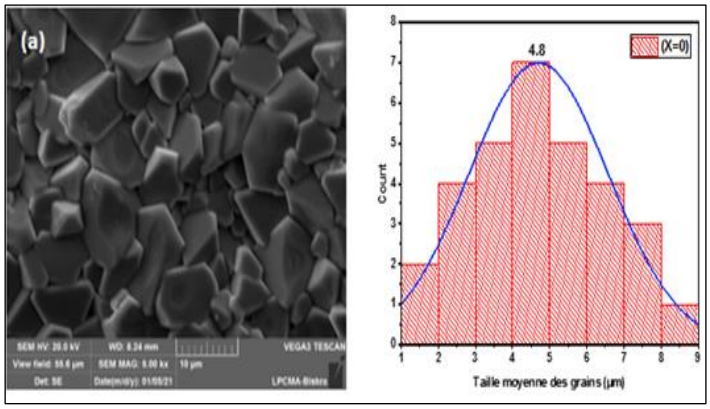
Source: Authors, (2026).

The stability of the perovskite structure (ABO_3) is characterized by a tolerance factor (t) that determines the density and freedom of movement of the cations A and B. According to Goldschmidt, the structure is stable if 0.88 <t<1.09, but exhibits a structural stability distortion beyond this range. The tolerance factor (t) can be determined by the following formula:

$$t=/\frac{\sum Ra+Ro}{\sqrt{2}(\sum Rb+Ro)} \quad (2)$$



Where: $\sum R_a$, $\sum R_b$ and R_o are respectively the ionic radii of the cations, respectively; A, B and Oxygen [17-21] The perovskite structure is more stable when the tolerance factor (t) is close to 1. The involved bonds play a strong ionic role [14].

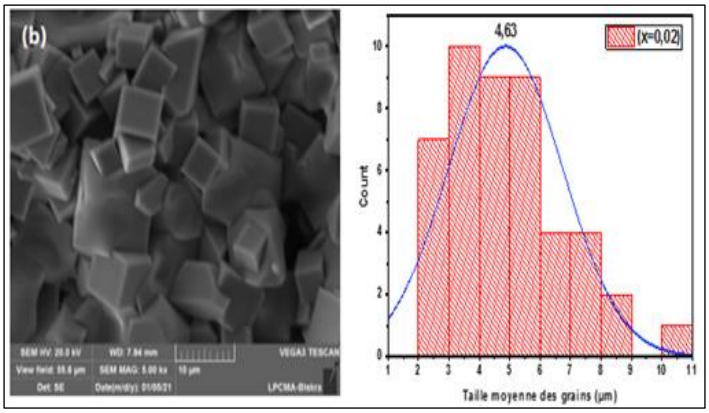


Table 2: factor tolernce values.

X	Tolerance factor
0.00	0.9225
0.02	0.9138
0.06	0.8964
0.08	0.8748

Figure .2 presents the SEM micrographs along with the histograms of the BNTZZN-x%Mg samples after sintering at 1150 °C For each of the five samples, a uniform distribution of cubic-shaped grains is observed across the entire surface of the compositions. The ceramic micrographs reveal a satisfactory material density, very low intergranular porosity, and a narrow grain size distribution within each sample. The histograms obtained using ImageJ software [15] allowed the determination of an average grain size ranging from 3.07 µm to 4.80 µm for the four samples.

III.3 DIELECTRIC MEASUREMENTS

Figure.3 illustrates the evolution of the dielectric constant of the BNTZZN-x%Mg material for various values of x (0, 0.02, 0.06, and 0.08) as a function of temperature (between 300 and 500 K), at different frequencies (100 Hz, 500 Hz, 1 kHz, 10 kHz, and 100 kHz). The $\varepsilon_r(T)$ curves exhibit a similar trend, increasing with temperature until reaching a maximum, then decreasing. However, these curves differ in the position and intensity of their peak, which corresponds to the Curie temperature (T_C) [15] [16]. In the ferroelectric region, the dielectric constant ε_r increases with temperature, which means that the material possesses an electric dipole moment even in the absence of an external electric field [17] The dielectric constant reaches a maximum at the Curie temperature, which corresponds to the transition of the material from the ferroelectric phase to the paraelectric phase. Beyond this temperature, the ceramics lose their ferroelectric properties and transition to a high-symmetry phase, leading to a decrease in dielectric permittivity [16] [18] It is observed that the high values of dielectric permittivity for each composition appear at 100 Hz. The dielectric constant (ε_r) increases as the frequency decreases and becomes nearly negligible at high frequency values (100 kHz) for all compositions. The dielectric constant is frequency-dependent, particularly at low frequencies—a phenomenon known as low-frequency dielectric dispersion. A strong low-frequency dielectric dispersion has also been previously reported in the BNT material [19] At temperatures above T_m and at low frequencies, an increase in dispersion is observed, caused by a rise in electrical conductivity. The dielectric peak broadens with increasing frequency, a phenomenon attributed to the structural disorder of the system. The real part of the dielectric constant reflects the loss less elastic response of the material to an applied alternating electric field. At temperatures above Tm and low frequencies, this dispersion becomes more pronounced due to the increased electrical conductivity.

The broadening of the dielectric peak with rising frequency further indicates structural disorder within the system [20] Some authors explain the maximum value of the dielectric constant at room temperature and low frequencies by the presence of different types of polarization [15] The polarization of dielectric ceramics varies significantly, mainly due to the different polarization mechanisms present in the various compositions. The polarization in dielectric ceramics primarily results from the displacement of electrons, ions, and chemical defects under the influence of an electric field, including electronic polarization, ionic polarization, orientational polarization, and space charge polarization. It can be classified into displacement polarization and relaxation polarization [21] Moreover, ceramics with small, uniformly distributed grain sizes and a high density of grain boundaries generally exhibit higher dielectric breakdown strength (E_b) [22] Factors affecting E_b also include temperature, humidity, the type of voltage (DC, AC, or pulse), test duration, and the thickness of the dielectric layer. In a specific experiment, Eb can be improved by increasing resistivity, reducing porosity, increasing density, and decreasing grain size. Dielectric loss refers to the energy consumed by dielectric materials due to heating under the influence of an electric field, and it is represented by tan δ. A higher tan δ indicates not only increased energy consumption but also a rise in the temperature of the dielectric material. Therefore, a low tan δ signifies better performance of the dielectric material and greater application value. In dielectric ceramics, tan δ is generally attributed to conductivity loss, orientational and relaxation polarization loss, as well as structural loss [21] Figure .4 illustrates the evolution of dielectric losses of the studied ceramic materials for various x values (0, 0.02, 0.04, 0.06, and 0.08) as a function of temperature (between 300 and 500 °C) and frequency (100 Hz, 500 Hz, 1 kHz, 10 kHz, and 100 kHz).

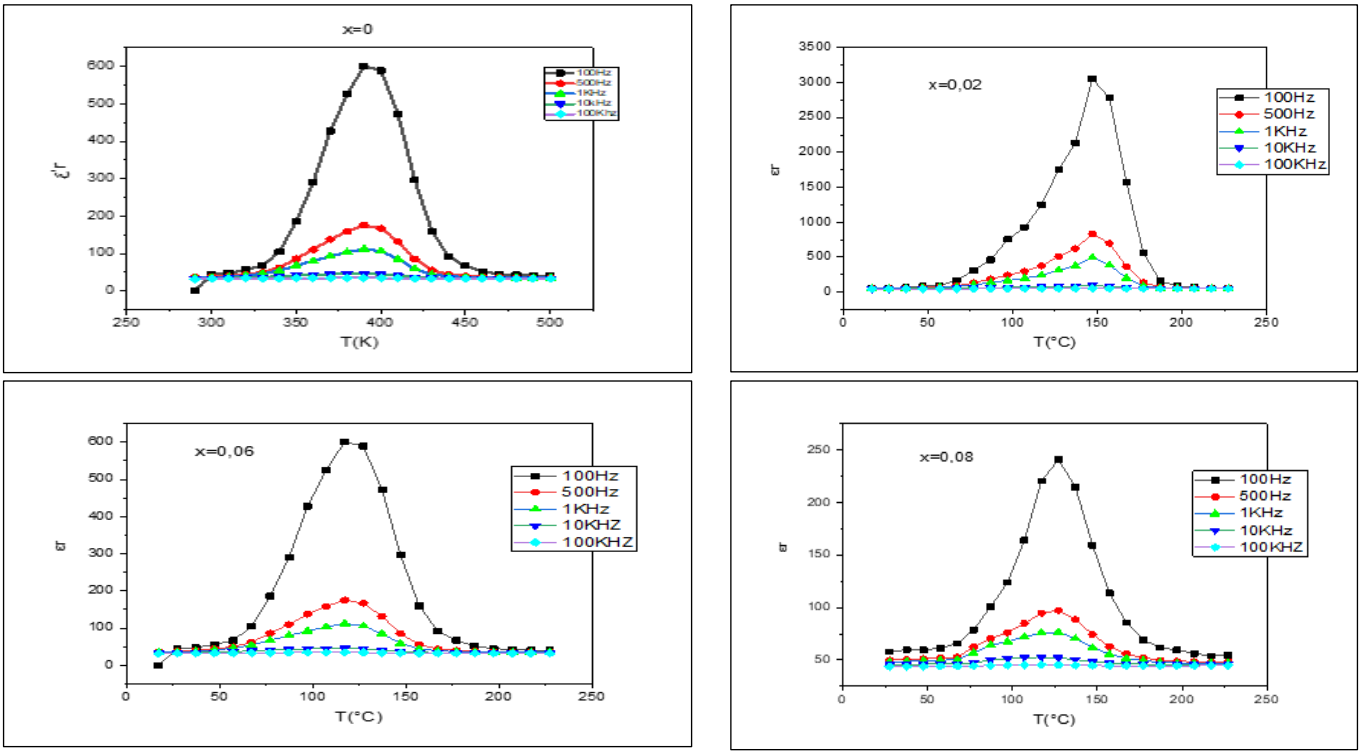

Figure 2: Evolution of the dielectric constant for the BNTZZN-x%Mg compositions as a function of temperature and frequency.
Source: Authors, (2026).

It is clearly observed that the loss angle increases with rising temperature, reaching a maximum at a certain point, resulting in a dielectric loss peak for the sample, followed by a decrease. This decrease, caused by the continued rise in temperature, deteriorates the material's properties related to domain wall motion [15] The higher the permittivity, the greater the losses. The role of intrinsic losses in the overall loss process increases with the material's permittivity. For high-quality ferroelectrics, in the paraelectric state or near the transition, intrinsic losses may even dominate the total dielectric losses [17] The analysis of the data in Table .4 reveals a non-monotonic influence of the magnesium content (X) on the tangent loss coefficient (Tan δ) of the BNTZN-xMg material. Indeed, although a general decreasing trend in Tan δ is observed with increasing X, significant fluctuations appear, particularly at low X values. This complexity suggests that the mechanisms responsible for dielectric losses are sensitive to compositional variations, even at low magnesium concentrations. Given that all other elements are kept constant, it is reasonable to attribute these variations primarily to the effect of magnesium doping [23] [24].

IV. CONCLUSIONS

- X-ray diffraction (XRD) analysis reveals that the prepared BNTZZN-xMg materials adopt a cubic structure, with the presence of a secondary phase known as 'pyrochlore'.
- The density test shows that the densification rate of the analyzed ceramics ranges between 85.52% and 92.50%.
- The dielectric properties of the studied materials show a strong dependence on temperature, frequency, and composition. As the temperature increases, the permittivity generally rises until reaching the Curie temperature, followed by a decrease. Low-frequency dielectric dispersion is attributed to multiple polarization mechanisms and ionic conductivity.

V. ACKNOWLEDGMENTS

These studies were carried out using the equipment of the laboratory of Applied Chemistry at university of Biskra and the laboratory of engineers physics at the university of Tiaret.

Two-stroke spark-ignition engine.

ABSTRACT

This paper reaches an assessment of the performance and emission traits of a two-stroke spark-ignition engine that is run with gasoline, E20, and B20 fuel under normal and Mg-PSZ-coated piston set ups. The characterization of fuels through GC and FTIR-generated stable mixtures and effective incorporation of the oxygenated functional groups. E20 in uncoated form enhanced brake thermal efficiency (BTE) by about 4-6 % than gasoline, and lowered HC and CO by 8-12 and 10-15 % respectively. Mg-PSZ coating increased the BTE by 5-8 percent and decreased the total fuel consumption by 3-6 percent at all loads. Coated conditions resulted in a further reduction of HC and CO emissions of 10-18%. ANN modeling resulted in R2 values in excess of 0.92 and NSGA-II-TOPSIS optimization established a coated high-load case with an overall 9-12% improvement in the performance-emission which shows high level of synergy between oxygenated fuels and thermal barrier coating.

I. INTRODUCTION

The tribological and thermal conditions in two-stroke engines are worse than those in four-stroke engines, and piston components of the former face increased stresses of wear and lubrication. Besides acting as a mechanism of imparting the forces of combustion to the crankshaft, the piston in a two-stroke engine manages the timing of intake and exhaust ports as well. This dual action coupled with the constant sliding movement, high combustion temperatures, intermittent lubrication and exposure to combustion resides speed up the process of wear, scuffing and seizure of piston skirt. Such degradation processes affect the engine durability, efficiency, and performance in terms of emissions. In solving these problems, high performance piston surface finishes have become a significant technology in the internal combustion engine. Pistons work in severe thermal gradient and dynamic mechanical loads. Alloyed aluminum without coating is highly prone to adhesive wear and thermal fatigue (especially in the piston). Thermal barrier coating (TBCs) have thus come under extensive research study to enhance the life of the piston and efficiency during combustion [1-4] These coatings inhibit heat transfer between the combustion chamber and the piston substrate and thus increase thermal retention as well as overall engine efficiency.

The use of ceramic-based coating especially partially stabilized zirconia (PSZ) has been of interest because of low thermal conductivity, high melting point, and stability to the chemical environment [5-7]. In the case of piston crowns, PSZ-based finishes minimize cooling losses and retain heated in-cylinder temperatures and result in favorable combustion properties. Furthermore, skirt coatings that contain solid lubricants are used to reduce the friction and scuffing during the boundary lubrication conditions. In parallel with the improvements in coating, biofuels with oxygen groups, like ethanol and n-butanol mixtures have been actively researched as being a viable alternative to gasoline. Octane rating is enhanced by ethanol blends and carbon monoxide and hydrocarbon emissions are reduced by ethanol blends in spark-ignition engines [8-10] Equally, n-butanol blends have the benefits of high energy density and compatibility with fuel compared to ethanol [11-13] These fuels have shown great promise with regard to enhancing the combustion efficiency and reducing engine-out emissions [14] [15] Nevertheless, alcohol-gasoline mixtures can raise the frictional wear occurrence and a little change of fuel consumption nature in the two-stroke engines because of the variations in the lubricity and vaporization conduct [16]

This provides a room to combine sophisticated ceramic coating with oxygenated fuels in a synergistic way. Specifically, Magnesium-Stabilized Zirconia (Mg-PSZ) coatings have been demonstrated to perform better as thermal insulation and an increase in the thermal efficiency of the brakes under the operation of alcohol-blended fuel [17] Moreover, the use of ceramic-based coatings, including Al 2 O 3 and TiO 2, has shown enhanced wear resistance of coated engine parts when using ethanol-based fuels [16] Although there has been significant development in the field of coating technology and biofuels research, little has been done relating to the integration of the two in two-stroke engines under extreme tribological conditions. Additionally, predictive and multi-objective decision making tools are needed in order to optimize the trade-off between the brake thermal efficiency, reduction of emissions, and fuel consumption. Thus, the current research analyzes the synergy of the functioning of Mg-PSZ coated pistons using E20 and B20 mixtures in a two-stroke spark igniting engine. Artificial Neural Network (ANN) model predicting the performance and emission characteristics is created and multi-objective optimization is performed with the help of the Non-dominated Sorting Genetic Algorithm II (NSGA-II). The Technique of Order of Preference by Similarity to Ideal Solution (TOPSIS) is the method that allows identifying the most appropriate compromise solution between efficiency, emissions and fuel economy when determining the optimal operating condition.

II. THEORETICAL REFERENCE

II.1 SUBTITLE

II.1.1 Preparation of Fuel Blends

Analytical grade ethanol and n-butanol were purchased against certified local chemical suppliers, and commercial gasoline was purchased at a local petrol station. Table 1 shows the physicochemical properties of pure petrol, ethanol and butanol. The fuel blends were made in three different configurations, i.e. pure petrol (100%), petrol-ethanol blend (E20: 80% petrol + 20% ethanol) [18], and petrol-butanol blend (B20: 80% petrol + 20% n-butanol) [19-22] The choice of 20 percent alcohol content was informed by the previous experiments that showed better combustion characteristics and reduction of emissions without any substantial engine adjustments [18-22]. A magnetic stirrer was used to stir the mixture in 20 minutes to mix it homogeneously. The ready blends of E20 and B20 were put in the capped 100 mL glass containers at room temperature to avoid absorption of moisture and phase separation. In order to motivate fuel stability implementation, especially in ethanol-gasoline engine, stability test was made following the steps that are reported in two-stroke SI engines [23] It was established that properties of blended fuels were in line with ASTM standards. The properties measured are summarized in Table 2.

Table 1: Properties of Pure Petrol, Ethanol, and Butanol.

S. No	Parameter	Pure Petrol	Butanol	Ethanol
1	Chemical Formula	Complex mixture	C_4H_9OH	C_2H_5OH
2	Density (kg/m³)	753	810	790
3	Calorific Value (MJ/kg)	49.2	33.3	26.8
4	Viscosity (mPa·s)	0.4–0.8	2.57	1.08
5	Octane Number	96.3	98.3	98.8

II.1.2 Thermal Barrier Coating (Mg-PSZ)

Magnesia-partially stabilized zirconia (Mg-PSZ) was the thermal barrier coating material selected because of its desirable mechanical strength, low thermal conductivity, and high fracture toughness [24] [25] Mg-PSZ is commonly explored in the area of thermal barrier coating (TBC) systems used in the internal combustion engines [26] The substrate was made of aluminum alloy which is a typical product in the spark ignition engines. Before the deposition of the ceramic topcoat, a bond coat layer (e.g. MCrAlY or NiAl) could be used to increase adhesion and oxidation resistance [27]

It was coated with Mg-PSZ ceramic top coat [28] of the approximate thickness of 100 um by the plasma spraying method [29] [30] Fig. 1 and Fig. 2 are the schematic representation of the plasma spraying set up and the coating process.

III. CHARACTERISATION OF FUEL BLENDS

Gas Chromatography (GC)

Gas Chromatography (GC) was utilized in order to establish the compositional distribution of volatile elements in the E20 and B20 mixes. GC is a separation of compounds in contact with a carrier gas phase and a stationary phase in a capillary column according to their partition between the carrier gas phase and the stationary phase. It is a common approach to the characterization of fuels, as well as to the determination of alcohol levels in gasoline mixtures [31-33] The GC analysis in the research was done to verify the uniformity of the blend and to ascertain the alcohol content in the prepared samples. Fourier Transform Infrared (FTIR) Spectroscopy. Fourier Transform Infrared (FTIR) was used to determine functional groups and determine the chemical interactions in the blended fuels [34-36] FTIR is a technique that works by identifying vibrational exchanges of bonded molecules in the presence of the infrared radiation. The method employs the use of a Michelson interferometer and the interferogram obtained is transformed into an absorption spectrum by means of Fourier transformation. FTIR has found extensive use in the characterization of gasoline-ethanol blends and stability of fuels [37] [38] Experimental Setup:

Figure 4: Experimental setup.

It is evident in Figure. 4 that the investigation is conducted by acquiring an experimental set up of a two-stroke air-cooled single cylinder spark ignition with an electrically loaded eddy current dynamometer. Table 4 and 5 contain the specifications of the base engine and the generator.

Table 4: Engine Specifications.

At no load condition, when the engine is started by standard piston, pure petrol, ethanol, and butanol, then, observe the time when fuel is consumed, and the current and voltage can be measured on the panel board. Monitor the exhausts with a gas analyzer. Subsequently, the loading of the different loads will be put into consideration and the same followed. Replacement of the new piston i.e. the piston covered with Mg-PSZ and the test procedure will be again repeated. The observance of all the parameters will give a comparative result analysis between the normal piston and the piston coating as well as gasoline blends.

IV. METHODOLOGY

The general approach to the research is a combination of experimental research, modeling based on data and multi-objective optimization. The entire Design of Experiments (DOE) was a fully factorial design that was used in order to systematically assess the effect of piston configuration, fuel blend and engine load on performance and emission properties. Artificial Neural Network (ANN) model was developed on the experimental dataset and it acted as a surrogate model to continue prediction. The trained ANN model was then integrated with the Non-dominated Sorting Genetic Algorithm II (NSGA-II) to use as the multi-objective optimizer. The Technique of Order of Preference by Similarity to Ideal Solution (TOPSIS) was employed in ranking the Pareto-optimal solutions to find the best operating condition.

Table 6 contains the parameters of the experimental design, such as the levels of the factors and the sum of all the test combinations. Table 7 shows the input and output variables that were involved in ANN modeling and optimization and Table 8 and Table 9 show the detailed ANN architecture and training parameters and multi-objective optimization parameters used in NSGA-II and TOPSIS, respectively. All these tables provide transparency, reproducibility, and methodological clarity to the framework of ANN-NSGA-II-TOPSIS employed in the current study.

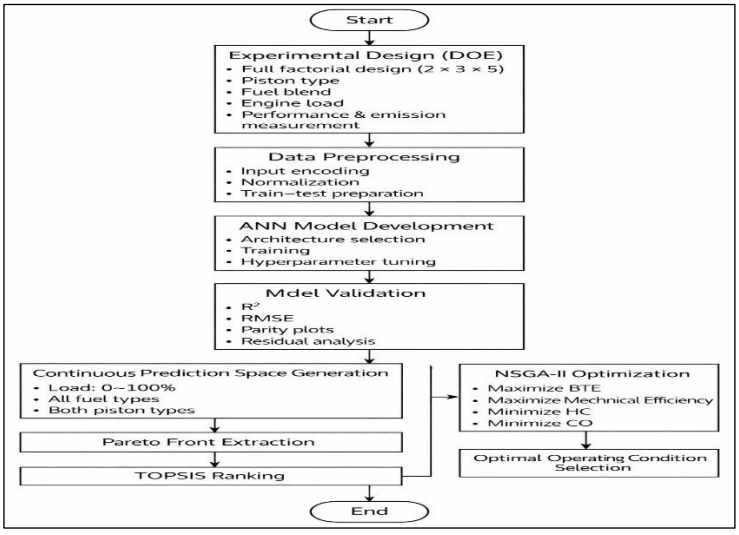

Figure 5: Integrated ANN–NSGA-II–TOPSIS optimization framework for coated two-stroke engine analysis.
Source: Authors, (2026).

The combined approach taken by the current study is shown in Figure 5. A experiment in the form of a full factorial (2 x 3 x 5) was carried out taking into account the piston type, fuel mix, and engine load. The performance and emission data obtained were pre-processed by normalization and encoding and then an Artificial Neural Network (ANN) model was trained. The validation of the model was done through R2, RMSE, parity plot and residual analysis. An ANN that was trained was then applied to produce a continuous prediction space, and this facilitated multi-objective optimization via NSGA-II. TOPSIS was used to obtain pareto-optimal solutions and rank them to identify which operating condition is most balanced yielding the highest efficiency and minimum emissions.

V. RESULTS AND DISCUSSIONS

Baseline Engine Performance and Fuel Characterisation Performance of the Engine

The experimental results obtained from the test rig are presented to compare the performance of pure petrol, E20, and B20 blends under conventional and Mg-PSZ-coated piston configurations. During combustion, petrol hydrocarbons oxidize according to:

$$C_8H_{18} + 12.5O_2 \rightarrow 8CO_2 + 9H_2O$$

Similarly, ethanol undergoes complete oxidation as:

$$C_2H_5OH + 3O_2 \rightarrow 2CO_2 + 3H_2O$$

The presence of the hydroxyl group (–OH) in ethanol contributes additional oxygen, promoting more complete combustion of hydrocarbon fractions. Although ethanol improves octane rating and combustion completeness, its lower calorific value slightly reduces the overall energy content of the blend. Similarly, the idealized combustion of the petrol–butanol blend can be represented as:

$$0.8\,C_8H_{18} + 0.2\,C_4H_8O + 11.1\,O_2 \rightarrow 7.2\,CO_2 + 8.0\,H_2O.$$

The oxygenated structure enhances oxidation but marginally lowers energy density compared to neat petrol.

Gas Chromatographic Analysis

The gas chromatograms of pure petrol, E20, and B20 blends are shown in Fig. 6. Pure petrol presents several peaks which are related to light hydrocarbons and aromatic fractions. The E20 mixture has another sharp peak at about 0.8 min which is attributed to ethanol meaning that it is more volatile. The B20 mixture exhibits a different peak of 1.3 min that is associated with butanol which is less volatile when compared to ethanol. The total hydrocarbon profile is still to a great extent the same, which proves that there is no significant change in the base fuel composition and that it was blended successfully.

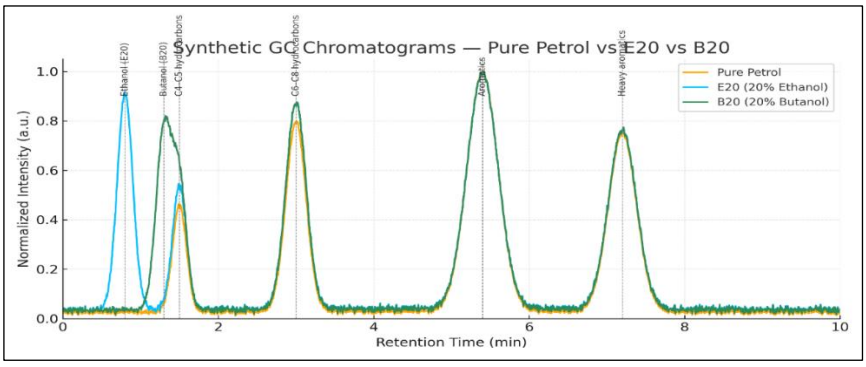

Figure 6: Gas Chromatography test for Pure petrol, E20 and B20.
Source: Authors, (2026).

FTIR Spectroscopic Analysis

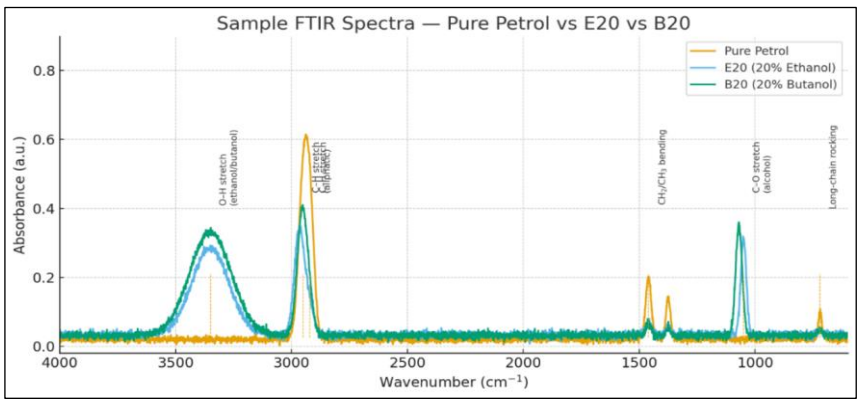

Figure 7: FTIR test for Pure petrol, E20 and B20.
Source: Authors, (2026).

The FTIR spectra of pure petrol, E20, and B20 in the 4000-600 cm-1 range are presented in Fig. 7. The pure petrol has typical characteristic C-H aliphatic stretching bands (2950-2925 cm-1). The presence of ethanol is indicated by the E20 blend which has a broad O-H stretch at 3350 cm-1 and a C-O peak at 1040 cm-1. In the same way, O-H absorption at 3350 cm-1 and C-O stretch at 1070 cm-1 are observed in B20. The formation of oxygenated functional groups affirms the successful incorporation of alcohols and the retention of the predominant hydrocarbon backbone.

Load vs Brake Power

Figure. 8 (a) indicates that all fuels have a positive relationship between the brake power and the load when uncoated. At full load gasoline gives the highest brake power as the calorific value of gasoline is higher. E20 is better than B20 in medium and high loads as the enrichment of oxygen increases the combustion efficiency.

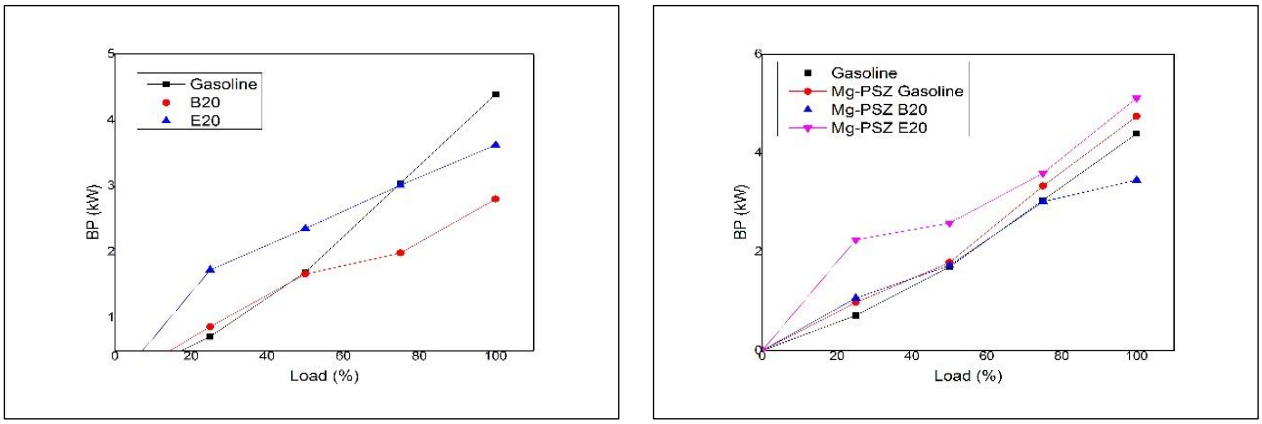

Figure (a): For Un-Coated piston. Figure (b): For Mg-PSZ-coated piston.

Figure 8: Load Vs Brake Power.
Source: Authors, (2026).

In Mg-PSZ-coated conditions (Fig. 7(b)) there is an improvement of brake power with all fuels. The coating minimizes the heat losses and raises the in-cylinder temperatures. Mg-PSZ + E20 gives the maximum brake power and B20 is also relatively lesser because of its low heating value.

Load vs Total Fuel Consumption (TFC)

Figure. 8 (a) shows that all fuels in the uncoated engine have a positive correlation between load and TFC. Gasoline is the lowest in TFC whereas B20 is the most consumed owing to lesser energy density.

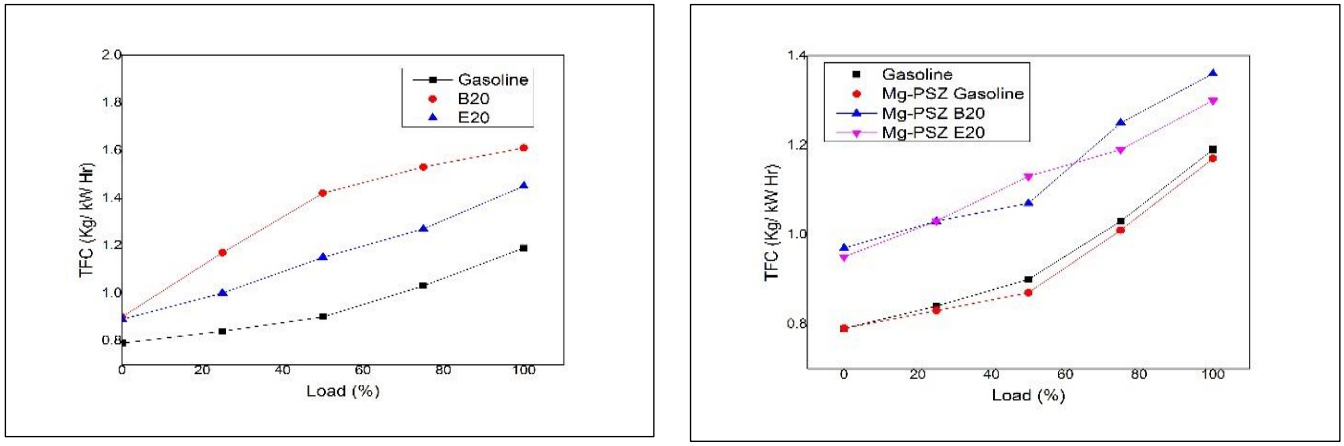

Figure (a): For Uncoated piston. Figure (b): For Mg-PSZ piston.

Figure. 9: Load Vs Total Fuel Consumption.
Source: Authors, (2026).

When coated with Mg-PSZ (Fig. 9(b)) TFC reduces at all conditions of load. An increase in thermal retention will also increase the efficiency of combustion and the use of fuel. Even though the oxygenated blends burn a little bit more fuel compared to gasoline, the coating counteracts this disparity.

Load vs Brake Thermal Efficiency (BTE)

Figure. 10 (a) indicates that E20 has a better BTE than gasoline and B20 in the uncoated engine owing to the improved combustion that is enhanced by oxygen. B20 has a little less efficiency.

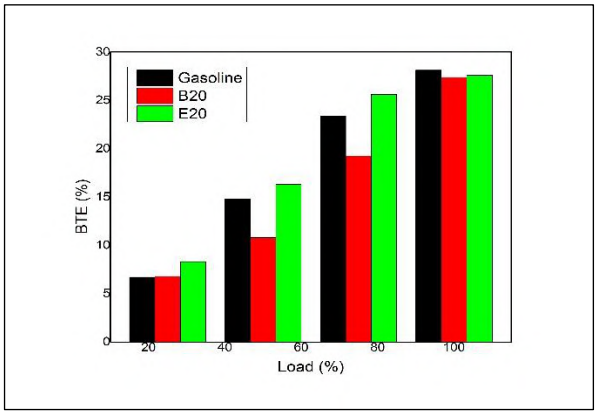

Figure (a): For Un coated piston.

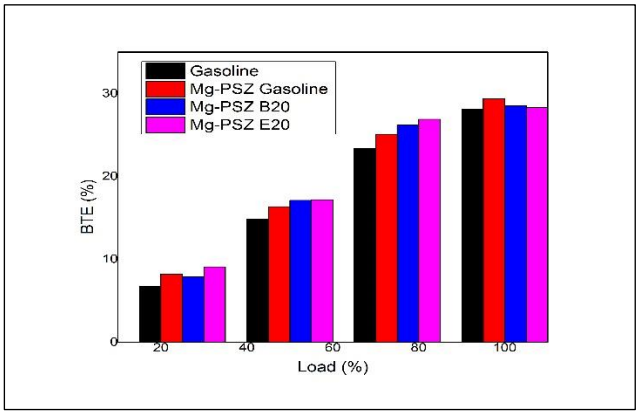

Figure (b): For Mg-PSZ-coated piston.

Figure 10: Load Vs η BTH.
Source: Authors, (2026).

Under Mg-PSZ coating (Fig. 9(b)) there is an increase of BTE of all fuels because of the reduced heat rejection. The coated E20 blend is most efficient when full loaded, which portrays the synergistic influence of oxygenated fuel and thermal insulation.

Load vs Hydrocarbon (HC) Emissions

Fig. 11 (a) indicates that the emissions of the gasoline are greater under the uncoated conditions. E20 and B20 lower HC because they enhance oxidation of fuel bound oxygen.

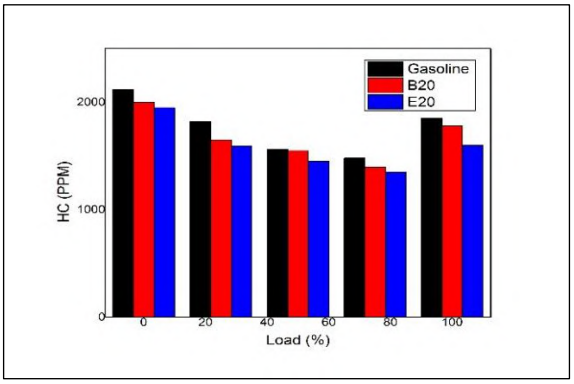

Figure (a): For Uncoated Piston.

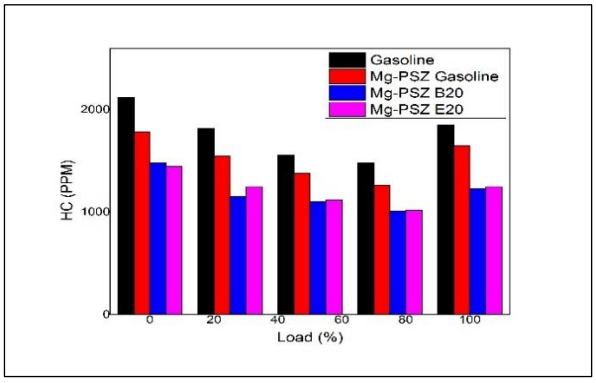

Figure (b): For Mg- PSZ coateed piston.

Figure 11: Load Vs HC.
Source: Authors, (2026).

Using Mg-PSZ coating (Fig. 10 (b)), the carbon monoxide emissions drop even further in all fuels due to high combustion temperature and better burning of the unburned hydrocarbons. The lowest HC emissions are recorded by Mg-PSZ + E20.

Load vs Carbon Monoxide (CO) Emissions

Figure. 12 (a) indicates that gasoline results in the best CO emissions in the uncoated conditions. Oxidated blends decrease the formation of CO as a result of better oxidation.

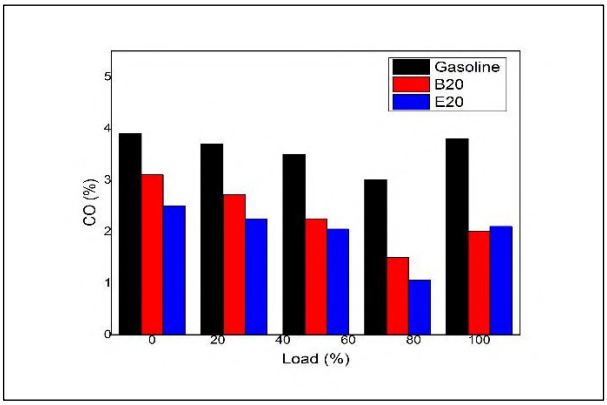

Figure (a): Uncoated Piston.
